
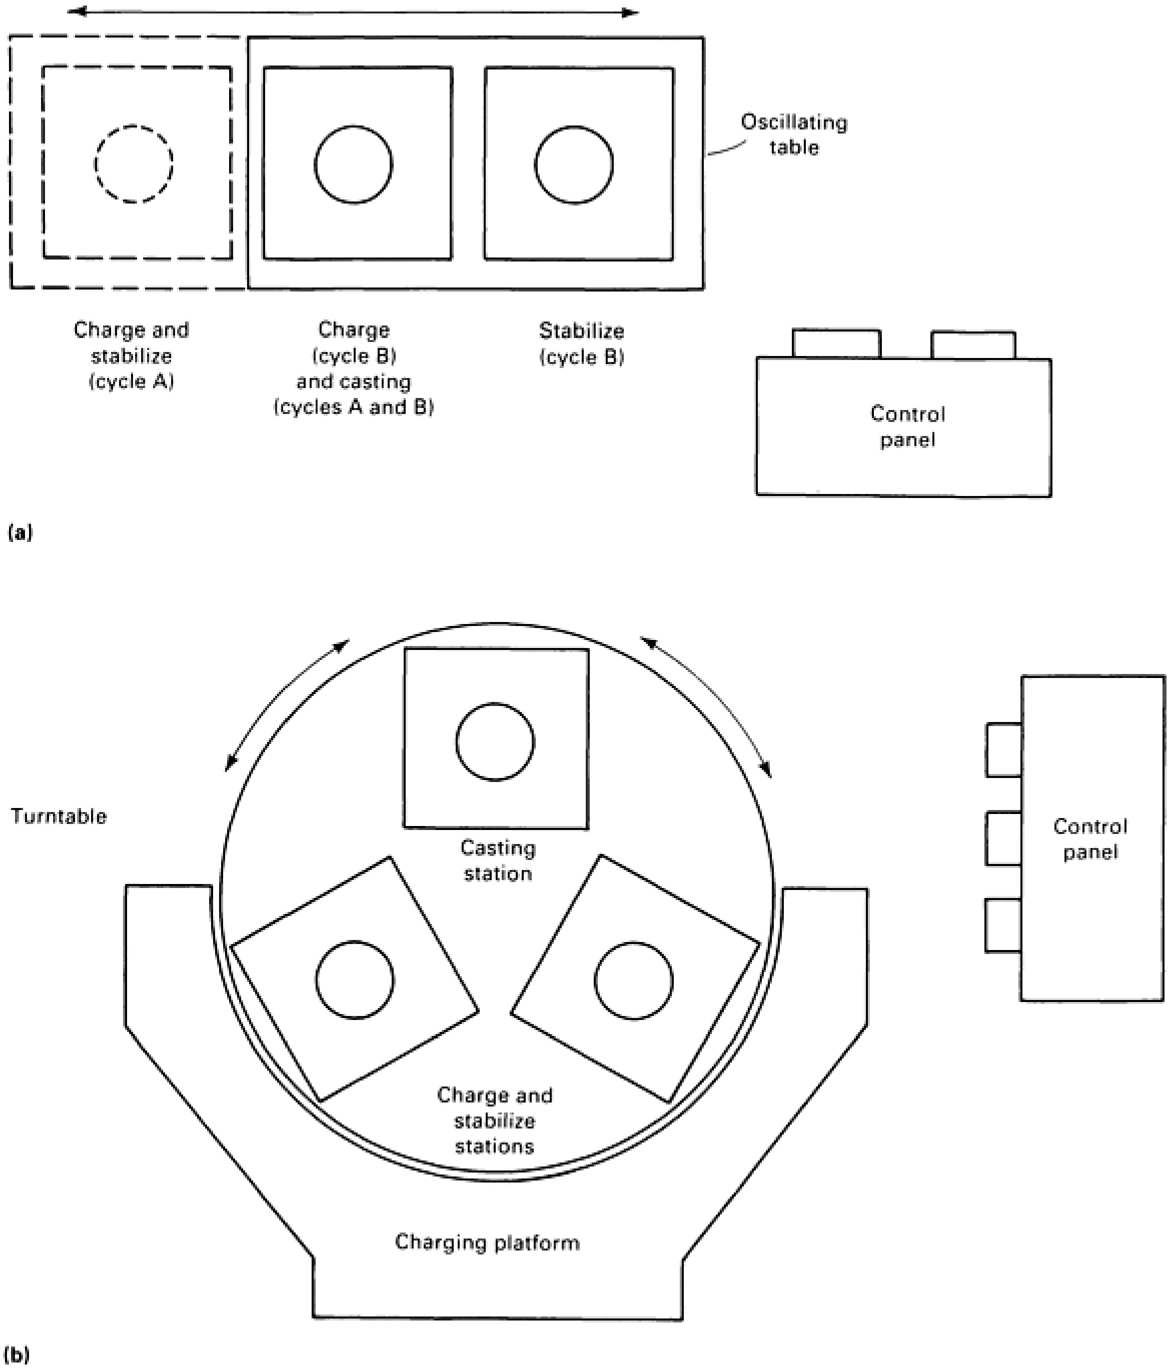

Fig. 17 Two versions of an automated modular melting operation used to produce castings. (a) Shuttle. (b) Turntable. Either method can use two to four separate crucible-type melters.

In recent years, the quality of refractory crucibles has improved dramatically. Since the 1940s, for example, the practice of glazing the crucibles and a more thorough factory curing of crucibles have eliminated the need for a 3 to 4 day curing or heat-up operation at the foundry before actual crucible use. Modern crucible fabrication, curing, and inspection methods have also done much to improve the quality and length of crucible life.

Furnace Design Considerations

Furnace design and operation are critical for efficient operation. Key points are discussed in the following sections.

Proper Furnace Atmosphere. With few exceptions, a slightly oxidizing flame should be used. With aluminum alloys, this is a pale yellow color. For copper-base alloys, this will be tinged with green (due to the oxidation of the copper). A traditional test for the correct furnace atmosphere is to place a cold piece of zinc in the flame. A yellowish color indicates an oxidizing flame, and a black color indicates a reducing flame. The objective is to obtain a flame having a tinge of yellow, which indicates the presence of the desirable, slightly oxidizing atmosphere.

Oxidizing conditions were maintained in old coke-fired crucible furnaces at the crucible walls by burning the coke in a 75 mm (3 in.) space around the crucible sidewall. The burning coke maintained a slightly oxidizing atmosphere at the walls and ensured good heat transfer.

Burner Control. For efficient melting and optimum crucible life, it is necessary to have even heating of the crucible and to avoid hot and cold areas around the sides of the crucible bowl. Some furnace designers use two or four burners to minimize this problem. This will contribute to longer crucible life, better fuel economy, faster melting, and lower noise levels. Precise periodic adjustment of the burner(s) is essential to efficient crucible furnace operation.

Special care is required to avoid overheating of the bath. Approximately 80 to 95% of the heat required to prepare a heat for the foundry is used to heat the charge to the melting temperature and then to convert the solid to a liquid. Very little heat is required to raise the temperature of the newly melted liquid to the required pouring temperature. This can cause problems.

For rapid melting of the crucible contents, high heat inputs are normally used. As soon as the charge becomes entirely liquid, little or no additional heat is required. If the equipment or the operator does not immediately turn the heat down or off, the bath temperature can become far higher than required. For most metals, this causes quality control problems. Currently, most foundries depend on their furnace operators to control this harmful variable.

Burner Design. Because of the wide diversity in crucible applications utilizing many different fuels, a summary of these data is well beyond the scope of this discussion. It should be noted that developments in the design and operation of burners have significantly improved this furnace component. Any new installations of significance probably should include recent developments in both burner designs and burner control units.

Charging Techniques. The most efficient melting (in terms of heat transfer or efficient use of fuel) is achieved with faster melt times, and the highest metal quality is obtained when a heel of metal is used to start the melting. Here the heat travels easily from the flame through the crucible wall and into the metal. A crucible that contains only a solid charge provides little contact between the crucible wall and the metal to be melted. As a result, there is a considerable time lapse between charging and the initial melting of the charge. For efficient melting, a good heel size is roughly 25% of the crucible capacity.

A second point concerning charging is the need to keep a loose charge. When a cold charge is tightly jammed into the crucible, the expansion of this charge upon heating will often break or crack the crucible.

The third point concerns the need for gentle charging of all heavy or sharp-cornered material. Crucibles are fragile and easily broken. Many crucibles have been broken by rough and careless charging with heavy and/or sharp ingot or scrap.

Handling of Crucibles During Melting and Pouring. It is important to keep in mind that hot crucibles filled with molten metal are fragile and therefore deserve careful handling. Care should be taken to set them on sand or other nonconductive surfaces. Placing a hot crucible full of molten metal on a steel plate or damp floor can easily break or seriously weaken the bottom of the crucible.

Cleaning of crucibles is important in preventing premature failure. In many, if not most, metal-melting operations, slag or dross buildups develop at the metal surface line, and heavy unmelted slush residue collects on the bottom. Both of these residues shorten crucible life by causing hot and weak wall areas. The poor and uneven heat transfer around the crucible walls causes hot spots and uneven stresses within the crucible walls. The metallic residues that will expand faster than the crucible upon heating can easily rupture the wall. At times, these residues expand and fracture the crucibles during the normal heating and cooling cycles (Fig. 16). Cleanliness and careful workmanship on the melt room floor should be encouraged. However, in many foundries, the tradition and environment of this work area tend to foster an attitude of disdain among personnel for the meticulous work required for efficient operation. This is the source of many foundry problems. Quality begins with the melting and handling of metal, and failure in this portion of the operation can doom the final casting sequence.

Using the correct metal melting technique and equipment for each specific melt will produce high quality castings. In recent years, the introduction of statistical process control (SPC) methods to foundry operations in order to monitor each step of the casting production process has been helpful in keeping scrap losses to minimum levels previously unattainable.

Melting Furnaces: Cupolas

Sam F. Carter, Carter Consultants, Inc.

Introduction

THE CUPOLA is basically a cylindrical shaft furnace that burns coke intensified by the blowing of air through tuyeres (nozzles). Alternate layers of metal, along with replacement coke, are charged into the top. In its descent, the metal is melted by direct contact with the countercurrent flow of hot gases from the coke combustion. The molten metal collects in the well, where it is discharged for use by intermittent tapping or by continuous flow.

Melting in a cupola dates back several centuries to old cask-type units that were blown with hand-pumped bellows. The cupola as we know it today was patented in 1794 by John Wilkinson. Prior to the 1950s, the cupola was the predominant furnace for iron melting because of its simplicity and low cost of melting.

Through the years, the cupola has been progressively refined toward more efficient combustion, better control, and more flexibility in the use of more varied raw materials. However, the cupola emits considerable amounts of smoke and particulate matter. The emission has been cleaned to meet the highest environmental standards, but this has required much engineering effort and considerable expense. During the 1950s, with environmental laws requiring elaborate pollution control equipment, the cupola lost much of its advantage of low cost and simplicity, especially on small cupolas, for which pollution equipment was relatively more expensive.

In the meantime, progressive improvements were made in electric induction furnace equipment. Because induction furnaces required little or no pollution control equipment and yielded low-sulfur iron that was satisfactory for the fast-growing ductile iron industry, electric induction furnaces replaced many cupolas, especially in small-tonnage operations and where ductile iron or several types of iron were produced. Electric induction melting was found to have a lower melting cost under many of these conditions. The number of cupolas has decreased from 4000 in the early 1950s to less than 1400 today. However, the cupola remains the predominant tonnage melter with over 60% of the iron tonnage still melted in cupolas.

In high-tonnage operations, the cupola remains the most reliable source of the continuous high volumes of iron needed to satisfy multiple molding lines of high-production foundries or multiple casting machines of centrifugal pipe producers. The continuous stream of cupola-melted iron is not interrupted by charging, which is done independently upstairs on the back side, nor by slag removal, because the slag flows off to the side continuously from a front or rear slag spout without interrupting the melting process.

In such high-tonnage continuous-demand situations, the cupola has remained the lowest cost method of melting under the prevailing costs of coke and electric power. The cupola can melt a wide range of bulk scrap. Cupola iron is more difficult to control, but is favorably characterized by a low tendency toward chilling and good fluidity, machinability, and shrinkage characteristics due to natural nucleation resulting from continuous contact with the coke.

Progressive Refinements in Cupola Equipment

Since the early days of the simple cupola, continuing technological refinements have been progressively applied to the cupola to improve efficiency, flexibility, and control.

A preheated air blast was found to intensify the combustion reaction, thus increasing melting rate, temperature, and carbon pickup with the same amount of coke. Alternatively, the amount of coke can be reduced for the same melt rate, temperature, and carbon pickup.

Some of the early hot blast systems could preheat the incoming air only 150 to 260 °C (300 to 500 °F), but exhibited the advantages of the preheated blast. The most successful hot blast systems have been externally fired with gas and are

capable of 540 to 650 °C (1000 to 1200 °F) preheat. Higher blast temperatures continue to improve performance, but they complicate the construction of the hot blast equipment.

Recuperative hot blast systems, in recent years, have efficiently utilized the heat content in the effluent gas to preheat the blast air and have lowered effluent carbon monoxide content to very desirable environmental levels.

Oxygen enrichment and injection, which adds 1 to 4% O_2 to the blast air, also intensifies the combustion reaction by increasing temperature and melting rate.

Divided-blast cupolas divide the air between two rows of tuyeres in controlled proportions. In many cases, this improves combustion efficiency to accomplish either coke reduction or increased melt rate and temperature with the same coke ratio.

Humidity control of the blast air has been employed on some cupolas to eliminate the effect of varying humidity where very close control is important.

Injection of fine coke through the tuyeres has proved effective in increasing carbon content and in using fine coke as a substitute for premium coke.

Basic slags made possible the melting of very low sulfur iron directly from the cupola, and the higher carbon pickup made possible the use of more steel scrap. By regulating slag basicity, a wide range of compositions can be obtained from a wide range of materials.

Water cooling has extended the length of the melting period to 24 h and has permitted a single cupola stack to be banked and operated for weeks before requiring repairs during a weekend shutdown. Water cooling by removing the effect of refractory on the slag chemistry permits the same cupola to operate with a choice of basic, neutral, or acid slag simply by regulating the amount of basic flux added.

Pollution control equipment was progressively developed to meet the most rigid environmental standards, either with high-energy wet scrubbers or with dry baghouse collectors.

Duplex electric holders have ensured instant supply during variations in demand and have improved the consistency of composition and temperature. Large electric channel induction furnaces have become popular as receivers for large cupolas. These electric channels can boost temperature or maintain temperature over down periods.

Continuous analyses of top gases has made it possible to monitor combustion efficiency and to signal any water leaks to avoid explosive gas combinations.

Computer applications have been increasingly utilized to record, monitor, and progressively control more cupola conditions.

Cupola Construction and Operation

This section will discuss the shell, intermittent or continuous tapping, tuyere and blower systems, refractory lining, water-cooled cupolas, emission control systems, and storage and handling of the charge composition.

Shell

A vertical, cylindrical steel shell is the container of the combustion and melting operation, as shown in Fig. 1. The diameter is chosen for the required melting rate.

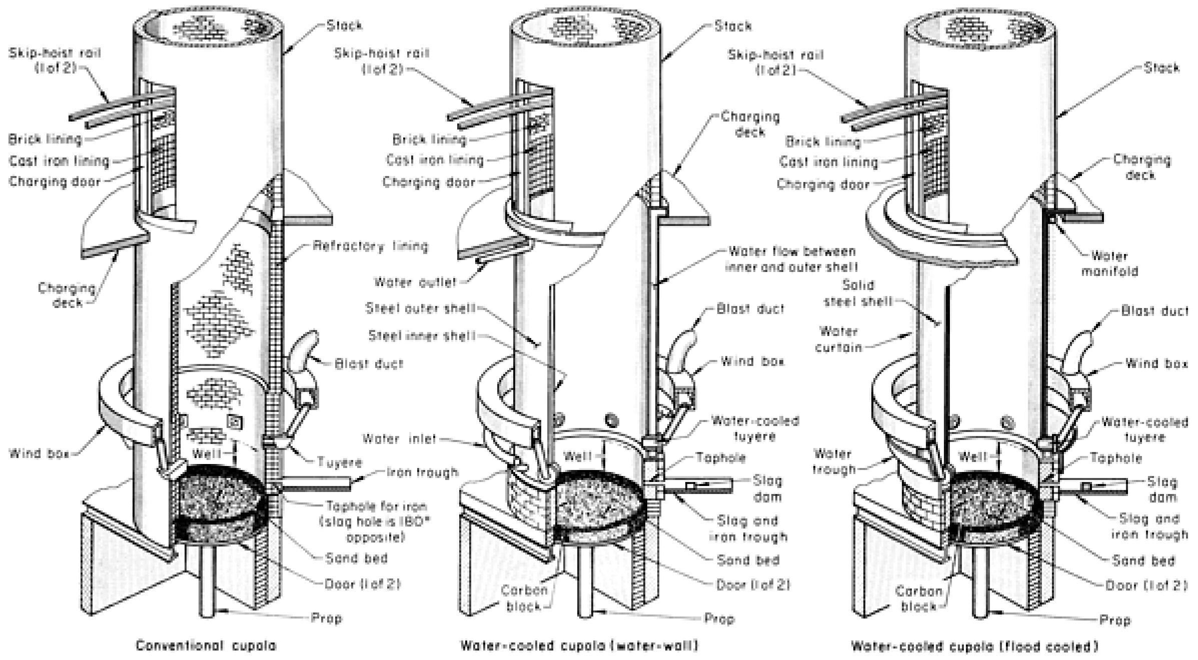

Fig. 1 Sectional views of conventional and water-cooled cupolas. The conventional type shown is refractory lined. Water-cooled types incorporate either an enclosed jacket or an open cascade flow.

Standard commercial cupolas are available in 15 sizes, as indicated in Table 1. Sizes range in diameter from No. 1 to 12:

- No. 1: 813 mm (32 in.) shell lined to 584 mm (23 in.) ID with a melting capacity of 0.9 to 1.8 Mg/h (1 to 2 tons/h)
- No. 12: 2.74 m (108 in.) shell lined to 2.13 m (84 in.) ID with a melting capacity of 23 to 36 Mg/h (25 to 40 tons/h)

Larger cupolas have been custom designed to 3.81 m (150 in.) in diameter with a melting capacity of 64 to 91 Mg/h or 70 to 100 tons/h.

Table 1 Range of sizes for conventional cupolas

Cupola size	Shell diameter		Minimum thickness of lower lining[(a)]		Diameter of inside lining		Area inside lining		Average melt rate[(b)]		Air through tuyeres[(c)]		Suggested blower selection[(d)]			Approximate holding capacity of cupola well[(e)]

(a) Proportional to length of heats.

(b) Specific melt rate will depend on coke required for thermal requirement and amount of oxygen available in blast.

(c) Based on 99.3 m^3/m^2 (325 ft^3/ft^2) of area inside lining and type of cooling.

(d) When auxiliary equipment is added to blast system or when piping is long or intricate, more pressure capacity may be required. Density and/or height of charge material is also a factor.

(e) Based on 305 mm (12 in.) average depth of metal--distance sand bottom to slag spout

A charge door opening at a vertical distance usually four to five times the diameter receives the charges of metal, coke, and flux dumped from drop-bottom buckets, side-dump skips, or shaker conveyors.

Drop-bottom doors at the bottom of the stack facilitate quick emptying of the stack at the end of an operation to expedite refractory repairs and the resumption of melting.

The foundation must be adequate for the size and load.

A sand bottom is rammed over the closed bottom doors to contain the melted iron in the well. This sand bottom, or refractory, is sloped toward a taphole that is properly sized and maintained for the outward flow of metal.

Intermittent or Continuous Tapping

Iron flow can be intermittent or continuous. Early cupolas were intermittently tapped by opening and closing the taphole as in a blast furnace. Slag was accumulated and flowed out a back slag hole at a higher level.

Most modern cupolas are tapped continuously, with clean metal flowing under a refractory knife and over a dam. This special trough skims off the lighter slag on top. This slag then flows continuously down a side spout into a water-sluicing trough and containers for handling. The levels of metal dam and slag notch must be carefully calculated and maintained to the proper relationship with blast pressure inside the cupola.

The dry-bottom cupola is a European development in which iron and slag are not collected in the well of the cupola but run into a special vessel outside and beside the cupola. In the special outside vessel, the accumulated metal and slag are separated as they flow out through the usual front slagging dam and spout. The advantages claimed for this setup include more consistent iron analysis and easier repair of refractories.

Tuyere and Blower Systems

Tuyeres. Air for the combustion of coke is introduced through tuyeres equally spaced around the cupola, with the number and size proportioned to cupola size for proper air volume, pressure, and velocity. Total tuyere area usually ranges from 3 to 10% of cupola area for optimum air velocity for penetration and combustion efficiency. On large, water-cooled hot blast cupolas, the desirable air velocity range is 4600 to 7600 m/min (15,000 to 25,000 ft/min). On water-cooled cupolas, the tuyeres are projecting water-cooled copper nozzles that protrude into the cupola 152 to 457 mm (6 to 18 in.) and are inclined downward 10 to 15°.

Blowers for generating the necessary blast air volume and pressure have been of the positive displacement, fan, or centrifugal type. The latest preference on large cupolas has been toward two or three multistage centrifugal blowers with automatic air weight control.

The air required to melt 900 kg (1 ton) of iron is 620 to 680 m^3 (22,000 to 24,000 ft^3) STP or 770 to 835 kg (1700 to 1840 lb). Air from the blower is transmitted into tuyeres through a duct system and windbox. Back pressure normally ranges from 3.3 to 8.5 N (0.75 to 1.9 lbf) or more, depending on charge density and stack height.

Refractory Lining

Conventional cupolas are lined with refractories to protect the shell against abrasion, heat, and oxidation. Lining thicknesses range from 114 to 305 mm (4.5 to 12 in.). The most popular lining is fireclay brick or block. As the heat progresses, the refractory lining in the melting zone is progressively fluxed away by the high temperature and oxidizing atmosphere.

Early general practice was to drop the bottom and repair the lining at the end of the day's melt, restoring it to original dimensions. Generally, a pair of cupolas were alternately used each day to facilitate the repair and preparation of the furnace lining after each day of use.

Several methods have been satisfactorily used for this refractory patching. Among them are combinations of fireclay brick and mortar as well as monolithic ramming mixtures of clay, ganister, and sand.

The newest and most widely used method of lining repair uses a pneumatic gun to blow a mixture of clay and ganister through a nozzle containing water that becomes entrained in the stream as it exits the mixing nozzle.

Basic Refractories for Basic Slag. The advent and growth of ductile iron in the 1950s made it desirable to find a way to remove sulfur inside the cupola using a sufficiently basic slag, as is accomplished in basic steelmaking furnaces. Obviously, a highly basic slag could not be maintained in contact with the acid refractories. In addition, because the lining consumed during melting is a major source of slag, the lining must be basic or neutral in order to contribute an excess of basic constituents to the slag.

After considerable experimentation, successful basic refractories were developed for use in cupolas. Originally, linings were either magnesite or dolomite brick. Basic patch materials composed of dolomite or magnesite aggregate were developed that could be rammed or blown in using the pneumatic gun. Basic refractories cost several times more than comparably sized acid clay refractories, which increase the need for water cooling on basic slag cupolas.

Water-Cooled Cupolas

When the melting operations of high-production foundries were extended to 16 to 20 h, the continuous attack on the refractory lining left little or no lining remaining in the melting zone after hard blowing for two shifts. The need for two- and three-shift melting operations encouraged the development of water-cooled cupolas. Water cooling was first used as a backup to the refractory lining.

Because of the increasing dependence on water cooling, it was found that the refractory lining could be eliminated from the melting zone and that the cupola could be operated continuously without a lining for a full week, dropping the bottom on the weekend for minor refractory repairs to the well, taphole, and trough. The liningless water-cooled cupola has its shell offset at the tuyere level to accommodate adequate lining thickness in the well area (usually lined with carbon refractories) below the tuyeres.

When iron was needed for only two shifts, the liningless water-cooled cupola was banked during a down shift and readily brought back on stream when needed. It was then learned that these water-cooled cupolas could be banked over a weekend and operated continuously for 2 to 4 weeks before dropping the bottom for repairs. Some of the largest cupolas are equipped with double tapholes and double rear siphon slag spouts to enable the cupola to be operated continuously for long periods.

Two types of water cooling have replaced the consumable refractory lining located in the melting zone (Fig. 1b and c). Figure 1(a) shows the refractory lining of the conventional refractory-lined cupola. Figure 1(b) shows a sectional view of an early water-cooled cupola design that uses an enclosed jacket or tank through which water is circulated. Water introduced into the enclosed jacket must be at sufficient pressure to maintain a velocity and flow pattern that provide adequate cooling and prevent the buildup of steam pockets and hot spots. A major problem with the enclosed jacket is a buildup of deposits which reduces cooling effectiveness. The enclosed jacket also limits accessibility when a hot spot occurs.

A more widely used cooling system incorporates open external water sprays or cascade cooling (Fig. 1c). At the top of the liningless area, a water curtain is applied to the shell, usually by spray rings encircling the cupola, with a neoprene wiper to even out the distribution or with an overflow moat. The water curtain cools the shell as it cascades down the tapered shell and is collected in a trough where the shell is offset at the well. Figure 2 shows a cutaway view of a water-cooled cascade flow cupola.

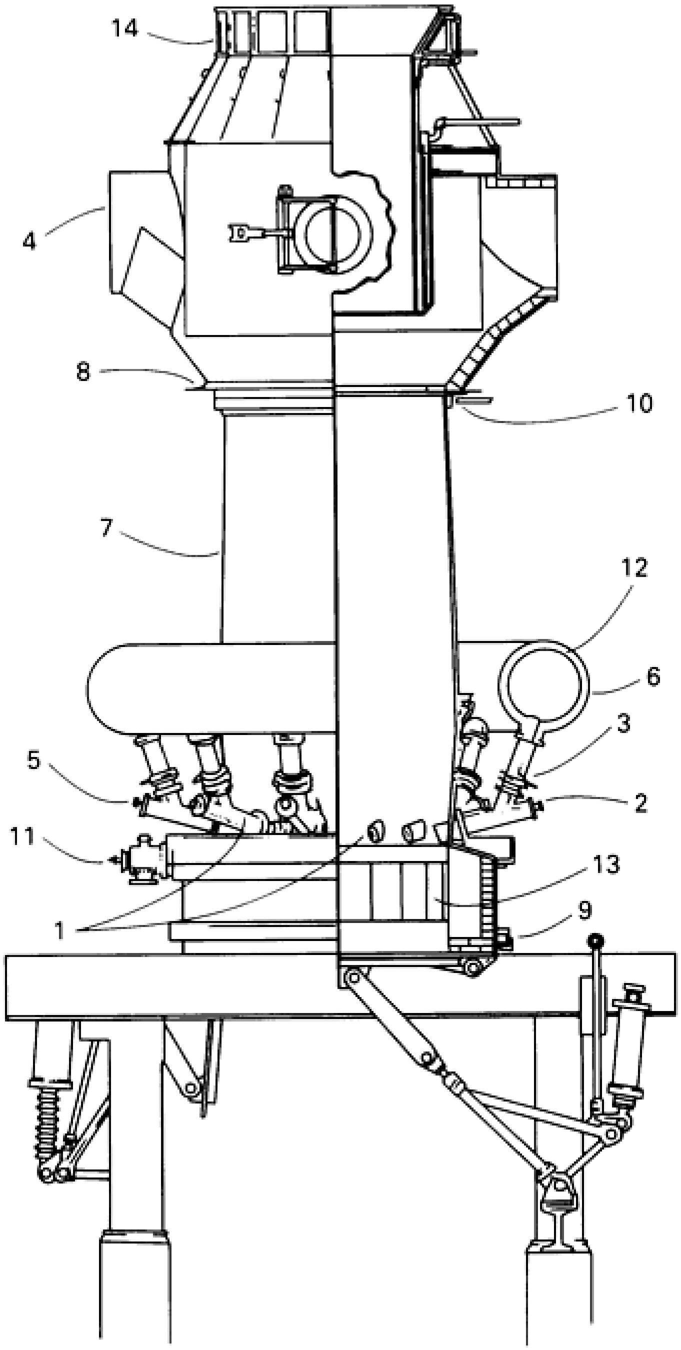

Fig. 2 Cutaway view of an open cascade flow water-cooled liningless cupola showing component parts. 1, water-cooled tuyeres; 2, tuyere elbows; 3, control dampers; 4, gas take-off; 5, sight port; 6, detached windbox; 7, welded body; 8, dry expansion joint; 9, selective well cooling; 10, upper spray ring; 11, overflow spout; 12, windbox lining; 13, carbon lining; 14, upper stack, independently supported

One advantage of the open external cooling is that the shell can be blasted at intervals to remove excess deposit and to maintain thermal conductivity. In addition, any areas of inadequate cooling are made apparent by visible steaming, which can be easily corrected with increased water flow to the area.

Water-cooled cupolas have greatly extended the duration of melting operations and have reduced refractory repair costs. On basic cupolas, water cooling is especially attractive for reducing the consumption of the higher cost basic refractories. In addition, with the need for expensive pollution control systems, water cooling made it possible to reduce the number of cupola stacks, which meant reduced investment in emission control equipment.

However, these advantages of water cooling were achieved at some loss in thermal efficiency. Higher heat losses through the water-cooled shell necessitate the use of more coke to maintain equivalent temperature and melting conditions.

In recent years, some plants have installed thin refractory linings inside the water-cooled shell. With the water-cooled backup, the lining thickness is maintained for a full week of operation. In addition, the thin lining provides sufficient insulation to reduce heat loss and coke use. This combination of water cooling behind a thin lining is gaining acceptance throughout industry.

Emission Control Systems

Equipment has been successfully engineered to enable the present-day cupolas to meet the most rigid environmental regulations. The two most common types of collectors currently used are the high-energy wet scrubber and the dry baghouse.

High-Energy Wet Scrubber. In this unit, high-velocity water jets impinge upon effluent particles passing through a venturi scrubber. The resultant sludge is piped to a remote settling pond, where the sludge is dewatered. Figure 3 illustrates a wet scrubber emission control system connected to a recuperative hot blast system.

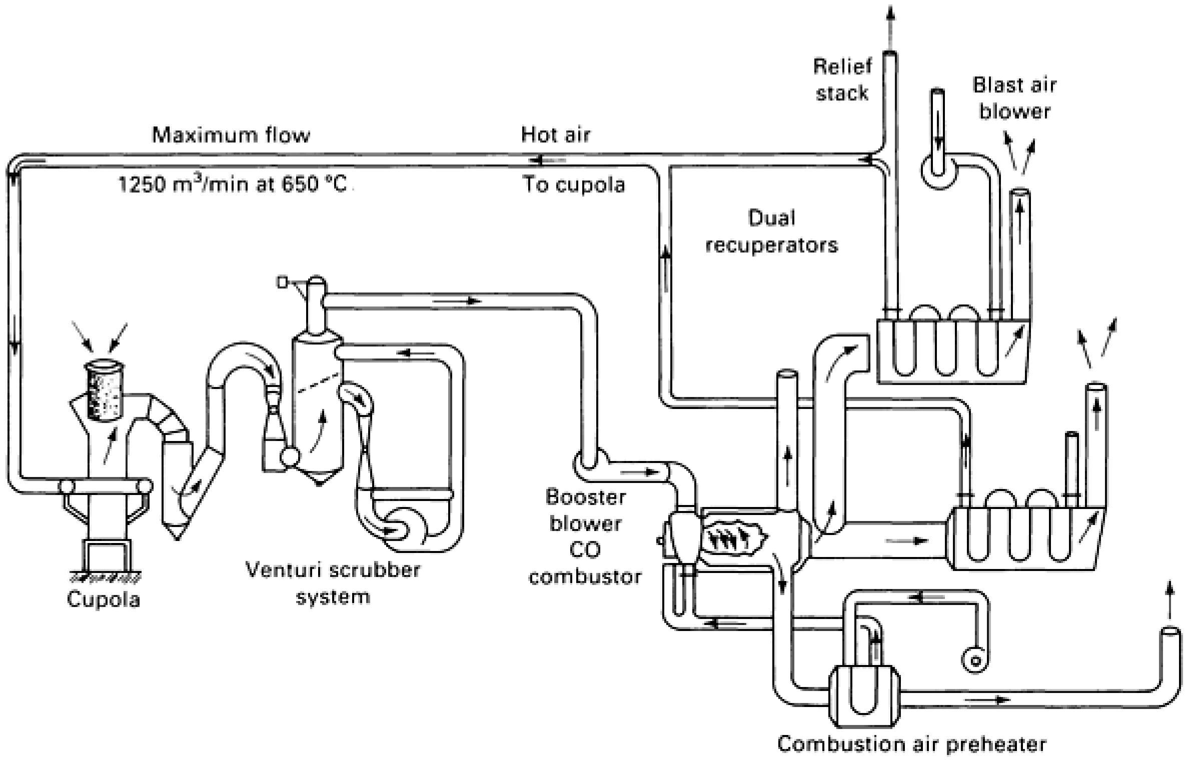

Fig. 3 Recuperative hot blast cupola with wet scrubber emission control

Dry Baghouse. In this unit, the effluent is collected in a series of interconnected fabric bags.

Electrostatic precipitators have also been used on some cupolas primarily in Europe. Recently developed precipitators show more promise in controlling emissions.

Storage and Handling of Charge Components

Essential to efficient cupola operation is a good material storage and handling system. Figure 4 illustrates the essential components of such a system. Metal charge components are unloaded into storage bins using a crane magnet and transferred to a weigh hopper to designated weight values as charge components are progressively added.

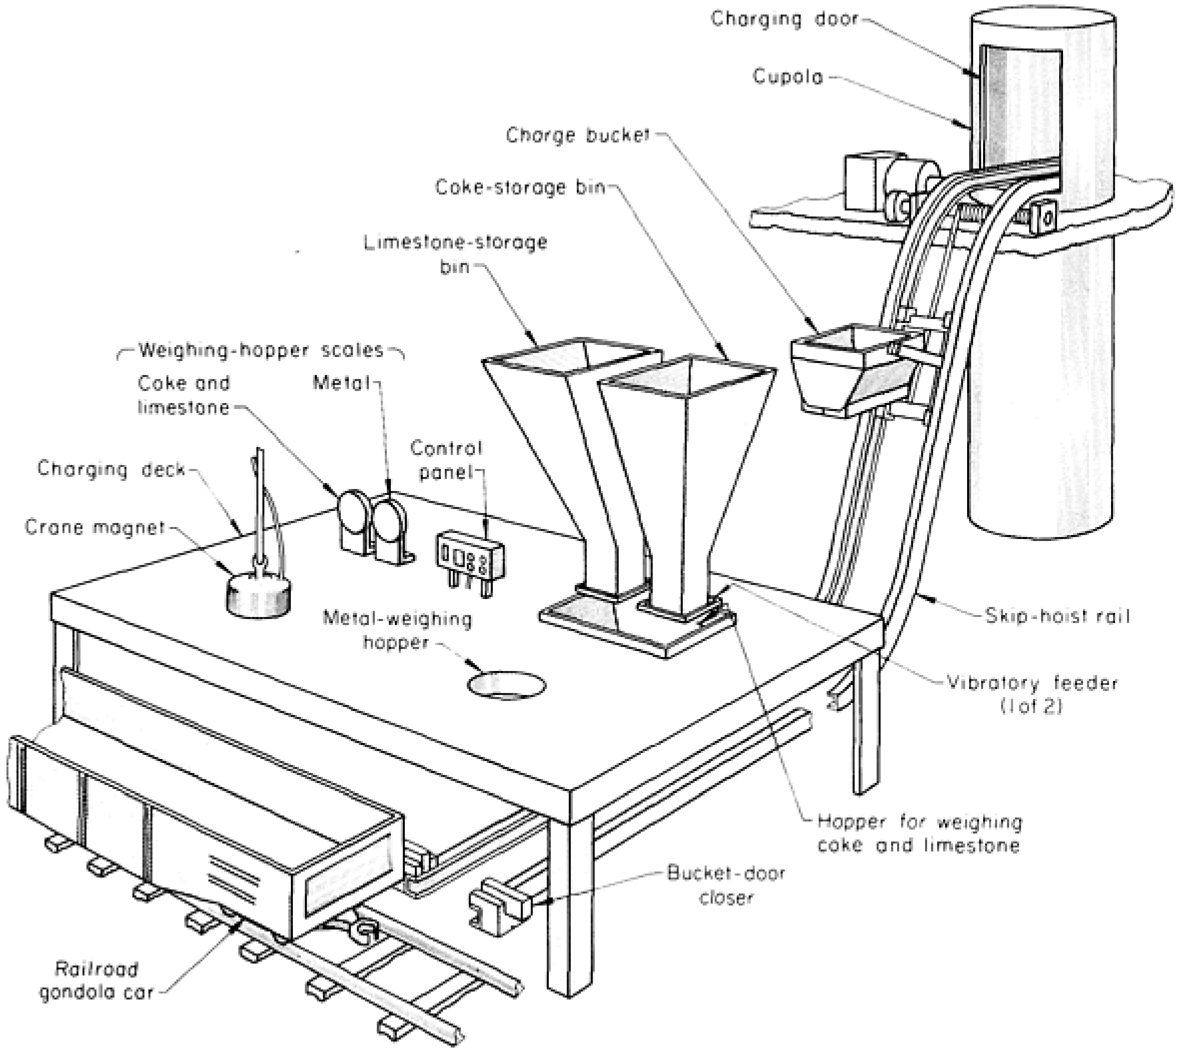

Fig. 4 Typical mechanized system for charging a cupola

Coke and limestone from overhead storage bins are discharged into a weigh hopper and into the charge bucket. The charge bucket with all weighed amounts of metal, ferroalloys, coke, and flux is elevated to the charge door and dumped either with an overhead crane or with a skip hoist up an inclined track.

Charge Materials

This section will discuss coke specifications, the metal charge, trace element control, scrap limitations, ferroalloys, charge calculations, and fluxes for fluidizing slag.

Coke Specifications

As the major fuel, coke is the most important charge material. High-quality, foundry grade coke is essential for optimum cupola performance. Good foundry grade coke requires longer coking time and more careful blending of coals and is therefore higher in price than other grades of coke.

Foundry coke must be strong and sufficiently impact resistant to maintain adequate lump size to provide permeability, blast penetration, and air availability to the center of a large cupola. Experiments and production experience have shown that performance is optimized when coke size is within a range proportional to cupola diameter, preferably 8 to 12% of cupola diameter.

Fine coke should be screened out because it fills interstitial space, limits air distribution, and overloads the emission system. On large cupolas, the largest available coke size is preferred, but on small cupolas, coke screened to proper size ranges provides the best performance.

One foundry, when operating four sizes of cupolas, ordered coke screened to three size ranges:

- For a 711 mm (28 in.) cupola: 50 × 127 mm (2 × 5 in.) coke
- For 914 and 1220 mm (36 and 48 in.) cupolas: 75 × 178 mm (3 × 7 in.) coke
- For two 2130 mm (84 in.) cupolas: ≥127 mm (≥5 in.) coke

Coke should have low ash content (<10%) and a chemical structure that provides for optimum carbon pickup and combustion efficiency. Low sulfur content (<0.70% S) is required for preventing excessive sulfur pickup. Volatiles should be less than 1.0% and fixed carbon above 90% for maximum cupola performance.

Efforts have been directed toward the economical use of limited amounts of less expensive substitutes for quality coke, such as briquetted fine coke, anthracite coal, injected fine coke, and various substitute fuels. However, all of these substitutes require some sacrifice in cupola efficiency, which must be weighed against fuel cost savings. The amount of coke in the charge usually ranges within 8 to 16% of the metal charge, depending on the temperature required, the percentage of steel scrap used, and many other variables.

Metal Charge

The modern cupola can melt a wide range of charge materials, mostly scrap iron and steel. Through its efficient use of scrap materials, the casting industry contributes to environmental cleanup and resource utilization.

Foundry returns, such as gates, runners, and internally generated scrap castings, usually constitute 30 to 50% of the pouring weight and should be remelted in the proportions generated.

Pig iron is considered a premium charge material because of its uniformity of composition and size and its lack of undesirable trace elements. In the early years, pig iron was the predominant charge component for ensuring quality iron with sufficient carbon content, and it was free of detrimental tramp elements. As economics encouraged the use of more scrap and less pig iron, pig iron has remained the best material for restoring iron quality whenever excessive tramp elements or poor-quality iron are produced.

Cast iron scrap has been increasingly used as faster spectrometer analyses have given assurance of chemical control and as more knowledge has been gained about the characteristics of various types of scrap. With the cooperation of scrap dealers and their trade organization, cast iron scrap has been separated and sold in 10 to 15 designated types with specific composition ranges and inclinations. Through careful blending, anticipation of trends, avoidance of excessive proportions of certain extremes, and fast spectrometer checks on trace elements, high proportions of cast iron scrap have been successfully used in some of the highest-quality irons.

Steel scrap in select grades was first melted in low percentages to lower the carbon content of gray iron in order to meet the higher strength levels of class 30 and class 40 irons. In low-carbon malleable irons, steel scrap in considerable proportions is needed to obtain a low carbon content.

The Scrap Institute has classified steel scrap into 15 to 20 categories. Based on experimentation and experience, adjustments can be made to compensate for the effects of size, thickness, and surface-area-to-volume ratio affecting the various reactions in the cupola.

With the advent of ductile iron that requires the lowest possible phosphorus content, steel scrap became a more attractive charge material for cost reduction. The basic cupola allows the adjustment of fluxes and slag chemistry to permit the melting of 50 to 80% steel scrap.

Trace Element Control

The use of considerable miscellaneous scrap increases the likelihood of traces of many undesirable elements getting into the iron melt. These extraneous elements may be alloyed in some scrap parts; may be attached to the iron as bearings, die castings, and so on; may be found in chromium plating; or may be present in paint or coatings.

Zinc and Cadmium. The more reactive zinc and cadmium will volatilize out of the iron, but if highly concentrated in the effluent, they can cause the baghouse dust or wet scrubber sludge to earn a hazardous material rating and cause expensive disposal costs.

Lead and bismuth can be sufficiently recovered to cause detrimental effects on graphite and properties, especially in ductile iron, and must be avoided. In addition, a high concentration of lead can cause the collected effluent to be designated as a hazardous waste.

Aluminum, zirconium, and titanium are essentially oxidized out into the slag, but the initial presence of aluminum within critical ranges can increase hydrogen absorption and gas porosity tendencies.

Other elements include inadvertent alloying elements such as chromium, tin, copper, molybdenum, and nickel, which increase pearlite content and contribute to strength and hardness. When pearlite is needed for increased strength and hardness, these trace alloys become part of the total alloy factor, reducing the amount of alloys to be added. However, these alloys should be avoided in ferritic ductile iron, in which pearlite is undesirable.

Scrap Limitations

A wide range of scrap metals can be melted in the cupola. However, some forms of scrap metal are not practical to use in a cupola charge. Cast iron borings charged directly into the cupola would be excessively oxidized if not blown out of the stack. With briquetting, limited proportions can be used. Steel turnings are more impractical. Thin sheet steel cannot be used without being compressed into bundles. Slugs and compact punchings tend to clog interstitial coke passages and hinder combustion efficiency. Very thick steel parts and large-diameter shafts are not completely melted within the melting zone, and this results in lower iron temperatures and cupola problems.

Ferrous Alloys

Silicon, which is added to allow for oxidation losses and to yield the desirable final silicon content, is usually added in any of the following forms:

- Lump ferrosilicon: 50 or 75% Si
- Silvery pig: 16 to 20% Si
- Silicon briquets: approximately 40% Si with bricks containing a known weight of silicon that can be counted rather than weighed
- Silicon carbide: provides deoxidizing influence in addition to silicon

Manganese can be in the following forms to obtain the net desirable final manganese content:

- Spiegel: 20% Mn
- Ferromanganese: usually 80% Mn
- Manganese briquets

Charge Calculations--Least Cost Mix

Based on the market price of various types of scrap available and the safety precautions taken for the castings produced, the first decision is to determine the percentage of various scrap types that can be safely used. A metal charge is then calculated using preferred percentages of available types of cast iron and steel scrap, pig iron, and returns. The charge input of each element from each component is totalled and allowances calculated for anticipated losses and gains. Ferrous alloys are calculated to complete the necessary silicon and manganese contents.

Determining the lowest cost charge combination previously required several time-consuming trial-and-error calculations. Today, the computer can calculate the least cost mix quickly.

Fluxes for Fluidizing Slag

The addition of limestone or dolomite is necessary to fluidize the slag. Natural sources of slag such as coke ash, oxidized silicon, and lining consumed, as well as any sand and dirt on the scrap, are predominantly acid and produce a very viscous slag without the addition of sufficient basic flux.

Limestone or dolomite additions of 2 to 5% are generally needed in an acid cupola to contribute enough basic constituents of calcium oxide and magnesium oxide to impart sufficient fluidity for the slag to flow freely through the coke spaces, into the well, and down the front stagging trough. In the basic slag cupola, either with basic refractories or neutral water cooling, more basic flux is added to net a sufficient excess of basic slag constituents.

Limestone is a natural calcium carbonate stone. A lump size of 50 × 19 mm (2 × $\frac{3}{4}$ in.) is preferable. Silica is a neutralizing impurity and should be less than 2%. Several special or supplementary fluxes are occasionally used.

Soda ash (Na_2CO_3) is a strong slag liquefier used as briquets on the bed to supplement the limestone.

Fluorspar (CaF_2) is a powerful fluidizer used to clean up a cupola clogged with excessively viscous acid slag. In highly basic slags, fluorspar is needed to maintain fluidity. However, excessive fluorspar can cause environmental problems.

Calcium carbide (CaC_2) serves the multiple functions of deoxidizing, raising carbon, raising temperature, and providing a strong calcium oxide (CaO) flux contribution.

Combustion Reactions and Zones

In the cupola, heat for melting is generated by the combustion of carbon in the coke to carbon dioxide and carbon monoxide mixtures as the blast air penetrates the cupola and reacts with the hot coke. As the air enters from the tuyeres and contacts the first hot coke, oxygen in the air reacts with carbon in the coke according to the reaction:

$$C + O_2 = CO_2$$

As the gases penetrate the coke bed, oxygen is progressively depleted, along with the formation of carbon dioxide, and a zone of maximum temperature up to 1650 to 1705 °C (3000 to 3100 °F) is created.

As the gas high in carbon dioxide moves up through the excess coke, some of the carbon dioxide reacts endothermally to form a balance of carbon monoxide and carbon dioxide. This secondary reaction is:

$$CO_2 + C = 2CO$$

The top effluent gas typically yields 10 to 14% CO_2 and 15 to 10% CO. Effluent gas with carbon dioxide content on the high side and a carbon monoxide content on the low side indicates a more oxidizing net condition from hard blowing and/or a minimum coke percentage or reactivity. This condition will give the highest melting rate, but will also produce lower iron temperature, less carbon pickup, and more oxidation of silicon.

Effluent gas higher in carbon monoxide and lower in carbon dioxide indicates a less oxidizing net condition from more coke and/or softer blowing. This less oxidizing condition will melt less iron but at higher temperature with less oxidation of silicon and greater carbon pickup.

Cupola Zones

Cupola zones are designated functionally as follows:

- Preheat zone in the upper stack, in which the charge metal is preheated progressively by the ascending hot gases as the metal descends into the melting zone
- Melting zone is generally located 508 to 1270 mm (20 to 50 in.) above the tuyeres, where maximum temperature is generated and the metal charge is melted
- Well zone collects the melted metal and slag as it drips through the coke, accumulates in the well, and flows out the taphole

Chemical Zones. There are several chemical zones in the cupola. The zone immediately out from the tuyeres is very oxidizing until the excess oxygen is burned. The hottest melting zone where high carbon dioxide content prevails is slightly oxidizing. A reducing zone develops in the upper melting and preheat zones where coke and carbon monoxide predominate.

As it descends, the metal charge melts and drips through the coke bed and passes through varying combinations of these reducing, neutral, and oxidizing zones. The net effect is slightly oxidizing, but it varies depending on coke ratio, coke reactivity, and blast air volume and velocity.

Because of a net oxidizing influence, silicon loss is generally 8 to 15% in the acid cupola and 25 to 40% in the basic slag cupola. Silicon in the charge is calculated to make allowance for the expected loss.

The oxidation loss of manganese is 10 to 20% in the acid cupola and 5 to 10% in the basic cupola. During melting, sulfur is absorbed from the sulfur present in the coke.

Carbon is generally absorbed to maintain an equilibrium carbon saturation level. Hypereutectic pig iron generally loses some carbon. Low-carbon steel scrap is carbon hungry and continuously absorbs carbon. More coke is needed for high-steel charges to provide the dissolved carbon. Return and cast iron scrap absorb less carbon because they contain considerable carbon and are less hungry for absorption.

The molten bath that accumulates in the well has further contact with coke and further opportunity to absorb carbon, depending on many factors. In addition, some slag reaction can occur because the molten slag and molten metal have further opportunity to react toward equilibrium. Although cupola control is complex, an understanding of the various chemical interactions, accurate records, and diligent correlation of experiences will provide good control, quality, and efficiency.

Coke Bed

Preparation of the coke bed is vital to the initial start of the melt and to the maintenance of the melt at the specified level in the cupola combustion zones. Before metal is charged, a bed of good-quality, sized coke is ignited and blown to a red heat by any of several methods. The height of the bed coke is adjusted to a specific height above the tuyeres (usually within 1020 to 1525 mm, or 40 to 60 in.) that is determined by experience and based on blast volume, cupola diameter, and desired melting conditions. Bed flux and metal charges are then added, the blowers are turned on, and the melting begins within a few minutes.

With a high bed, melting occurs higher in the stack, slower and hotter with less oxidation and more carbon pickup. A low bed melts lower, faster, and colder with more oxidation.

Charge coke is intended to replace coke burned in the melting of each charge in order to maintain the effective melting zone within a desirable position in the combustion zones. If the bed drops too low during the heat, booster coke additions may be needed to restore operating bed height.

Control Principles

Melt Rate. A cupola is expected to maintain a melting rate sufficient to meet the needs of mold production. The cupola size must be chosen for the midrange of production demand. A general rule is that 4.5 kg (10 lb) of iron can be melted per hour for each square inch of cross-sectional area.

By increasing or decreasing the blast, melt rate can be varied ±20% with reasonably good efficiency and control. Varying the hot blast and/or oxygen injection can extend this control range.

Beyond these limits, overblowing a cupola increasingly oxidizes the iron, causing lower carbon and silicon levels and decreasing the temperature. Underblowing will lower the temperature because the blast will not penetrate the cupola with sufficient air distribution for optimum combustion efficiency.

Iron Temperature. The iron temperature at the cupola spout must be adequate to survive handling losses and to be poured into the molds at sufficient temperature and fluidity to produce sound castings. Iron temperature is measured by optical pyrometers, thermocouples, and continuously recording radiamatic instruments.

Iron temperature is primarily influenced by the coke concentration in relation to the metal charge. If coke percentage is increased from 8 to 12% of the metal charge, the iron temperature is usually increased approximately 65 °C (120 °F), while the melting rate is reduced 20 to 25%, especially if air volume is maintained at the same level. Increasing the preheat temperature on the blast air or increasing the percentage of oxygen injected will instantaneously increase metal temperature.

Carbon and Silicon. Carbon and silicon concentrations are most important in the control of iron properties because both elements are strong graphitizers. In malleable iron, carbon and silicon concentrations must be kept low to encourage a carbidic structure as-cast and to avoid graphitization until heat treatment.

In gray iron, sufficient concentrations of carbon and silicon must be maintained, within control limits, to avoid chill and to encourage graphitization in desirable flake form and a structure most suitable for the section size of the castings and strength levels specified. In ductile iron, sufficient carbon and silicon concentrations must be maintained within controlled ranges for graphitization in nodular form and control of matrix structure. In gray iron, and more critically in ductile iron, a postinoculating ladle addition of ferrosilicon is essential to nucleate most favorable graphite precipitation and structure.

Silicon is controlled from the cupola with the addition of ferrosilicon alloy, allowing for the anticipated oxidation loss of total silicon in the charge. Carbon content is primarily controlled by the percentage of steel scrap in the charge. Because steel contains relatively little carbon, increases in the percentage of steel decrease carbon content. Some carbon is absorbed as steel scrap melts in the presence of coke but does not have time to reach carbon saturation equilibrium; therefore, the net effect is a lowering of the carbon level.

This carbon absorption rate is influenced by coke properties, coke ratio, and slag basicity. In addition, carbon pickup is increased by increases in blast temperature and oxygen injection as well as by fine coke injection. The need for immediate increase in final carbon can be quickly realized from an increase in one of these supplementary boosters of combustion.

Sulfur in gray iron is not detrimental until the level is above 0.120% or possibly 0.150% S if manganese is maintained at a sufficient ratio in relation to sulfur. Sulfur in ductile base iron should be below 0.03% and preferably below 0.015%, because base sulfur reacts with the magnesium from nodulizing alloys and complicates magnesium control and iron cleanliness.

Manganese is needed in gray iron at an amount of 1.7 times sulfur plus an additional 0.30% to ensure that the sulfur is precipitated as manganese sulfide rather than iron sulfide. In pearlitic ductile iron, manganese can contribute beneficially to the total alloys needed to produce a pearlitic matrix. However, in ferritic ductile iron, manganese should be as low as possible to minimize pearlite in the as-cast structure.

Phosphorus is controlled by a variety of charge materials that are low in phosphorus.

In gray iron, phosphorus contents should be below 0.20% and even below 0.10% because high phosphorus levels are detrimental to machinability and soundness in complex shapes. In ductile iron, phosphorus content below 0.10% and preferably 0.05% is desirable for the maximum impact resistance and ductility potential of ductile iron. For these low phosphorus levels, considerable pig iron is sometimes required. Steel scrap is generally the lowest phosphorus scrap material and is extensively used with ductile iron.

Residual Alloys and Tramp Elements. The effects of various inadvertent alloys and tramp elements should be understood, and control ranges and maximum levels should be established. Rapid analysis by modern spectrometers makes it possible to monitor trace element levels and to coordinate these levels closely with the composition of incoming

raw materials. Any scrap source contributing excessive concentrations of detrimental elements should be removed from the cupola charge.

Certain tramp elements detrimental to graphite forms, such as lead and bismuth, must be controlled well below the maximum level allowed. Titanium in trace amounts is beneficial to gray iron flake graphite, but is detrimental to the nodular graphite forms needed in ductile iron. Inadvertent alloys such as chromium, copper, tin, and molybdenum, if maintained within controlled ranges and combinations, can contribute to the pearlitic matrix structure of high-strength gray irons and pearlitic ductile iron. However, for ferritic ductile iron with the highest ductility, acceptable limits for residual alloys are much lower.

Control Tests and Analyses

The chill test was one of the earliest control tests and is still a good indicator of the graphitizing balance of an iron. A chill specimen is cast either as an elongated wedge in a sand mold or as a bar cast against a metal chiller on one side.

After a few minutes, the test specimen is broken, and the depth of carbidic white iron chill indicates the carbon, silicon, and total balance of graphitizing elements against carbide-forming elements. This chill depth signals the need for more or less silicon and/or carbon or an adjustment in the postinoculation.

Wet chemical analysis provides a guide for subsequent iron control, but analysis time is too long for immediate correction.

Eutectic arrest methods were developed to provide, within a few minutes, carbon equivalent and carbon content with reasonable accuracy, as well as calculated silicon content. These rapid determinations make possible the immediate corrective adjustments of carbon and silicon and with much better composition control.

Spectrometer equipment greatly facilitates iron control, with complete analysis of important elements within a few minutes. In large plants, samples are conveyed to the laboratory in pneumatic tubes, and analyses are reported to the melting center by phone, autowriter, or computer readouts within a few minutes.

Mechanical tests of several types are conducted to ensure the uniformity of iron properties and compliance with specifications. Tensile tests of gray iron ensure that the iron meets the strength level expected from the specified class of iron. On ductile iron, tensile tests verify that the specified grade is being met. Each grade specifies ultimate tensile strength, yield strength, and percentage of elongation. Brinell hardness tests of castings monitor uniformity and general matrix structure.

On ductile iron, rapid microscopic evaluation of each treatment batch is essential to ensure graphite modularity before castings reach the shakeout operation and lose their identity. Nodular graphite structure in a casting can be verified with properly calibrated ultrasonic test equipment. Ultrasonic testing of all castings is performed by some companies to ensure modularity on critical parts or to evaluate a questionable lot.

Basic Slag Composition Effects

In conventional acid slag operation, no sulfur removal or refinement is expected from the slag. Enough basic flux, such as lime-stone, is added to fluidize the acid sources of slag and mechanically cleanse the cupola for efficient combustion. Tables 2 and 3 give the compositions of several acid cupola slags with a predominance of acid silicon dioxide and a ratio of basic constituents (CaO + MgO)/SiO_2 of less than 1.

Table 2 Acid slag compositions

Acid slag	Acid constituent SiO_2	Neutral Al_2O_3	Basic constituents		
			CaO+MgO	MnO	FeO

(a) Limestone.

(b) Total iron as FeO including small portion of Fe_2O_3

Within normal ranges and adequate fluidity, the acid slag exerts little effect on iron chemistry. However, very viscous high silicon dioxide slags, because of insufficient flux, tend to cling to the coke and tend to clog interstitial air passages and the coke surface, resulting in lower iron temperature, lower carbon content, and increased oxidation. Heavy flux additions yield a very fluid neutral or mildly basic slag that is corrosive to acid refractories but cleanses the coke, resulting in higher carbon and lower sulfur than normal.

Basic cupola operation was developed to yield low-sulfur iron directly from the cupola by supplying sufficient excess of basic constituents so that the slag will absorb and remove sulfur from the iron. Sulfur removal from the iron into the slag

increases with slag basicity, volume, and fluidity, and low iron oxide content improves the desulfurizing potential of the slag. Table 4 lists the compositions of various basic cupola slags.

Table 4 Compositions of various basic cupola slags

Basic slag	**Composition, %**								
	SiO_2	**Al_2O_3**	**CaO**	**MgO**	**MnO**	**FeO**	**S**	**CaF**	**Basicity[(a)]**

	27.6	11.4	37.2	20.4	. . .	0.4	2.01	. . .	1.50

(a) CaO + MgO/SiO_2 + Al_2O_3

Some investigators consider the effective basicity ratio to be (CaO + MgO)/(SiO_2 + Al_2O_3). Others find that aluminum oxide is more nearly amphoteric and neutral with little effect as an acid constituent and therefore consider the basicity ratio (CaO + MgO)/SiO_2 to be a more accurate and simple guide.

When sufficiently basic and low in ferrous oxide, basic slags can reach a level of 1.0 to 2.0% S that has been removed from the metal. Metal sulfur contents as low as 0.004 to 0.02% have been obtained from a basic slag cupola.

In addition to sulfur removal, the basic slag increases carbon pickup as basicity increases. Increased carbon pickup permits the use of higher proportions of steel scrap, which is economically attractive in producing ductile iron. However, the highly basic slags that yield the desired, very low sulfur levels can yield carbon levels sometimes higher than wanted. Consequently, control is very sensitive on a highly basic cupola, and silicon loss is much higher--in the range of 25 to 40%. For these reasons, some basic slag operations in water-cooled cupolas have been shifted to neutral or acid slag operations, with desulfurization performed externally by one of several desulfurizing methods.

Desulfurization Methods

Several successful desulfurizing techniques have been developed in the search for methods of obtaining low-sulfur base iron for ductile iron. In earlier years, the removal of some excessive sulfur in gray iron was accomplished by the forehearth or ladle addition of sodium carbonate (soda ash), but refractory attack made it impractical to reach very low sulfur levels.

Calcium carbide has proved to be the most effective desulfurizing agent for low sulfurs. Lime is also an effective desulfurizing agent, but it requires more volume, time, and agitation. Small percentages of fluorspar and various salts improve the desulfurizing effectiveness of lime.

Metal stirring or agitation is essential for promoting optimum desulfurization. The spent carbide or lime slag containing sulfur is then removed from the metal. Disposal of the carbide slag requires attention to safety and environmental considerations.

The following stirring methods have been found to be effective:

- The injection of carbide with inert gas through graphite or refractory lances that supply the carbide and simultaneously stir the melt
- A porous plug in the bottom of a ladle through which inert gas is bubbled, with desulfurizing agent fed onto the surface with a vibrating feeder
- The shaking ladle system places a ladle of iron in a gyrating shaking mechanism that stirs in the desulfurizing agent
- The refractory stirrer system rotates a refractory paddle in the bath, stirring the carbide or lime into contact with the iron

Injection and porous plug desulfurizing systems can be either batch type, treating individual ladles, or they can be a continuous system, with the cupola stream flowing through a special forehearth outfitted with a porous plug and a carbide feed (or injection lance). The spent carbide or lime overflows or is raked off, and the desulfurized metal flows continuously into the holder or duplex electric furnace.

With any of these stirring methods, additions of 0.50 to 1.0% CaC_2 have desulfurized irons of 0.07 to 0.10% S, as-melted, down to a final 0.01 to 0.02% S. A temperature loss of 30 to 55 °C (50 to 100 °F) can be expected. Lime alone or with various salts can be used as the desulfurizing agent; the efficiency is lower than that with carbide, but there are fewer environmental problems.

Computer Use in Cupola Operation

The ultimate refinement in cupola operation is the use of the computer to record, monitor, and control many of the important variables in cupola operation. Computer applications are continually being expanded. Some of the earliest and most significant applications have been:

- Least cost charge calculations by quickly calculating the charge cost of various combinations of available raw materials; the lowest cost charge can thus be determined
- Metal weight compensations in the dropping of metal components from crane magnets into weigh hoppers, any over-shooting or undershooting can be balanced out by the computer on subsequent charges
- Automatic weighing of coke, flux, and ferrous alloys has been done by computer
- Adjustments in coke weight to compensate for atmospheric humidity, as well as adjustments in coke weight for overshooting or undershooting on metal charge weights
- Continuous analysis and recording of top gas composition; in addition, alert signals are activated when explosive levels of hydrogen are approached from water leaks
- Display of chemical analyses with statistical process control limits and alert signals when any element is approaching limits
- The indicating, recording, or controlling of any data important to maintenance or control

Further computer applications are continually being directed toward better control of iron content and cupola performance.

Specialized Cupolas

Cokeless Cupola. In the 1970s, a cokeless cupola fired with gas or oil was developed in Europe and was put into operation in several countries. It was a refractory-lined shaft furnace with a water-cooled grate supporting a bed of refractory spheres, as illustrated in Fig. 5.

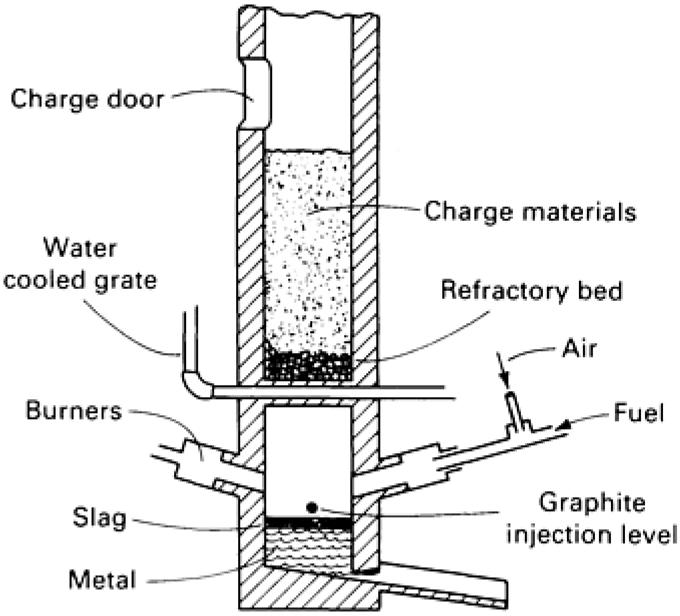

Fig. 5 Schematic of the Taft cokeless cupola

Heat for melting is generated by either gas or oil burners located below the grate and refractory bed. The iron melted in a cokeless cupola has the advantage of having a low sulfur content but also has a low carbon content, both of which are due to the absence of coke. In the Taft cupola, the iron is carburized to a specified carbon content by injecting a fine carburizer (either petroleum coke or graphite) into the iron in the well.

Pollution from the cokeless cupola is minimal and reportedly would meet environmental standards in some countries without expensive emission control equipment. In countries where coke must be imported at a high price and oil or gas is readily available, the cokeless cupola is economically attractive. Production experiences have been reported on small cupolas in the 4.5 to 9.1 Mg/h (5 to 10 ton/h) range, with no practical experience reported on large cupolas. Fuel cost can be attractive in some countries, but the high cost of refractory sphere replacements and the restrictions on the percentage

of steel scrap used limit the attractiveness of this equipment in many raw material markets. In the United States, some pilot heats have been run on a gas fired cupola. This project was sponsored by the Gas Research Institute, but no reports are available.

Plasma-Fired Cupola. In the 1980s, a pilot plant plasma-fired cupola was built, and a number of experimental heats were run with some encouraging results. In the 762 mm (30 in.) ID cupola, a single 2 MW plasma torch was projected into the cupola at tuyere level, as shown in Fig. 6.

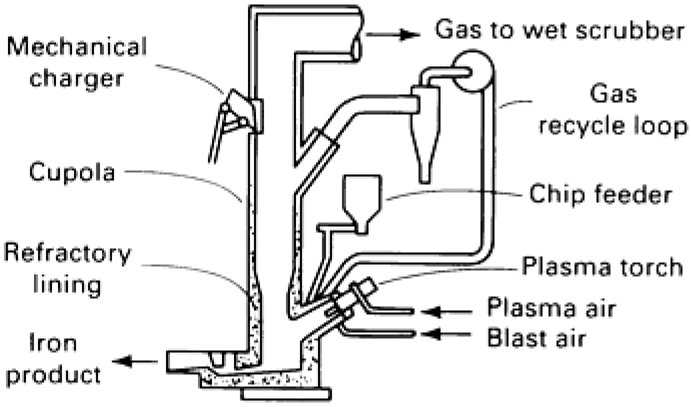

Fig. 6 Schematic of a plasma-fired pilot cupola

In the water-cooled torch, an electric arc from a high-amperage direct current is maintained across a gap between two copper sleeves, and the arc is rotated by a magnetic field. Air (or gas) is passed through the electric arc, where it is ionized and heated to very high temperatures unattainable with fossil fuels.

The approximately 30 experimental heats conducted thus far have indicated several advantages of using a plasma-fired cupola:

- Coke could be considerably reduced by supplementing electric power from the torch
- Lower-quality coke could be used; blast furnace coke, fine waste coke, and anthracite coal have melted successfully
- Direct melting of borings and turnings proved practical because of lower air velocity and lower oxidation level
- The generation of silicon from injected sand and coke breeze
- Iron reduced from as much as 20% iron oxide injected at tuyere level

Many possibilities of the plasma-fired cupola merit further exploration. Economically, the most attractive immediate application is the direct melting of 70% or more iron borings or steel turnings. A large plasma-fired cupola is being installed in an automotive foundry scheduled to start operation in 1988.

Vacuum Induction Melting (VIM)

A. Choudhury and H. Kemmer, Leybold AG, West Germany

THE PRODUCTION OF LIQUID METAL under vacuum in an induction-heated crucible is a tried and tested process. It has its origins in the middle of the 19th century, but the actual technical breakthrough occurred in the second half of the 20th century.

Vacuum induction melting can be used to advantage in many applications, particularly in the case of the complex alloys employed in aerospace engineering. The following advantages have a decisive influence on the rapid increase of metal production by vacuum induction melting:

- Flexibility due to small batch sizes
- Fast change of program for different types of steels and alloys
- Easy operation
- Low losses of alloying elements by oxidation
- Achievement of very close compositional tolerances
- Precise temperature control
- Low level of environmental pollution from dust output
- Removal of undesired trace elements with high vapor pressures
- Removal of dissolved gases, for example, hydrogen and nitrogen

Vacuum induction melting is indispensable in the manufacture of superalloys, which must be melted under vacuum or in an inert gas atmosphere because of their reactivity with atmospheric oxygen and nitrogen. The process is suitable for the production of high-purity metals under oxygen-free atmosphere. This limits the formation of nonmetallic oxide and nitride inclusions. However, problems can arise in the case of alloying elements with high vapor pressures, such as manganese.

Figure 1 shows the various installation and application possibilities of the vacuum induction furnace. The casting weight can vary from a few kilograms to 30 Mg (33 tons), depending on whether the furnace is being used for precision casting or for the production of ingots or electrodes for further remelting.

Metallurgy of the Vacuum Induction Furnace

In contrast to the electric arc furnace (ladle metallurgy), there are many different factors that arise with induction furnace melting and significantly affect the metallurgical process. In a VIM furnace, slag would be transported to the crucible wall by the characteristic bath movement. The result is that the slag solidifies at the wall and therefore has an insufficient reaction with the melt. For this reason, metallurgical operations such as dephosphorization and desulfurization are limited.

Crucible Materials. In addition to the slag movement, the rammed crucible wall lining is susceptible to significantly higher erosion than the brick wall of a ladle. Therefore, VIM metallurgy is primarily limited to the pressure-dependent reactions, such as carbon, oxygen, nitrogen, and hydrogen, and the evaporation of undesired elements with high vapor pressures, such as copper, lead, bismuth, tellurium, and antimony. Figure 2 shows a typical process profile for the vacuum induction melting of nickel- and cobalt-base superalloys.

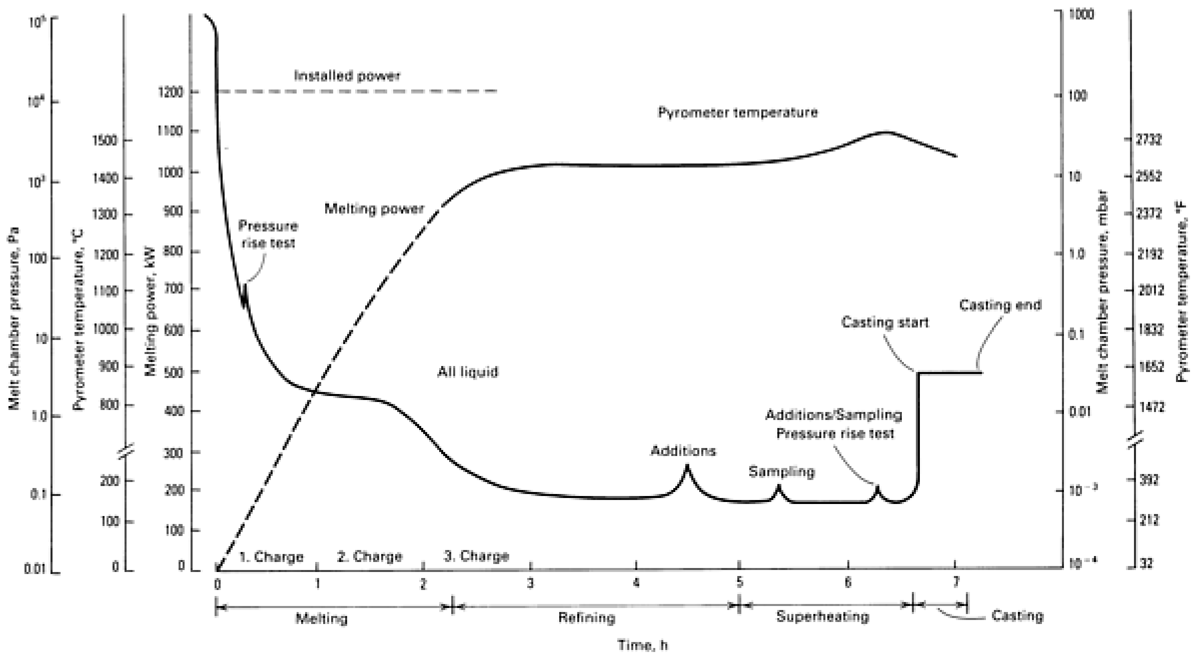

Fig. 2 Typical VIM melt protocol for nickel- and cobalt-base superalloys.

The crucible material has an extraordinary effect on the metal/slag reaction because the ceramic outer wall reacts with the liquid metal and with the slag. It is therefore beneficial to use a slag that is more or less saturated with the oxides of the crucible lining in order to minimize heavy slag attack of the lining.

The refractory material used for the crucible lining is based on oxides such as Al_2O_3, MgO, CaO, or ZrO_2 (Table 1). The lining is almost always rammed and sintered; prefabricated brick is used in larger furnaces. Dried silicate, combined with small oxide additions, appears to be very suitable for crucible lining because of its thermal characteristics. Because of an irreversible thermal expansion of 8% above 1000 °C (1830 °F), a high densification of the lining takes place during sintering. For this reason, this active lining is suitable for foundries. The behavior of the lining refractory with regard to stability at high temperature under vacuum must also be considered.

Table 1 Typical refractories used to line VIM crucibles

Refractory	Maximum melt temperature	Refractory density	Resistance to thermal shock	Applications

	°C	°F	g/cm^3	lb/in.^{3}		
MgO	1600	2910	2.8	0.101	Good	Superalloys, high-quality steels
Al_2O_3	1900	3450	3.7	0.134	Good	Superalloys, high-quality steels
MgO-spinel	1900	3450	3.8	0.138	Poor	Superalloys, high-quality steels
Al_2O_3-spinel	1900	3450	3.7	0.134	Relatively good	Superalloys, high-quality steels
ZrO_2	2300	4170	5.4	0.195	Poor	Superalloys, high-quality steels
Graphite	2300	4170	1.5	0.054	Excellent	Copper, copper alloys

The carbon monoxide partial pressures at which the lining oxides are reduced by carbon in the melt are:

Lining material	**Carbon monoxide partial pressure**	
	kPa	**torr**
CaO	0.04	0.3
ZrO_2	0.13	1.0
MgO	0.53	4.0
Al_2O_3	0.53	4.0
SiO_2	81.1	610.0

It is evident that CaO represents the stable crucible material, while SiO_2 is reduced at relatively high pressure. Apart from that, SiO_2 can be reduced by alloying elements such as manganese, chromium, aluminum, titanium, or zirconium. This can cause a heavy chemical erosion of the lining, accompanied by an undesired silicon pickup in the melt. Because of these undesired reactions with a silica lining, a spinel-forming basic refractory material is used for the melting of high-grade steels and superalloys. The spinel formation during sintering leads to volume growth; therefore, as with the oxidic material, a densification of the rammed lining takes place.

Trace Element Removal. The removal of undesired volatile trace elements such as arsenic, antimony, tellurium, selenium, bismuth, and copper, from the vacuum induction furnace is of considerable practical importance. These elements must be held to very low concentrations to avoid the risk of premature part failure, particularly for the production of superalloys for critical applications, such as jet engine parts. Figure 3 shows the influence of some trace elements on the stress rupture properties of Alloy 718. Because of the high vapor pressures of most of the undesirable trace elements, they can be kept to very low levels by distillation during melting under vacuum.

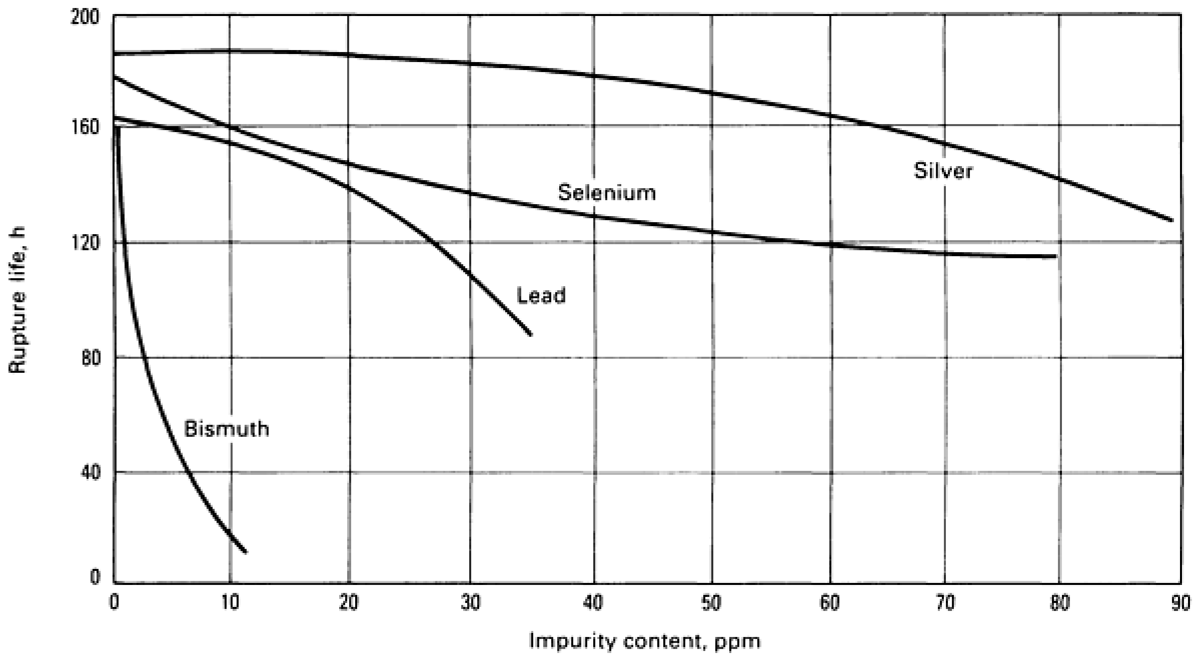

Fig. 3 Effect of trace elements on the stress rupture properties of Alloy 718. Test conditions: 650 °C (1200 °F), 690 MPa (100 ksi). Source: Ref 2.

Figure 4 shows how the different trace elements behave under vacuum. In a nickel-chromium melt, arsenic, antimony, and tin cannot be reduced over the gas phase, while copper, lead, selenium, and bismuth can be reduced to a level far below 10 ppm.

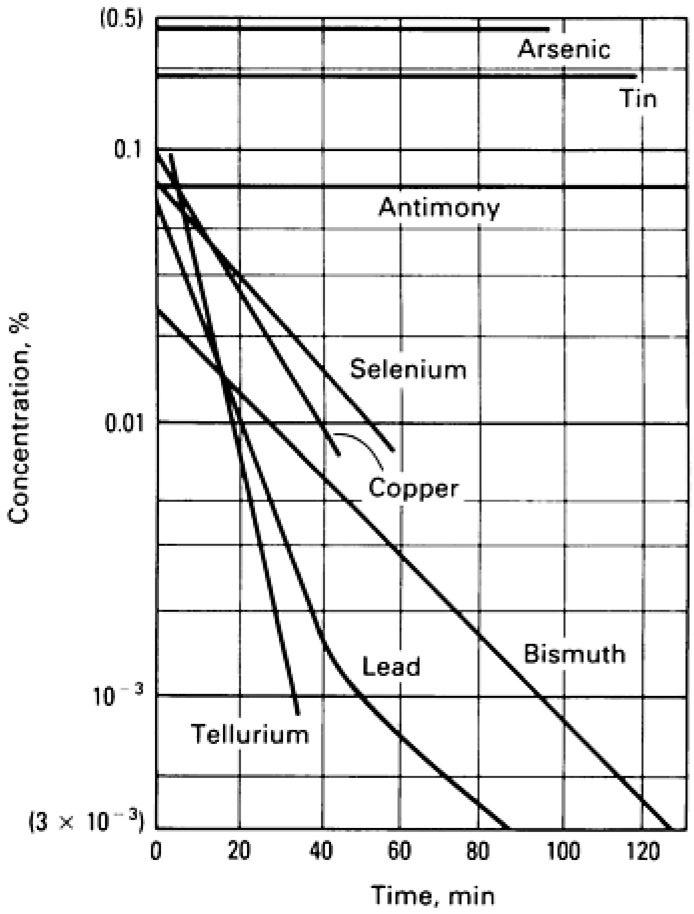

Fig. 4 Evaporation of trace elements from Ni-20Cr melts under vacuum. Source: Ref 3.

Degassing. Nitrogen and hydrogen can be decreased via the gas phase because the solubilities of these gases at constant temperature are directly proportional to their partial pressures.

Nitrogen Removal. As long as no strong nitride-forming elements are present in the melt, there is no difficulty in reducing the nitrogen content to 20 ppm (Ref 4, 5, 6). When nitride-forming elements such as chromium, vanadium, aluminum, and titanium are present, the activity of the nitrogen is very low; therefore, removal of nitrogen under high vacuum is difficult. If low nitrogen contents are desired in alloys containing nitride-forming elements, raw materials low in nitrogen must be used.

Figure 5 shows the reduction in nitrogen levels obtained in the vacuum induction melting of a die steel. From an average level of about 400 ppm at the beginning of treatment, the nitrogen has been reduced to a level of 50 ppm. Additional argon purging during melting of the steel did not improve nitrogen removal. In the case of iron-nickel melts, however, the additional argon purging reduces nitrogen to much lower values.

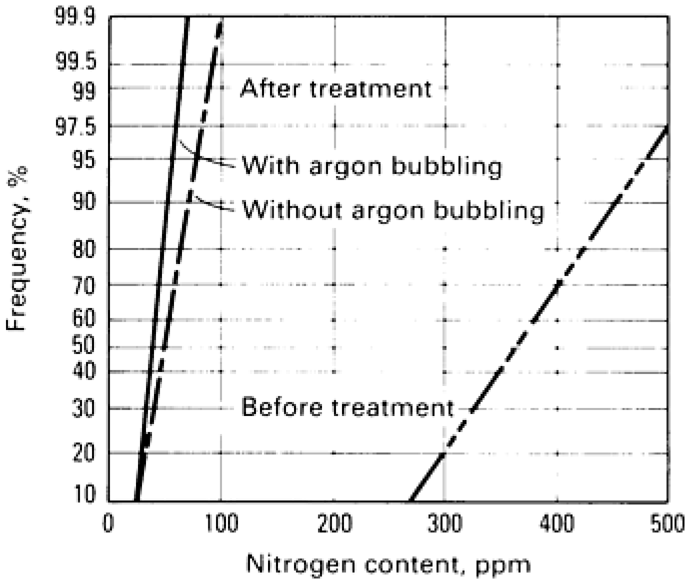

Fig. 5 Reduction in nitrogen content of X38CrMoV51 (Fe-0.38C-5.2Cr-1.3Mo-0.4V-1Si-0.4Mn) die steel after VIM processing.

Hydrogen Removal. The solubility of hydrogen at atmospheric pressure and at 1600 °C (2910 °F) in iron or nickel melts is in the range of 30 ppm. During vacuum induction melting, the hydrogen can be removed to very low concentrations. Figure 6 shows the hydrogen contents of a die steel before and after vacuum treatment.

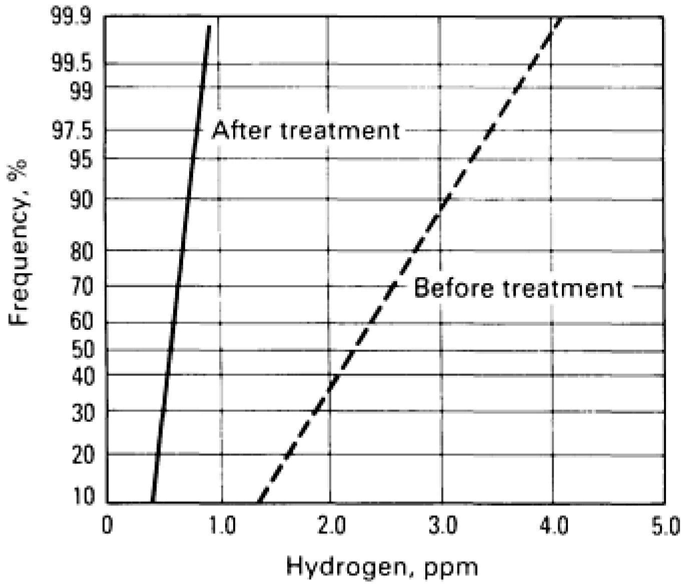

Fig. 6 Reduction in hydrogen content of X38CrMoV51 die steel after vacuum induction degassing.

It is evident from Fig. 6 that final hydrogen contents below 1 ppm can be routinely achieved. The reduction in hydrogen during the degassing treatment amounts to approximately 80%. Argon purging had no perceptible influence.

The bath agitation in the case of this furnace, which is operating at normal frequency, is sufficient for hydrogen removal. Similar results were also obtained for the VIM processing of superalloys.

Deoxidation of the melt in the vacuum induction furnace can be done via the gas phase, as described below:

$$C + O \rightarrow CO \text{ (gas)}$$

The final attainable oxygen content for a given carbon content is directly proportional to the carbon monoxide partial pressure.

The theoretical equilibrium values for oxygen are below 1 ppm in carbon-containing iron or nickel melts at 1600 °C (2910 °F) and at a pressure of 0.1 Pa (10^{-3} mbar, or 7.5×10^{-4} torr). However, the actual values are up to one order of magnitude higher. These higher oxygen contents result from impurities in the crucible lining, crucible outgassing and leakage, and above all the fact that the reaction does not reach equilibrium with decreasing oxygen content because of the difficulty of carbon monoxide nucleation.

In addition, the hydrostatic pressure of the liquid metal in the melt must be taken into account because only a relatively small bath surface area is in direct contact with the prevailing vacuum pressure. However, the influence of the liquid-metal hydrostatic pressure can be minimized through the use of additional agitation effects.

The carbon monoxide reaction occurs in two stages (Ref 1). The first stage is boiling, that is, the formation of carbon monoxide bubbles within the melt along with a strong bath agitation as a result of this gas formation. The second stage is desorption, in which no more carbon monoxide bubbles form inside the melt and carbon monoxide formation takes place only at the bath surface.

Deoxidation with carbon is also a decarburization reaction, which is used for the production of low-carbon high-chromium steels. By using the carbon monoxide reaction under vacuum, very low carbon contents can be achieved without a noticeable loss of chromium. The oxygen content in such alloys is higher because of the decrease in oxygen activity due to chromium. In this case, precipitation deoxidation using aluminum, silicon, or titanium must be applied.

Cleanliness of VIM Melts. Freedom from oxide inclusions is extremely important for vacuum induction melted alloys, particularly for superalloys with extremely high strength properties at higher operating temperatures. Figure 7 shows the effect of oxygen content on the rupture lives of two superalloys.

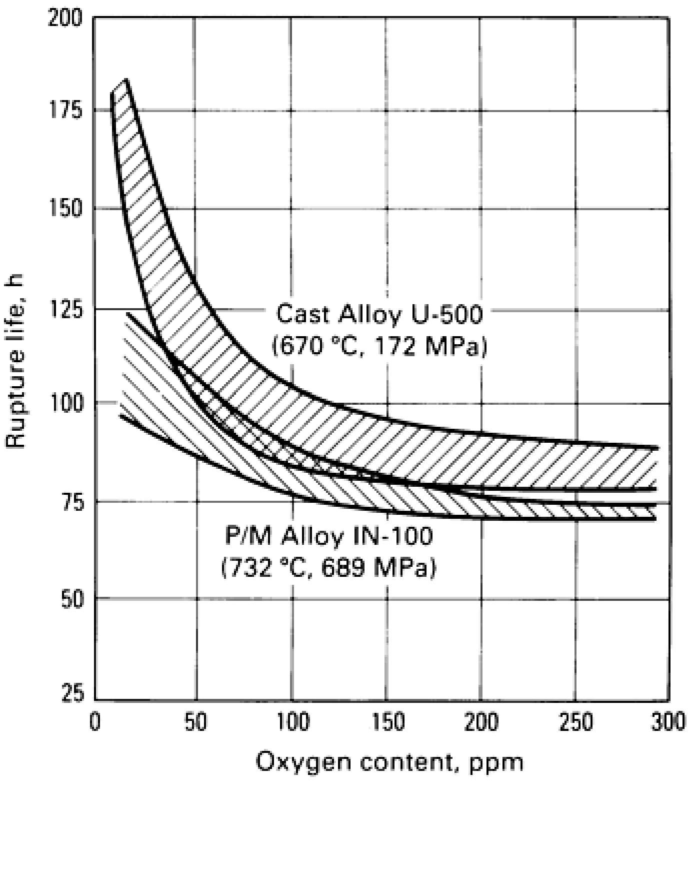

Fig. 7 Effect of oxygen on the rupture life of two superalloys. Source: Ref 7.

Cleanliness can be significantly improved if a reactive liquid slag capable of absorbing oxides and sulfides is in contact with the melt. Vacuum induction furnaces are generally not operated with active slags. Therefore, reaction products can precipitate only on the crucible walls, and the melt may not be as clean as with other processing methods.

Because the various alloys produced in vacuum induction furnaces must meet the highest quality requirements and because the vacuum induction furnace is primarily a consolidation unit and only secondarily a refining unit, the following methods are used to produce clean melts:

- Selection of a more stable refractory material for the crucible lining
- Rinsing of the melt with inert gas
- Minimizing the contact time of the melt in the crucible
- Exact temperature control to minimize crucible reactions with the melt
- Suitable deslagging and filtering techniques during pouring
- Conception of a suitable tundish and launder system for good oxide removal

For particular applications, however, the quality of the material produced by vacuum induction melting will not be sufficient to satisfy the highest quality requirements with respect to cleanliness and primary structure. In this case, the VIM-produced material must undergo another remelting process.

Production of Nonferrous Materials

Apart from melting high-grade steels and superalloys, vacuum induction melting is being increasingly used for the production of nonferrous metals and alloys. Table 2 shows some examples for possible use in nonferrous metallurgy.

Table 2 Possible applications for VIM in the processing of nonferrous metals and alloys

Metal or alloy	Metallurgical results	Achieved by
Aluminum, aluminum alloys	Low oxygen content, effective removal of oxides	Vacuum tank degassing without additions of polluting gases or materials
High-purity metals	Oxygen-free copper (2 ppm O)	Melting and pouring under steady, controlled atmosphere or vacuum; gas stirring; carbon as reducing agent

"New" alloys	Al-Mg, Al-Ce, Al-Zr, Al-Hf alloys; copper alloys with beryllium, cobalt, titanium, zirconium, and lithium; avoidance of lithium losses in production of Al-Li alloys	Furnace and casting system under inert gas atmosphere; vacuum-tight, highly automated furnace
Metal production and recycling	Production of calcium, barium, lithium, strontium, and magnesium; recycling of hard metals; purification of alloys or melts; removal of zinc and lead	Thermic/alumino-thermic vacuum distillation; leaching with zinc and subsequent vacuum distillation melting; vacuum distillation

Aluminum alloys with additives such as zirconium, titanium, beryllium, cerium, tellurium, and cadmium must be melted under vacuum or under inert gas atmosphere because of their high reactivity with air and in some cases their toxicity. Aluminum-lithium alloys are also candidates for VIM processing.

Copper Alloys. The production of high-purity copper having less than 2 ppm O can be accomplished only in a vacuum induction furnace. Oxygen content influences the electrical conductivity of copper alloys; the lower the oxygen content, the higher the electrical conductivity (Ref 8). For the production of oxygen-free copper, melting and casting must be carried out under vacuum.

Selective Evaporation of Alloying Elements. The use of vacuum metallurgy is primarily linked with degassing and decarburization. A side effect of these treatments is the evaporation of elements with high vapor pressures. In nonferrous metallurgy, this effect is used for the distillation of metals--for example, for the separation of lead and zinc in lead refining, in zinc production, and for the reduction of magnesium and nonalkali metals. Similarly, copper can be refined from copper scrap by using the vacuum to evaporate volatile elements such as lead and zinc (Ref 9).

Furnace Design and Casting Technologies

Beginning with the original furnace design (Fig. 8), VIM equipment has continued to improve to adapt to special requirements. Equipment can be combined in various ways for maximum productivity. For example, in some designs, the mold chamber can be prepared for casting without disturbing the melting operations, and vice versa. In addition, the smaller vacuum chambers of modern equipment reduce the pumping capacity required and/or allow low pressures to be reached faster.

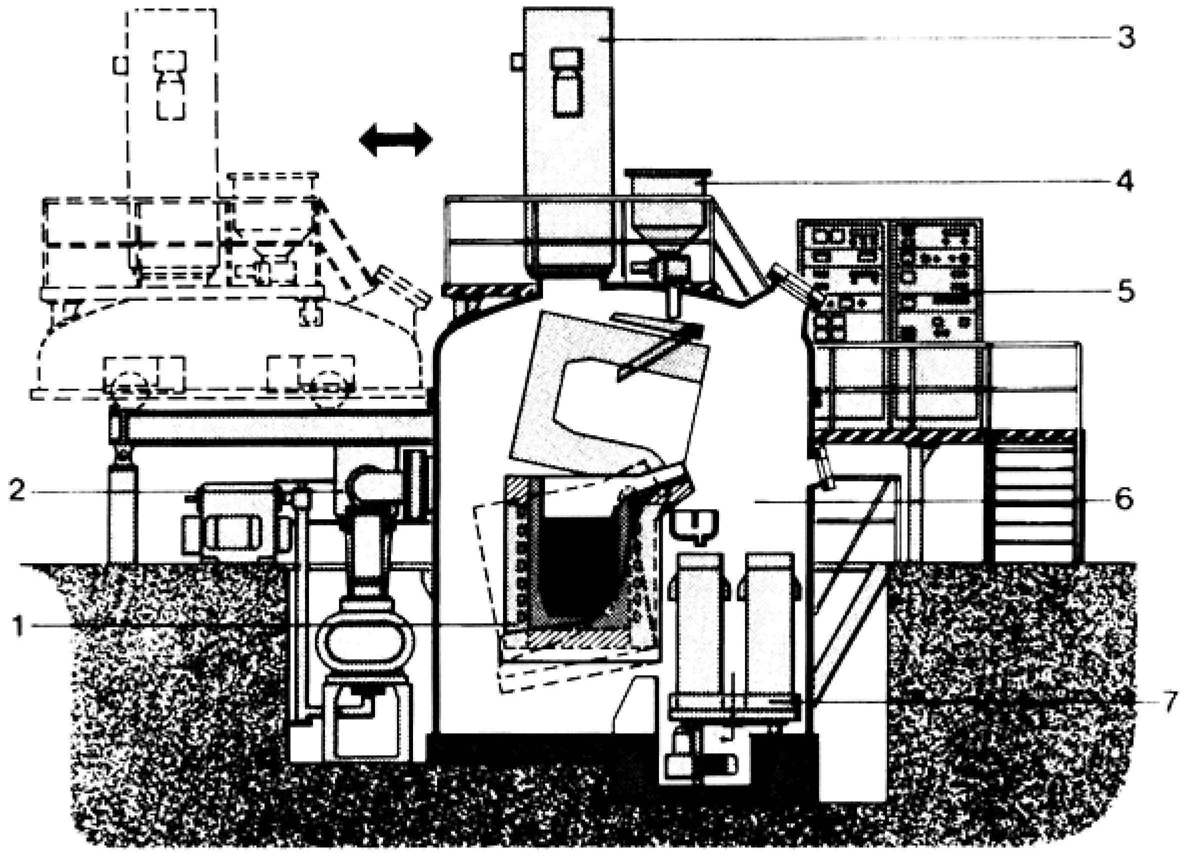

Fig. 8 Schematic of a typical VIM furnace. 1, furnace insert; 2, vacuum pumping system; 3, bulk charger; 4, fine charger; 5, control cabinets; 6, melting and mold chamber; 7, mold turntable.

Vacuum Induction Degassing and Pouring (VIDP). A new development has led to the VIDP furnace design (Fig. 9). This furnace is a further development of the conventional VIM furnace, which offers all the possibilities of metallurgical and process technology. The VIDP furnace design employs a melting and treatment unit that enables the use of different casting techniques. The modular concept allows for connecting it to casting units for ingot casting, horizontal and vertical continuous casting, or powder production. Because of the smaller volume of the VIDP furnace compared to the VIM furnace and significantly lower desorption and leakage rates, it is possible to obtain very low pressures with lower pumping capacity. The lower part of the furnace can be decoupled and replaced rapidly; therefore, the vacuum induction degassing and pouring furnace enables faster replacement of different furnace vessels with changes of alloy.

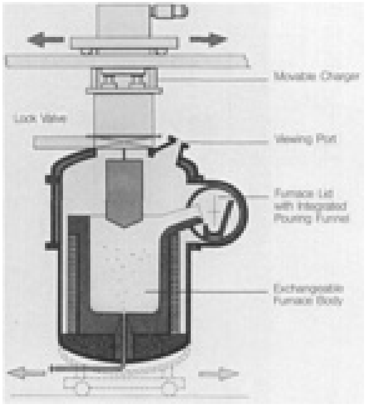

Fig. 9 Schematic of the VIDP furnace.

Melting bath agitation is caused by the induction coil itself, depending on the power input and the installed frequency. However, use of the coil to assist in the bath agitation is basically limited to the meltdown period. Degassing, for example, is improved by means of good bath agitation. However, this can be done with the induction coil alone only if there is a high-power input and therefore strong bath heating. This high temperature increase is not always metallurgically desirable.

For this reason, two agitation systems are offered in state-of-the-art vacuum induction furnaces, and one or the other can be used according to requirements. They are:

- Electromagnetic agitation with an additional coil
- Agitation by argon purging through the bottom of the crucible

The difference between the electromagnetic agitation by a separate coil and the agitation caused by the electromagnetic forces of the main coil lies in the fact that the bath can be circulated at 50 to 60 Hz without temperature increase. A second transformer is of course required. The second method of bath agitation is derived from the principle of argon purging usually applied in ladle metallurgy (see the section "Argon Oxygen Decarburization" in the article "Degassing Processes (Converter Metallurgy)" in this Volume).

Argon purging has a long history of use in open induction melting furnaces. A characteristic of this purging is that the porous plug is not in direct contact with the liquid melt. Instead, the plug is covered with refractory material identical to that used for the crucible lining. A new development (Fig. 10) has the basic difference that the porous plug is in direct contact with the melt and is suitable for operating under vacuum. This ensures that the admitted purging gas flows through the melt and does not take the path of least resistance through the lining of the crucible.

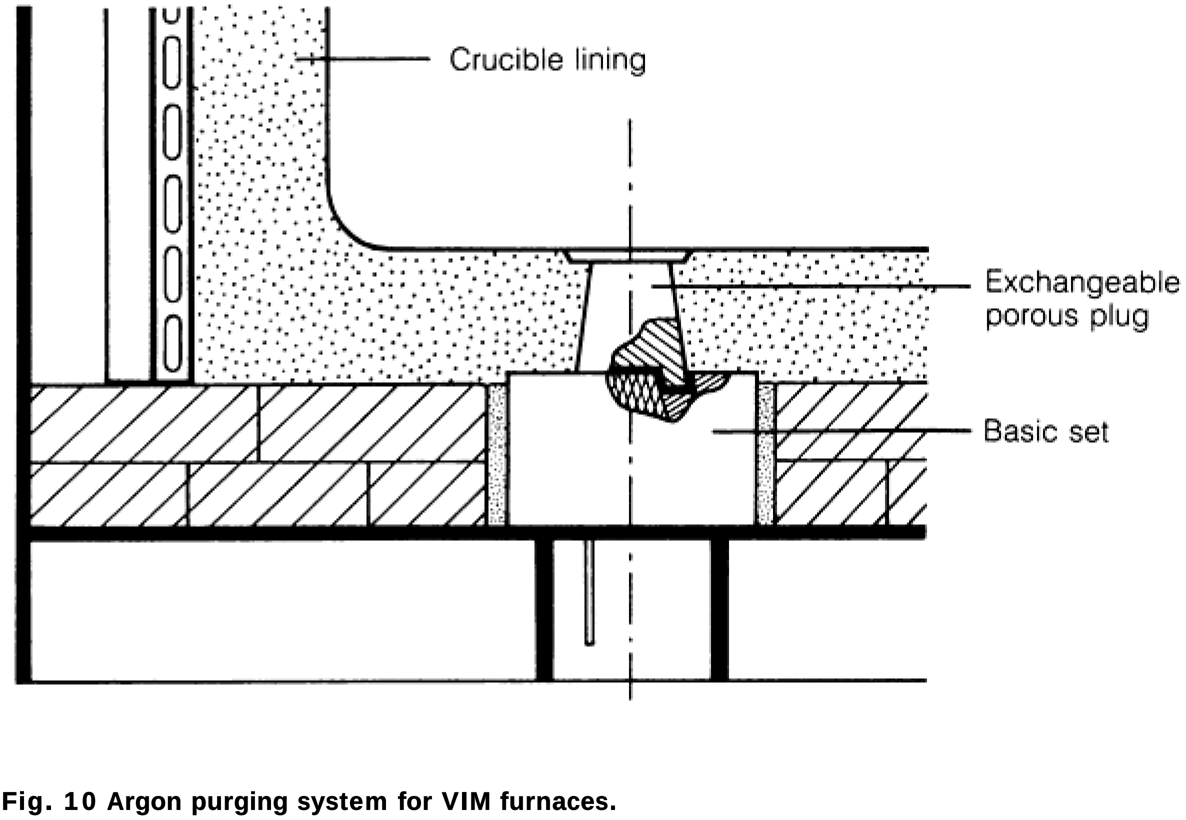

Fig. 10 Argon purging system for VIM furnaces.

Both agitation processes offer advantages with regard to higher reaction rates, correct temperature adjustment, homogenization with simultaneously lower erosion of the crucible lining, and better cleaning of the melt. Figure 11 shows the three different agitation methods operating in a typical VIM process sequence. The agitation effect at 200 to 500 Hz in the melting phase assists in shortening the melting time. In the refining and superheating periods, it is better to use electromagnetic agitation at 50 to 60 Hz or argon purging through a porous plug.

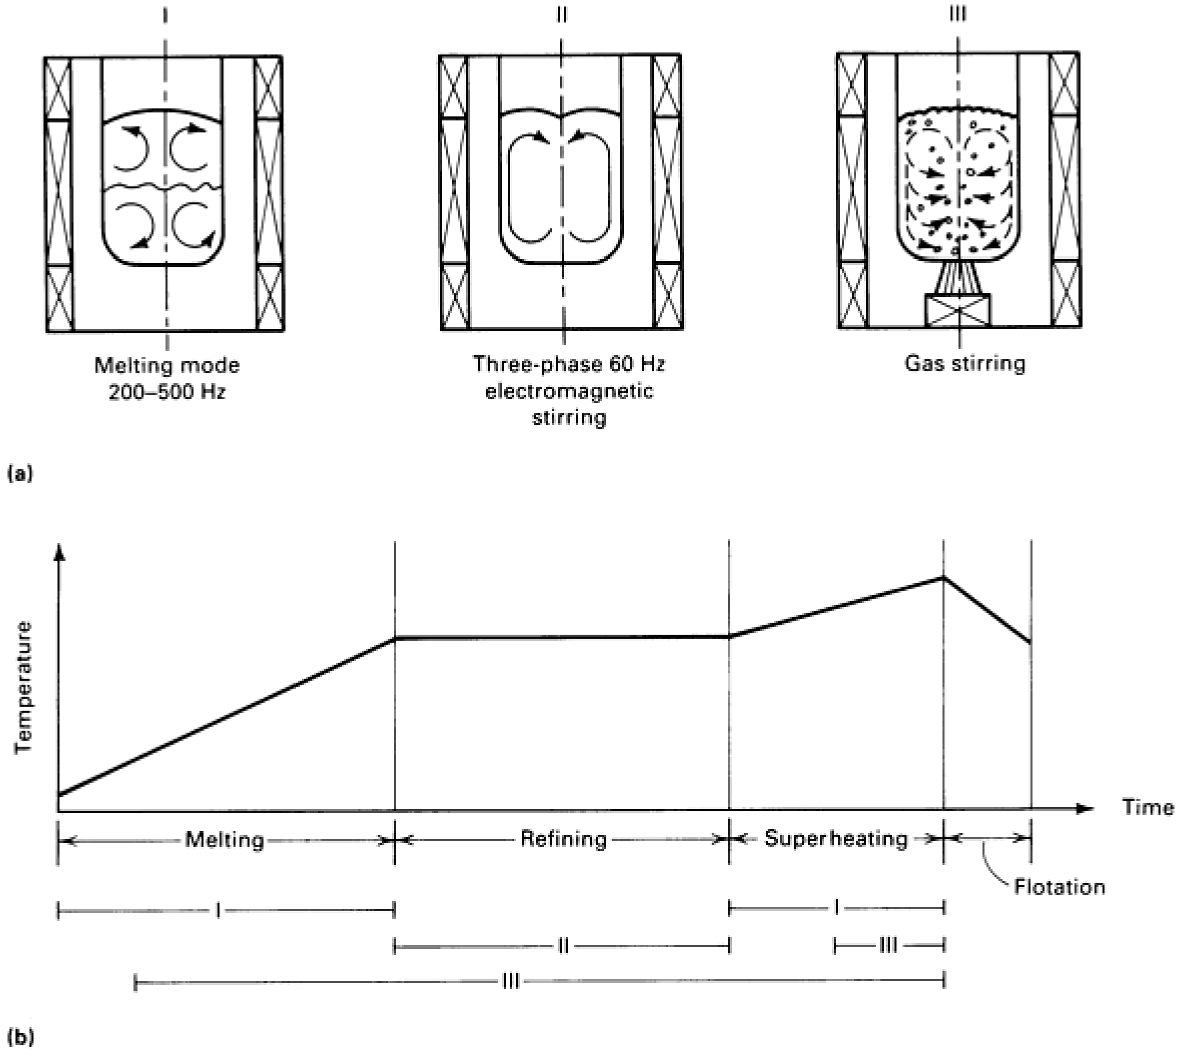

Fig. 11 Melting (a) and stirring (b) modes of the VIM process.

Process Technology and Automation

The installation of programmable control in combination with a process computer for automation provides better reproducibility of the melts. In this way, increasing metallurgical demands for cleanliness and homogeneity can be met.

In addition, close composition tolerances can be achieved, in which all of the data necessary for the process are registered, stored, and processed. The basic concept is 100% automation of the VIM process by using a combination of individual modules, such as control and regulation of the furnace, model calculations, and calculations for alloying additions.

For a number of years, these systems have been successfully used for controlling the vacuum system, recording the melting parameters, and recognizing and diagnosing defects. Figure 12 illustrates schematically a modern VIM process control.

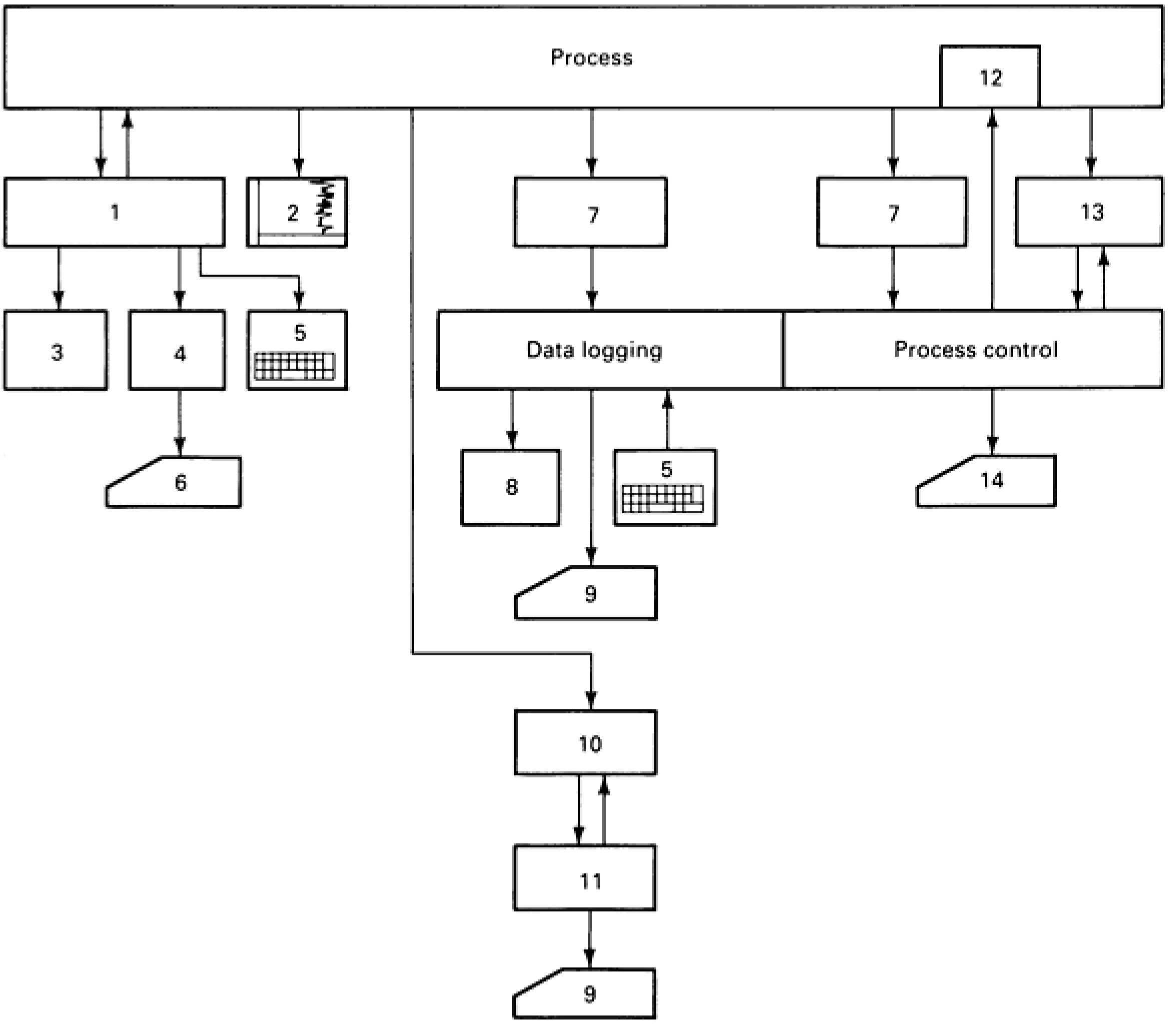

Fig. 12 Block diagram of modern VIM process control system. 1, PLC control; 2, recorder; 3, mimic diagram; 4, monitor screen; 5, keyboard; 6, fault printer; 7, analog/digital output; 8, monitor screen; 9, printer; 10, mass spectrometer; 11, personal computer; 12, melting power supply; 13, pyrometer; 14, graphic plotter.

A relatively new method is the use of a video screen display to provide a visual of the process. This technology will replace the conventional methods of recording the melting process, which involve the use of recorders and manual melting logs. Moreover, with computerized systems, all process control data can be displayed, printed out, or stored. With the installation of discontinuous or continuous bath temperature measurement, which is linked to a computer (theoretical thermal model), melting power can be automatically adjusted to give pre-specified bath temperatures.

Using charge and alloy calculations, it is easy to achieve the required chemical analysis with minimal cost. For this application, in the ideal case, the computer is linked to the analysis system computer so that the additives can be calculated and, if necessary, weighed and added directly after the analysis. If this alloy calculation is laid out as a charge calculation, the charges and the amounts of scrap necessary can be optimized. The complete calculation system enables a calculation of the alloying elements, starting with the amount of scrap needed and proceeding to the necessary alloy addition at the end of the refining period.

A computer-controlled mass spectrometer system, specially developed for the VIM process, can make a significant contribution to the optimization of the melting process and its economics. Using a computer evaluation of the gas composition in the furnace chamber, information about the state of the degassing process and of the chemical reactions in the melt can be continuously obtained.

The melting process can thus be controlled very exactly. Process parameters that can be closely controlled include:

- Determination of the correct time for the addition of chemically active elements and the sequence of addition of such elements
- Determination of the process steps, such as completion of the refining period and the suitable time for tapping
- Advance detection of leaks in the furnace chamber, cooling water system, or hydraulic system
- Monitoring of the state of degassing of the crucible refractory lining

Vacuum Induction Remelting and Shape Casting

R. Brink, Leybold AG, West Germany

Vacuum precision casting furnaces are used to remelt alloys that have already been treated in vacuum. The remelted alloy is then precision cast into preheated ceramic molds. Heating and melting in such furnaces almost always takes place by induction, although some electron beam melters and vacuum arc furnaces are used. Electron beam furnaces offer the advantage of ceramic-free melting, but they do not permit a sufficiently accurate and reproducible temperature control for charges of more than approximately 5 to 7 kg (11 to 15 lb). Vacuum arc furnaces are used for titanium precision casting.

Furnaces

The vacuum induction precision casting furnace is a two-chamber furnace with a melting chamber and a mold chamber (Fig. 13). The mold chamber is preferably placed under the melting chamber so that, in connection with another chamber for the charge or melting material, semicontinuous operation with minimal cycle times is possible.

Fig. 13 Computer-controlled vacuum precision casting furnace showing the mold chamber.

For cobalt- or nickel-base superalloys, the melting chamber pressure is of the order of 0.01 Pa (10^{-4} mbar, or 7.5×10^{-5} torr), while the mold lock would be evacuated to approximately 5 Pa (0.05 mbar, or 0.038 torr) within 1 min. To date, equipment for melting charges weighing 15 to 150 kg (33 to 330 lb) has been manufactured.

Processes

Until the 1970s, most furnaces were configured for the so-called equiaxed casting (that is, for the production of polycrystalline castings with equiaxed grains). Directional solidification (DS) and single-crystal (SC) casting are rapidly gaining acceptance. Figure 14 compares the structures obtained by these casting methods, and both methods are discussed in the article "Directional and Monocrystal Solidification" in this Volume.

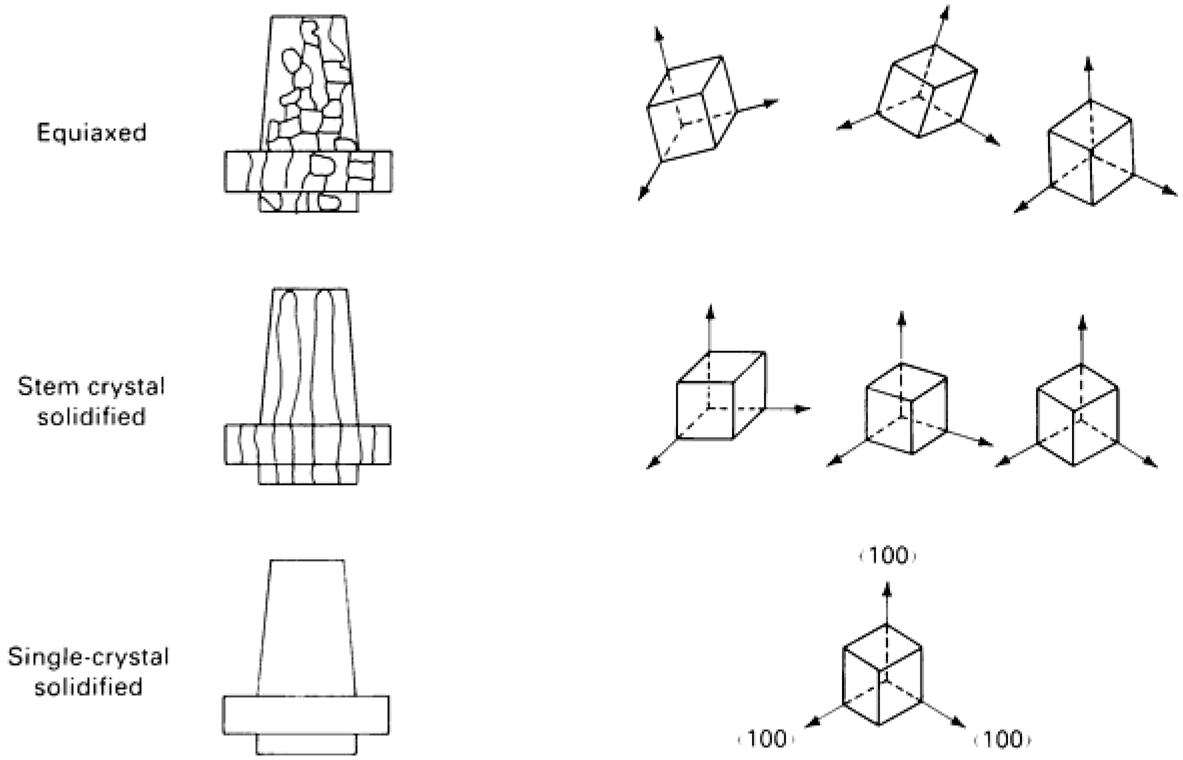

Fig. 14 Types of solidification in nickel-base alloy blades for gas turbines. (a) Equiaxed, randomly oriented grains. (b) Directionally solidified structure with all grains oriented the same. (c) Single crystal with preferred <100> orientation.

In the past, furnaces for casting were often modified for use with the DS process. The current trend for production furnaces, however, is toward dedicated, single-purpose melting equipment. Multipurpose furnaces will still be required in the future, but the changeover from equiaxed to DS processes involves necessary compromises that introduce too many limitations with respect to technology and economy. Therefore, multipurpose furnaces are almost exclusively used for research and development or as pilot furnaces.

Products

In addition to the casting of equiaxed, DS, and SC blades for gas turbine engines, vacuum precision casting can be used for large parts (melt weights up to 1000 kg, or 2200 lb) or for the large-scale production of small parts. Examples of large parts produced using vacuum precision casting include compressor sections of jet engines and structural parts for stationary turbines.

A typical small casting produced by this method is a turbocharger wheel for automotive engines (Fig. 15). Automotive turbocharger wheels weighing 400 to 500 g (0.9 to 1.1 lb) are produced in automatic precision casting machines. Total

cycle time, including 40 s for melting, is typically 90 to 100 s. In the production of such small parts, the crucible is often integrated into the mold. Casting yields of 80 to 90% are obtained.

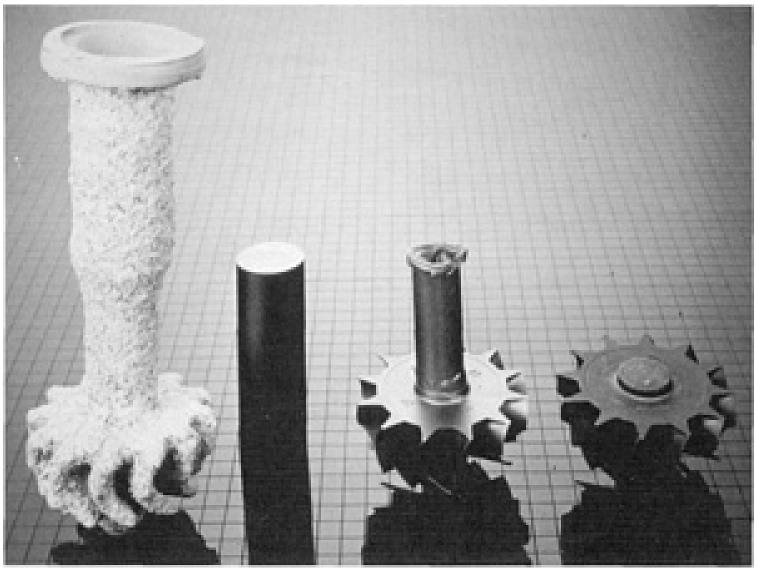

Fig. 15 Precision cast turbocharger wheels for automotive engines. From left: mold with integrated crucible, bar stick, cast part, machined turbocharger wheel.

Process Automation

Because of the increasing demand for productivity and constant casting quality under reproducible conditions, single-purpose furnaces for equiaxed casting are being automated in all decisive process steps. The primary objective is reproducibility, especially regarding temperature control during melting and casting. As a result of these requirements, modern precision casting furnaces are usually equipped with process automation devices for melting, melting bath temperature measurement, degassing, mold positioning, and casting. Automated units are outfitted with extensive monitoring devices which collect data for statistical process control.

Experiences with the automatic melting unit, which is controlled by a two-color pyrometer, confirm good measurement and control accuracy. For example, temperature differences of less than 5 K between the two-color pyrometer and a thermocouple were found to persist after ten charges had been processed. This reproducibility also enhances the endurance of ceramic melting crucibles.

Similar positive results have also been obtained with the automatic casting device. With this unit, single steps such as melt washing, preheating of the crucible lip, and tilting can be preprogrammed. The pouring process itself is adjustable against several parameters that can be preprogrammed individually, including:

- Pouring temperature
- Mold temperature
- Mold positioning
- Pouring height

The pouring profile or tilting of the crucible in order to fill the mold as rapidly as possible can also be preprogrammed. These data, which vary depending on the casting process chosen, are fed into the computer manually or automatically and can then be called up as often as necessary.

The objective of developments such as those outlined above is fully automated computer-controlled furnaces in which the manual portion of the process sequence is limited to inserting the molds and the material to be melted. This goal has been

realized, especially for DS and SC furnaces. With computer software and data recording, process parameters such as temperatures, times, and solidification rates remain freely selectable.

Equipment Developments. The development of certain furnace components was essential to the optimization and automation of precision casting furnaces for equiaxed castings. Examples of such developments include:

- Hydraulic, rotary coaxial feed cables for the induction coil
- Self-supporting induction coils, which can be easily and quickly exchanged and adapted to the use of crucible containers
- Crucible containers for melt weights to 25 kg (55 lb)
- Swiveling lock valves between the melting chamber and the mold chamber to facilitate mold transfer between the chamber and the casting position

Although furnaces for equiaxed casting can be used for DS and SC processes with some modifications, certain compromises must be made that result in less-than-optimum operation. The furnace modifications required for DS and SC casting will be outlined in the next section of this article.

Special Features of DS and SC Furnaces

Furnaces for directional solidification and single-crystal casting incorporate several features that distinguish them from furnaces used for equiaxed casting. These features include zone heaters, special motors for mold withdrawal movement, and water-cooled copper chills.

The zone heaters used in DS and SC furnaces consist of two or more resistance heating elements or graphite induction heating elements that can be independently controlled. The use of zone heating ensures that temperature gradients of at least 60 to 80 K/cm (150 to 200 K/in.) are obtained at the solidification front; temperature gradients of 30 K/cm (75 K/in.) are common in equiaxed casting. Macroscopic geometric distortions at the solidification front are also minimized by the high temperature gradients.

The motors used to lower the mold out of the heating system are extremely low vibration units. Low vibration is particularly important for single-crystal casting. The use of such motors is based on experience with Czochralski and Bridgman furnaces used to grow single crystals of semiconducting materials.

Water-cooled copper chills are used directly under the mold. They promote directional solidification and are particularly important for securing high temperature gradients in SC casting.

Furnaces for directional solidification and single-crystal casting also use bottom pouring of the melt rather than the tilt pouring used in equiaxed casting. This considerably reduces inclusions in precision cast parts.

Furnaces for DS and SC casting, like those for the casting of equiaxed parts, also have components that are designed to optimize the process. These include:

- One-shot crucibles, which are loaded along with the furnace charge. Such crucibles give almost abrasive-free melting at rates of about 1.5 kg/min (3.3 lb/min) and result in minimal inductive bath movement
- Temperature control of melting through the use of a two-color pyrometer and a thermocouple. In this way, both melt bath temperature and casting spout temperature can be monitored
- Easily accessible mold locks with movable chill plates allow reproducible mold positioning and adjustment

---

Electroslag Remelting (ESR)

A. Choudhury and F. Knell, Leybold AG, West Germany

The rapid development of modern technology places ever greater demands on engineering alloys. These increasing demands can scarcely be met by classical steelmaking processes. Metallurgists were required to develop new steel-refining processes that guarantee uniformly high quality. One of the refining processes used is electroslag remelting with consumable electrodes in a water-cooled copper crucible, usually under normal atmosphere.

The theory behind this process was known in the 1930s and was the subject of a U.S. patent (Ref 10), but a general break-through for this process took more than 30 years. Intensive studies carried out in the Soviet Union, Germany, United Kingdom, Austria, and Japan after World War II made the use of electroslag remelting possible on a production scale (Ref 11, 12, 13, 14, 15, 16, 17). In contrast to vacuum arc remelting (VAR), the remelting in the ESR process (Fig. 16) does not occur by striking an arc under vacuum. In electroslag remelting the ingot is built up in a water-cooled mold by melting a consumable electrode immersed in a superheated slag.

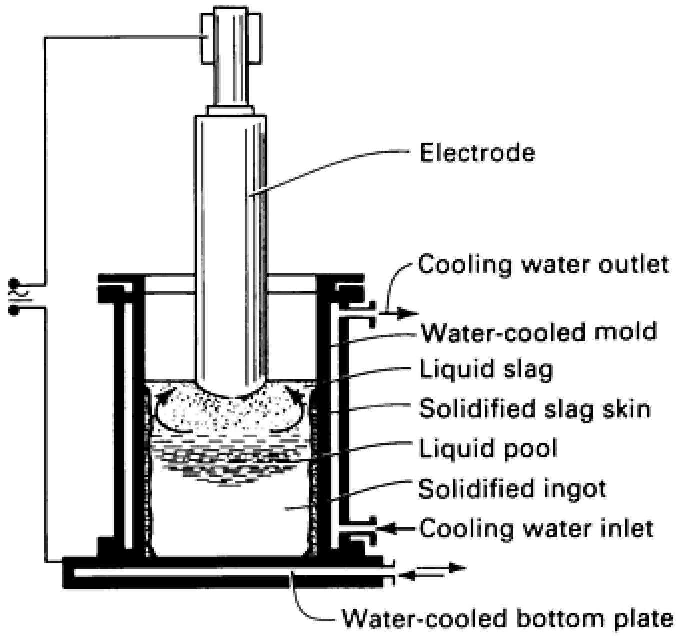

Fig. 16 Schematic of the electroslag remelting process.

The heat required is generated by an electrical current (usually ac) flowing through the liquid slag, which provides the electrical resistance. As the slag temperature rises above the liquidus temperature of the metal, the tip of the electrode melts. The molten metal droplets fall through the liquid slag and are collected in the water-cooled mold. During the formation of the liquid film, the metal is refined and cleaned of contaminants, such as oxide particles. The high degree of superheat of the slag and of the metal favors the metal/slag reaction. Melting in the form of metal droplets greatly increases the metal/slag interface surface area. The intensive reactions between metal and slag result in a significant reduction in sulfur and nonmetallic inclusions. The remaining inclusions are very small and are evenly distributed in the remelted ingot.

Another special feature of the ESR process, as in vacuum arc remelting, is the directional solidification of the ingot from bottom to top. The macrostructure is marked by an extraordinarily high density and homogeneity as well as by the absence of segregations and shrinkage cavities (Ref 13, 14).

The homogeneity of the ingot also results in uniform mechanical properties in the longitudinal and transverse directions after hot working. Because of the absence of macrosegregations or a heterogeneity in the distribution of nonmetallic inclusions, the yield of good ingot material is increased; the additional cost of the remelting process is therefore justified. In addition, the very clean and smooth surface of the ESR ingot, which is specific to this process, helps to reduce production costs because surface conditioning before hot working is not necessary.

Remelting of Steels

There are a number of publications that deal primarily with improvements in the physical properties of remelted steel (Ref 11, 12, 13, 14, 15, 16, 17). However, they discuss not only the directional solidification of the metal but also the influence of liquid, superheated, and therefore reactive slags (Ref 13, 18). The extent and direction of the metallurgical reactions in the ESR process are determined by the steel composition, the slag used, and the atmosphere used (inert gas, air, etc.).

The principal feature of the ESR process is the slag bath. A continuous transport of liquid metal through the slag takes place. During this transport, the slag and the metal compositions change, according to the kinetic and thermodynamic conditions. To perform its intended function, the slag must have some well-defined properties, for example:

- Its melting point must be lower than that of the metal
- It must be electrically efficient
- Its composition should be such that the desired reactions, such as removal of sulfur and oxides, are ensured
- It must have suitable viscosity at remelting temperature

Slags for electroslag remelting are usually based on calcium fluoride (CaF_2), lime (CaO), and alumina (Al_2O_3). Magnesia (MgO), titania (TiO_2), and silica (SiO_2) are also added, depending on the alloy to be remelted. Table 3 shows the compositions of some common ESR slags.

Table 3 Compositions of slags commonly used in ESR

Slag designation	**Composition, %**					Comments
	CaF_2	**CaO**	**MgO**	**Al_2O_3**	**SiO_2**

Behavior of Sulfur. One of the primary advantages of the ESR process for steel is the good desulfurization of the metal. The final desulfurization is determined by two reactions. The first is the metal/slag reaction, in which sulfur is transferred from the metal to the slag:

$$FeS + CaO \rightarrow CaS + FeO \qquad \textbf{(Eq 1)}$$

The second reaction is the slag/gas phase reaction. In this case, the sulfur absorbed by the slag is removed by the oxygen of the gas phase in the form of gaseous sulfur dioxide:

$$CaS + \frac{3}{2} O_2 \text{ (gas)} \rightarrow CaO + SO_2 \text{ (gas)} \qquad \textbf{(Eq 2)}$$

It is evident that a saturation of the slag with sulfur does not take place; therefore, the desulfurization capacity of the slag remains intact throughout the entire remelting process. With a highly basic slag ($CaO/SiO_2 > 3$), more than 80% of the sulfur can be removed.

Behavior of Oxygen. As mentioned previously, the ESR process is usually carried out under a normal air atmosphere. Oxidation of the metal is unavoidable. Oxygen can be transferred into the metal in several ways:

- Oxidation of the electrode surface above the slag bath
- Oxidation on the slag surface of elements with variable valences, such as iron and manganese
- Oxides attached to the electrode surface

Transfer of oxygen into the slag also takes place, and oxygen is transferred into the metal according to Eq 1. This results in losses of easily oxidizable elements, such as aluminum and silicon, during remelting. To counteract this oxidation, the

slag should be continuously deoxidized, preferably with aluminum. With proper slag composition and remelting techniques, oxygen contents of less than 20 ppm in unalloyed steel are possible. Figure 17 shows the influence of slag composition on the final oxygen content of remelted ingots.

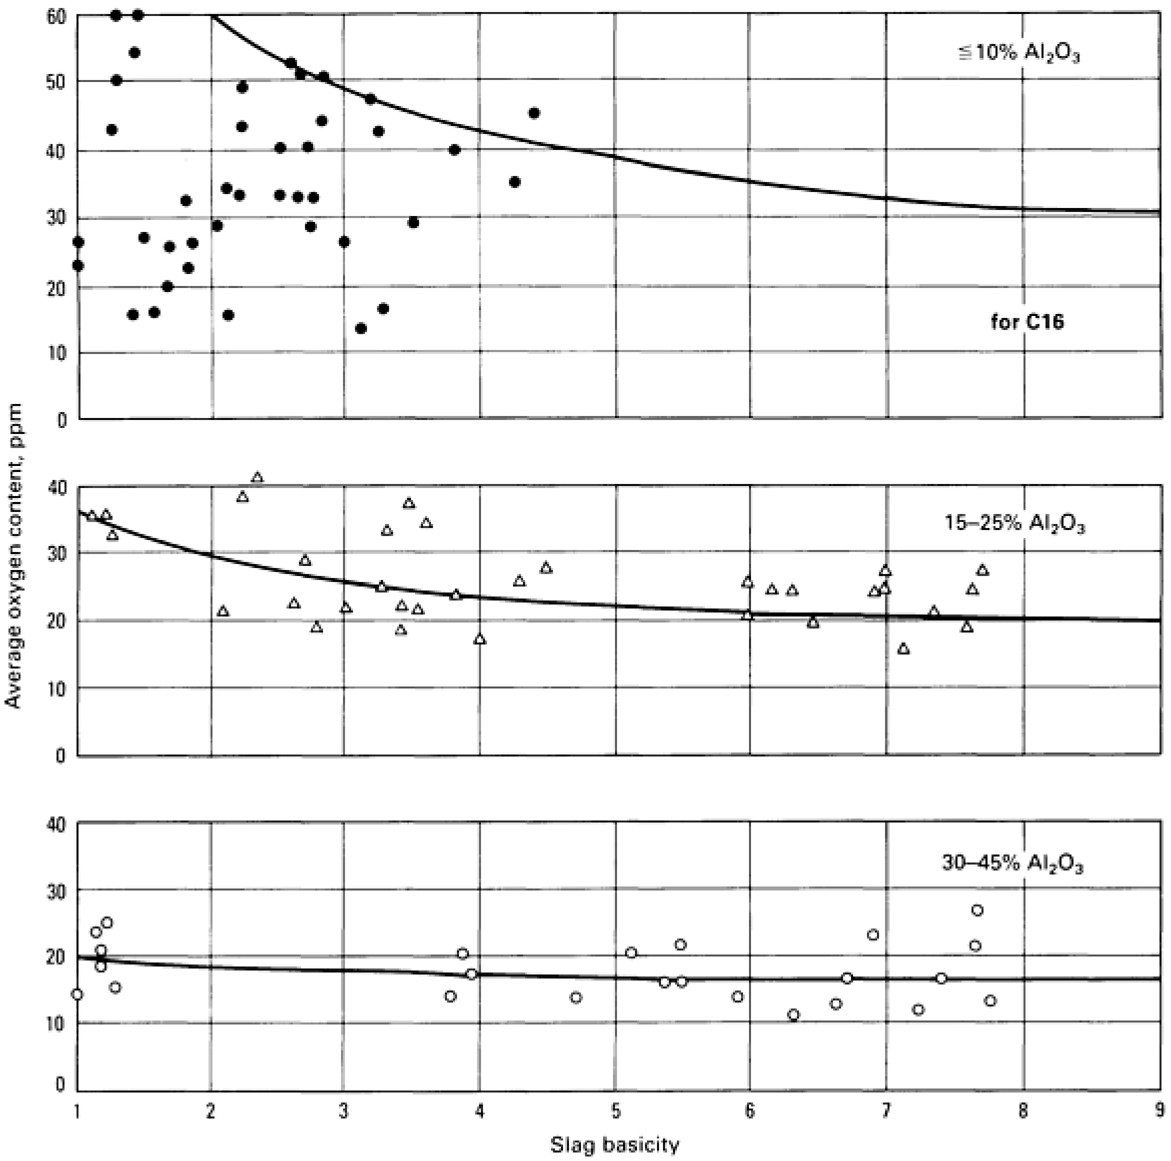

Fig. 17 Effect of slag composition on the oxygen content of the remelted ingot. Slag basicity is the ratio of CaO to SiO_2.

Ingot Solidification

The thermodynamics of solidification of an ESR ingot are the same as in the VAR process (see the section "Vacuum Arc Remelting (VAR)" in this article). The solidification structure of an ingot of a given composition is a function of the solidification rate and temperature gradient at the solid/liquid interface. For example, when remelting with a consumable electrode in a water-cooled copper mold, the solidification rate is constant because of the constant heat transfer through the cooling water; therefore, a relatively high temperature gradient at the solidification front must be maintained during the entire remelting period to achieve a directional dendritic structure.

Even in the case of directional dendritic solidification, the microsegregations increase with increasing dendrite arm spacing. For optimum results, the objective should be a solidification structure with dendrites oriented as close to parallel to the ingot axis as possible.

However, this is not always possible. To achieve a good ingot surface, there is a minimum energy requirement, and therefore a minimum melting rate, which is a function of ingot diameter. This means that the melting rate for large-diameter ingots cannot be maintained for axis-parallel dendrite growth. Figure 27 in the section "Vacuum Arc Remelting (VAR)" in this article shows the melting rates for different steels and alloys as a function of ingot diameter. The data are empirical values obtained from experience in operation. These melting rates resulted in low microsegregation while achieving reasonably good surface quality.

Ingot Defects. In spite of directional dendritic solidification, various defects, such as the formation of tree ring patterns, freckles, and white spots, can occur in a remelted ingot. These defects also occur in VAR ingots and are discussed in more detail in the section "Vacuum Arc Remelting (VAR)" in this article.

Current State of Plant Design

Significant advances have been made in the past few years in plant design in the area of process control and coaxial current supply. Figure 18 shows the basic design of a modern ESR furnace with a fixed mold for an ingot weight of 20 Mg (22 tons) and an ingot diameter of 1000 mm (39.4 in.). Figure 19 shows a schematic of an ESR furnace equipped with a retractable bottom plate.

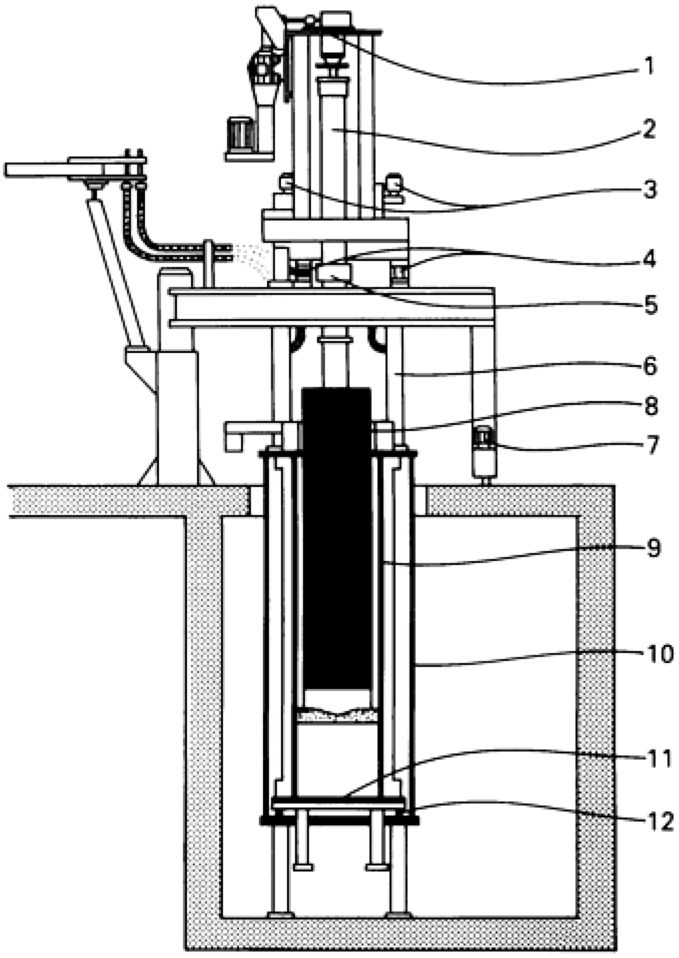

Fig. 18 Schematic of an ESR furnace with a stationary mold. 1, RAM drive system; 2, electrode RAM; 3, XY adjustment; 4, load cell system; 5, sliding contact; 6, four bus tubes; 7, pivoting drive; 8, electrode; 9, mold assembly; 10, coaxial bus tube; 11, base plate; 12, multicontacts.

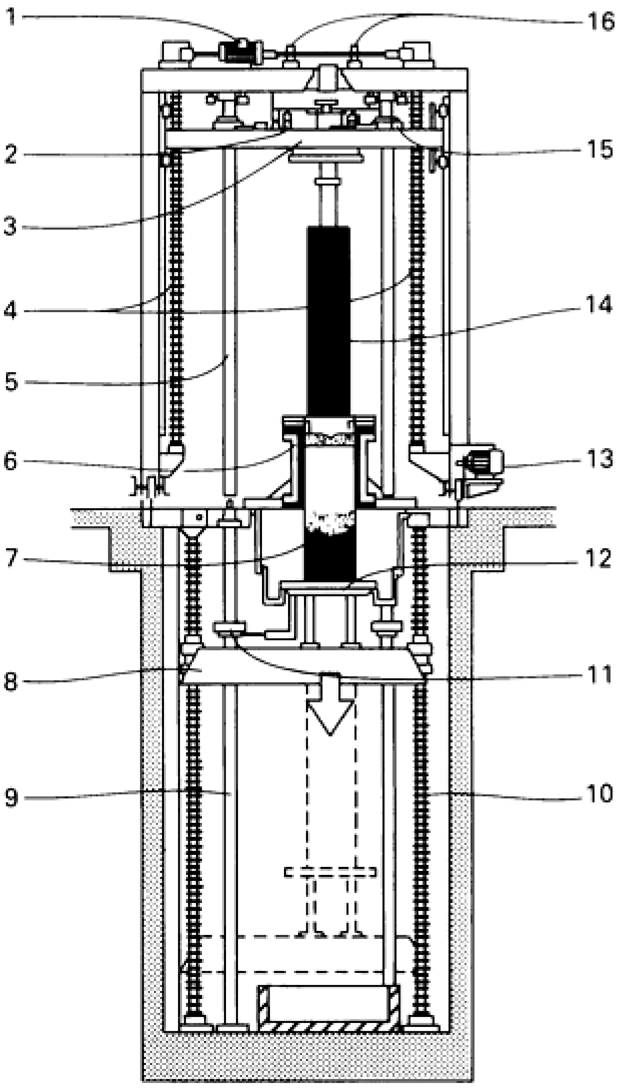

Fig. 19 Schematic of an ESR furnace with retractable bottom plate. 1, electrode drive system; 2, load cell system; 3, stinger crosshead; 4, two ball screws; 5, three bus tubes; 6, mold assembly; 7, ingot; 8, ingot withdrawal table; 9, three bus tubes; 10, three ball screws; 11, three sliding contacts; 12, base plate; 13, furnace head drive; 14, electrode; 15, three sliding contacts; 16, XY adjustment.

A fully coaxial furnace design is required for the remelting of segregation-sensitive alloys in order to prevent melt stirring by stray magnetic fields. In the case of the retractable bottom plate furnace, current feedback does not take place through a closed copper pipe; instead, it is accomplished with four symmetrically arranged current feedback tubes.

Automation of Process Control. The ESR process, like vacuum arc remelting, is fully automatic. Examples of process parameters for the remelting of a nickel-base alloy are shown in Fig. 20. Melting was accomplished in a fully automatic operational mode. Figure 21 shows a modern ESR control desk.

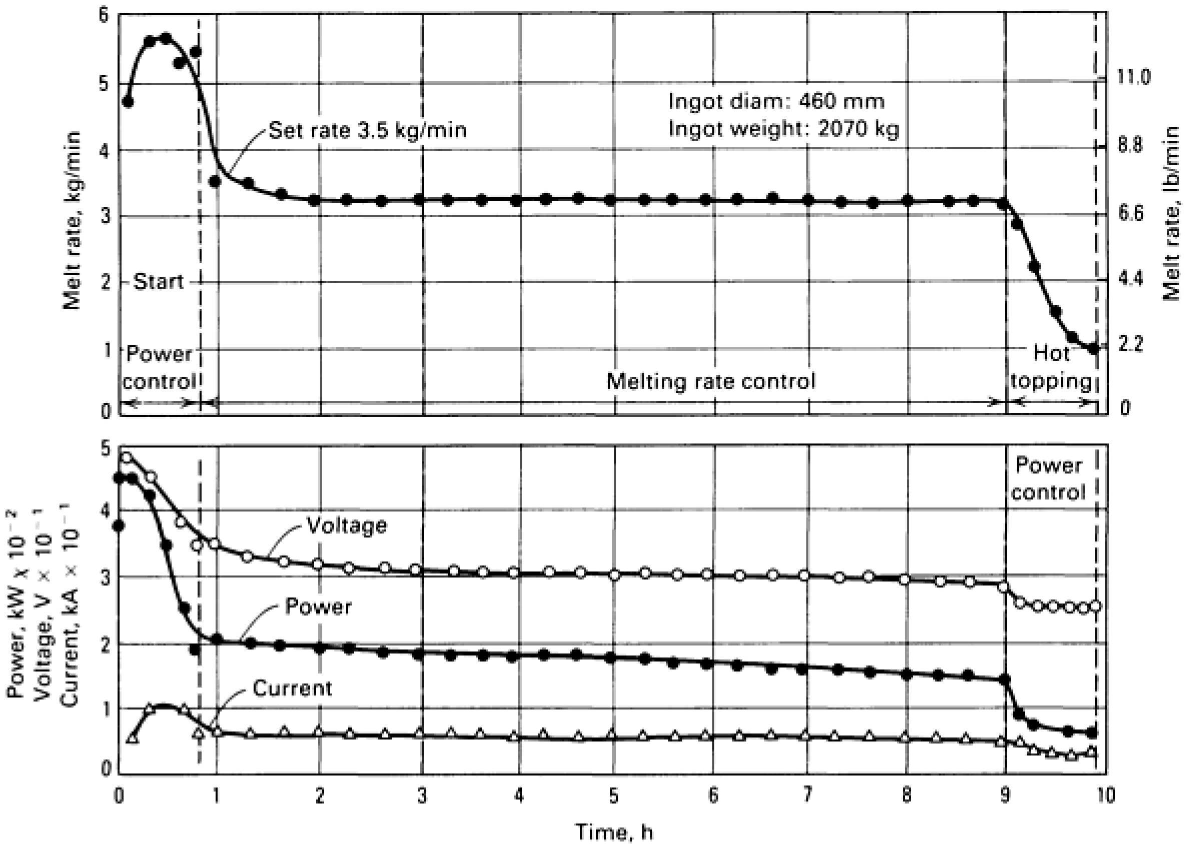

Fig. 20 ESR process parameters for the melting of a nickel-base alloy.

Fig. 21 Control desk of a modern ESR furnace.

Electroslag Remelting of Heavy Ingots

At the end of the 1960s, the concept of using ESR plants to manufacture large ingots weighing UP to 350 Mg (385 tons) gained acceptance (Ref 19). Increasing demands for energy and the trend toward larger electrical power generating units required cast ingots weighing 100 Mg (110 tons) and more for the manufacture of generator and turbine shafts. With ESR,

it is possible to achieve higher yields and to avoid such internal defects as porosity, macrosegregation, and the accumulation of nonmetallic inclusions.

Figure 22 shows a schematic of a large ESR furnace, which was brought on line in West Germany in 1971 to manufacture ingots 2300 mm (90.5 in.) in diameter and 5000 mm (197 in.) in length (Ref 20, 21, 22, 23).

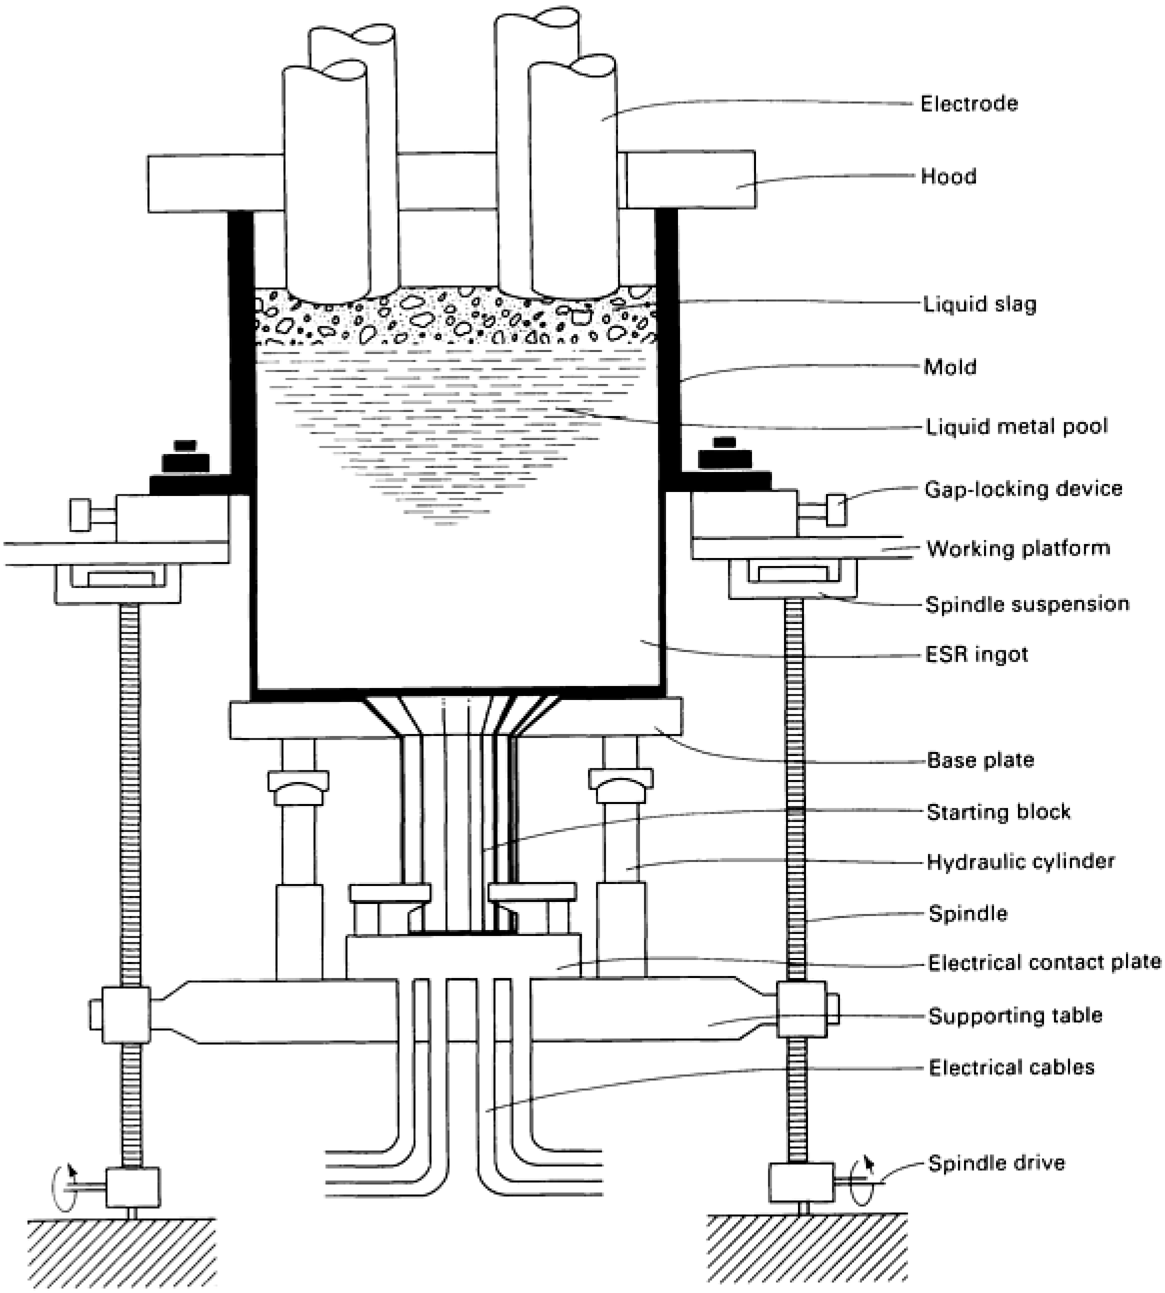

Fig. 22 Schematic of an ESR furnace for the manufacture of large (160 Mg, or 176 ton) ingots.

Ingots weighing up to 160 Mg (176 tons) can be manufactured using a retractable bottom plate. Several electrode changes are necessary to produce such large ingots.

Remelting of large ingots of this type in retractable bottom plate furnaces demands the solution of specific technical and metallurgical problems, such as:

- Ensuring consistent remelting over a period of several days without interruption

- Prevention of steel and slag breakout when remelting with a retractable bottom plate
- Achieving a good ingot surface
- Ensuring directional solidification to avoid macrosegregation and shrinkage cavities
- Controlling the steel and slag compositions over the entire ingot height
- Adjusting for low hydrogen content
- Adjusting for a low aluminum content (<0.010%) for rotor steels; this has a decisive influence on the creep rupture properties of the rotors

After these problems had been solved, heavy rotors for electrical generators could be manufactured from ESR ingots. Figure 23 shows a 160 Mg (176 ton) ESR ingot before forging.

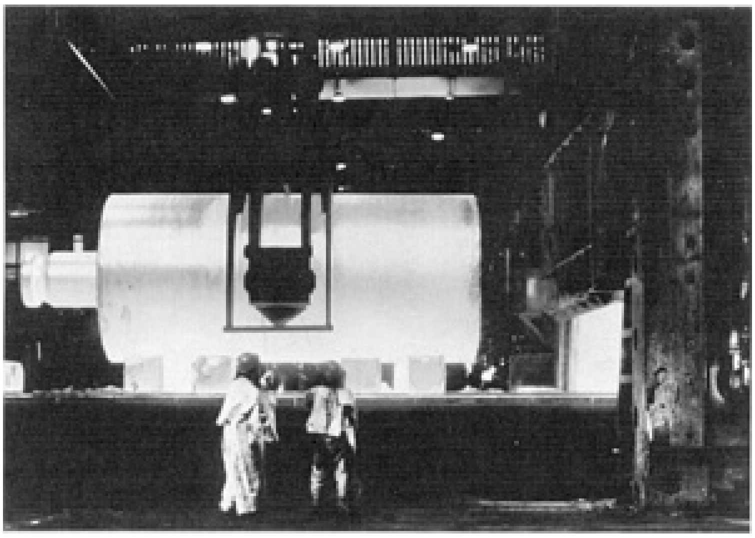

Fig. 23 160 Mg (176 ton) ESR ingot before forging into a generator rotor.

Interior defects such as macrosegregation, shrinkage cavities, and nonuniform distribution of inclusions can be avoided in large ingots only if directional solidification is ensured over the entire ingot section. By maintaining the correct melting rate and temperature of the slag, directional solidification can be achieved for ingot diameters of 2300 mm (90.5 in.) (Ref 21). Accordingly, the ESR ingot is free of macrosegregation in spite of the large diameter (Fig. 24).

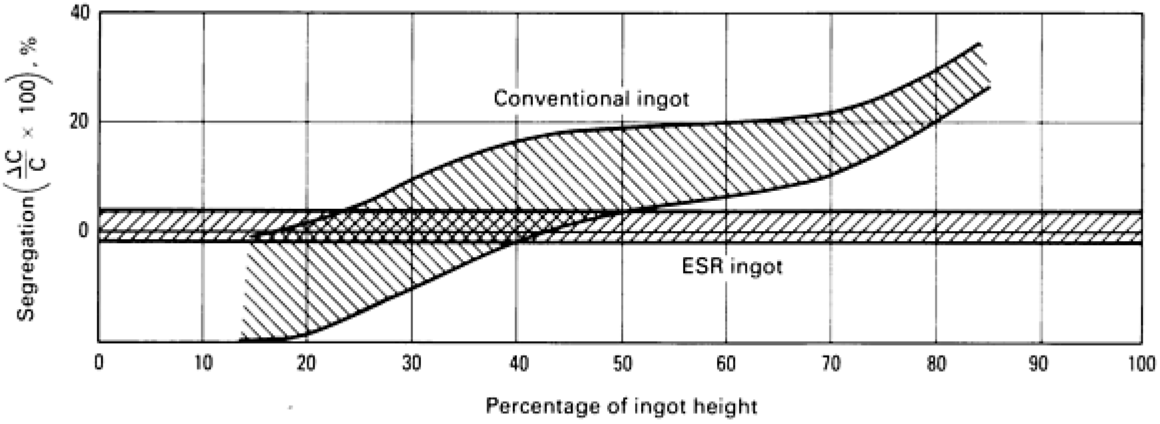

Fig. 24 Comparison of carbon segregation in conventional and ESR alloy steel ingots. Specimens were taken from the ingot axis along the entire ingot height.

The cleanliness and homogeneity of ESR ingots result in excellent mechanical properties. Figure 25 shows the superior toughness of ESR steel compared to conventionally manufactured steel.

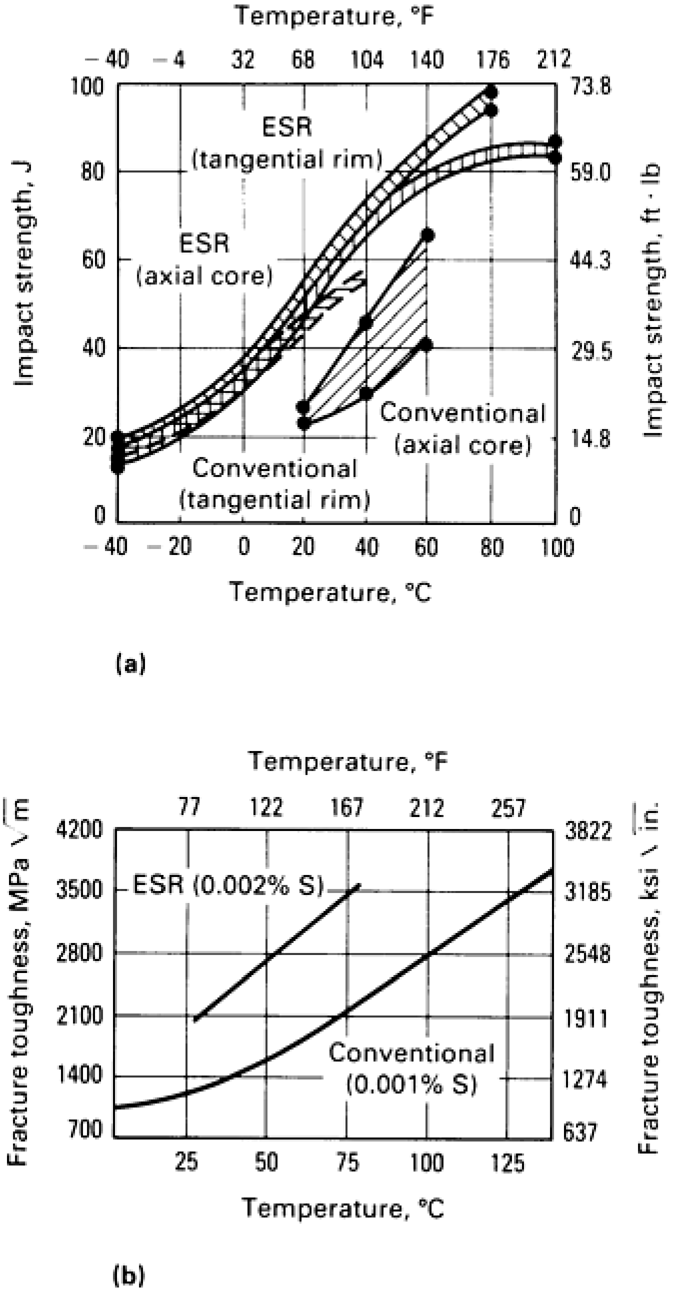

Fig. 25 Comparison of properties of steel rotor forgings made from ESR and conventionally melted ingots. (a) Impact strength of grade X22CrMoV121. (b) Fracture toughness of grade 30CrMoNiV511. Specimen orientation and location are indicated next to curves. Source: Ref 22, 23, and 24.

Process Variations

Two variations of electroslag remelting have recently been developed: remelting under high pressure (DESU) and remelting under reduced pressure VAC-ESR.

Remelting Under High Pressure. The strength of austenitic steels can be increased by alloying with nitrogen as long as the nitrogen is interstitially dissolved in a stable condition. Nitrogen solubility, however, is limited in the case of melting under atmospheric pressure for a given steel composition.

Because the solubility of nitrogen in iron is proportional to the nitrogen partial pressure in the furnace atmosphere, there is the possibility of alloying nitrogen into the melt under higher pressure and allowing it to solidify. The ESR process is suitable for this technique. The first trials in this area were carried out in 1971 (Ref 25).

For some years, a high-manganese steel has been successfully remelted in a DESU plant under a pressure of 4.2 MPa (610 psi). Up to 0.5% interstitial solubility of nitrogen in steel has been achieved. The nitrogen-alloyed austenitic steels are used for the manufacture of retaining rings in generators.

Electroslag remelting under vacuum is another interesting process. Alloy 718 has been remelted in a VAC-ESR pilot plant. A fluoride-free slag based on lime and alumina was used. Because the remelting is carried out under vacuum, problems of oxidation of the melt do not arise. In addition, dissolved gases, such as hydrogen and nitrogen, can be removed. Thus, the advantages of both ESR and VAR are combined in one process (Ref 26).

Vacuum Arc Remelting (VAR)

A. Choudhury and E. Weingärtner, Leybold AG, West Germany

The vacuum arc remelting process was the first commercial remelting process for superalloys. It was used in the late 1950s to manufacture materials for the aircraft industry. The primary feature of vacuum arc remelting is the continuous melting of a consumable electrode by means of a dc arc under vacuum. The molten material solidifies in a water-cooled copper mold.

The basic design of the VAR furnace has remained largely unchanged over the years; however, significant advances have been made in the fields of control and regulation of the process with the object of achieving a fully automatic melting procedure. This in turn has had a decisive positive influence on the metallurgical properties of the products. The manufacture of homogeneous ingots with minimal segregation requires careful control of remelting parameters. Of these, the melting current density has the largest influence on the melting bath geometry and conditions of solidification.

Process Advantages

The primary benefits of melting a consumable electrode under vacuum are:

- Removal of dissolved gases, such as hydrogen and nitrogen
- Minimizing the content of undesirable trace elements having high vapor pressures
- Improvement of cleanliness by removal of oxides
- Achievement of directional solidification of the ingot from bottom to top in order to avoid macrosegregation and to minimize microsegregation

Oxide inclusion removal is optimized because of the relatively short reaction paths during melting of the hot electrode end and because of a good drop dispersion in the plasma arc. Oxide removal is achieved by chemical and physical processes. Less stable oxides or nitrides are thermally dissociated or are reduced by carbon present in the alloy and are removed by conversion into the gas phase. However, in superalloys and in high-alloy steels, the nonmetallic inclusions (for example, alumina and titanium carbonitride) are very stable. The removal of these inclusions during remelting takes place by flotation.

The remaining inclusions in the solidified ingot are small and are evenly distributed in the cross section. The solidification structure of an ingot of a given composition is a function of the local solidification time and the temperature gradient at the liquid/solid interface, as shown schematically in Fig. 26.

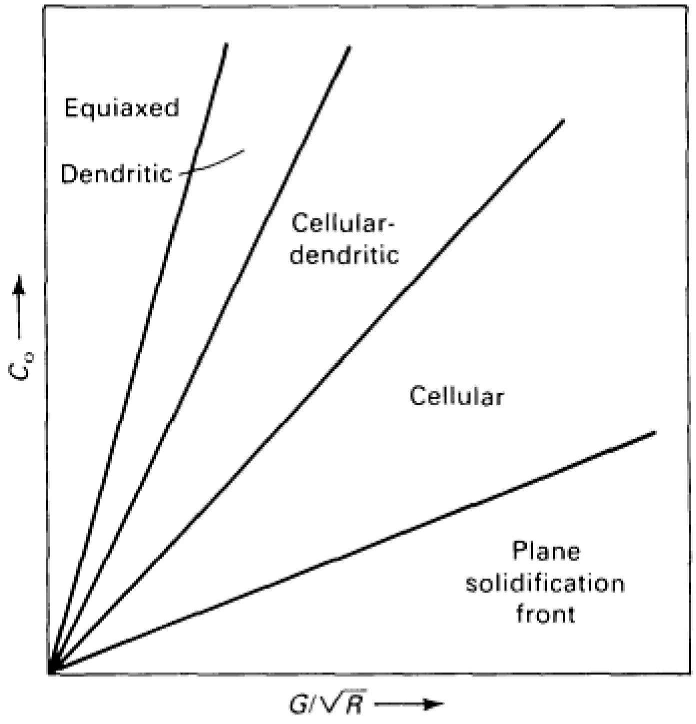

Fig. 26 Primary structure of a VAR ingot as a function of temperature gradient in the melt *G*, solidification rate *R*, and chemical analysis of the melt C_o. Source: Ref 27.

To achieve a directed dendritic primary structure, a relatively high temperature gradient at the solidification front must be maintained during the entire remelting period. The growth direction of the cellular dendrites corresponds to the direction of the temperature gradient or the direction of the heat flow at the moment of solidification at the solidification front. The direction of heat flow is always perpendicular to the solidification front or, in the case of a curved interface, perpendicular to the tangent. The growth direction of the dendrites is a function of the metal pool profile during solidification. For remelting processes in water-cooled copper molds, the pool profile has a rotationally symmetric paraboloidal shape in the first approximation. The pool depth increases with melting rate.

The gradient of the dendrites, with respect to the ingot axis, increases with melting rate. In extreme cases, the growth of the directed dendrites can come to a stop. The ingot core then solidifies nondirectionally in equiaxed grains, which leads to segregation and micro-shrinkage. Even in the case of directional dendritic solidification, the microsegregation increases

with dendrite arm spacing. A solidification structure with dendrites parallel to the ingot axis yields optimal results. However, this is not always possible. A good ingot macrostructure requires a minimum energy input and, accordingly, a minimum melting rate. Optimal melt rates and energy inputs depend on ingot diameter. This means that the necessary melting rate for large-diameter ingots cannot be maintained for axis-parallel crystallization.

Figure 27 shows melting rates for various steels and alloys as a function of ingot diameter. These are empirical values that were obtained from experience in operation. These melting rates gave low microsegregation while achieving acceptable surface quality. The importance of pool depth was also investigated by numerous researchers (Ref 28, 29, 30, 31, 32).

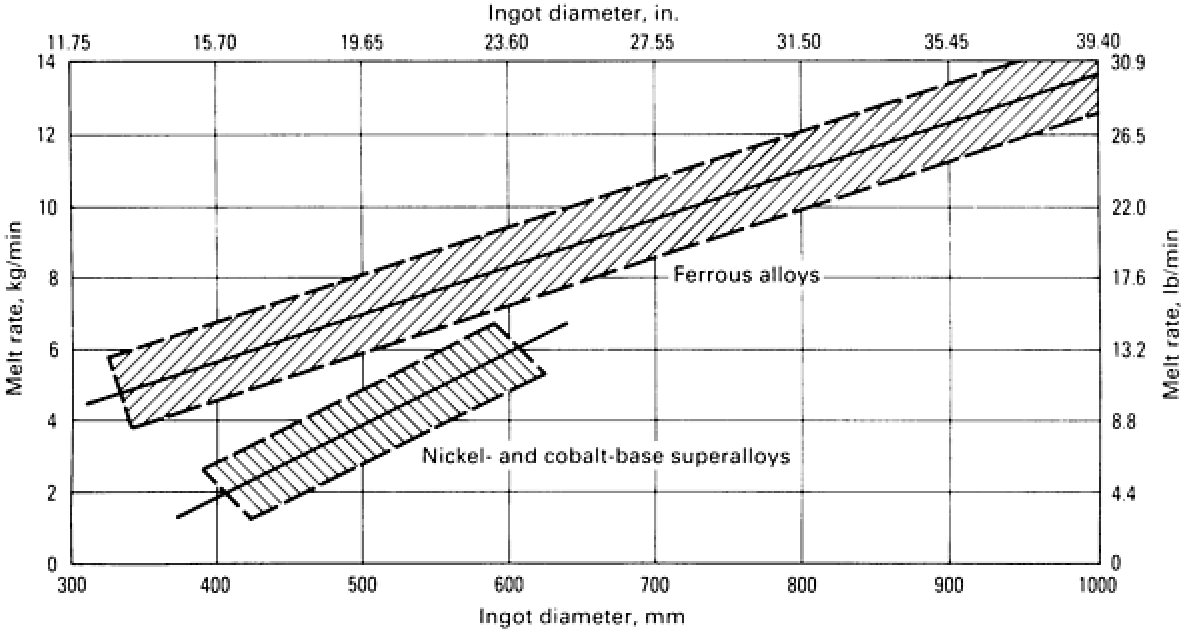

Fig. 27 Typical VAR melting rates for various steels and nickel- and cobalt-base superalloys.

Ingot Defects

In spite of directional dendritic solidification, such defects as tree ring patterns, freckles, and white spots can occur in a remelted ingot. This can lead to rejection of the ingot, particularly in the case of superalloys.

Tree ring patterns can be identified in a macroetched transverse section as light-etching rings. They usually represent a negative crystal segregation. Tree ring patterns seem to have little effect on superalloy material properties (Ref 33).

Tree ring patterns are the result of a wide fluctuation in the remelting rate. In modern remelting plants, however, the remelting rate is maintained at the desired value by means of an exact control of the melting rate during operation, so that the melting rate exhibits no significant fluctuations.

Freckles and white spots have a much greater effect on material properties than tree ring patterns, especially in the case of superalloys. Both defects represent an important cause of the premature failure of turbine blades in aircraft engines.

Freckles are dark-etching circular or nearly circular spots that are generally rich in carbides or carbide-forming elements. The formation of freckles is usually a result of a high pool depth or movement of the rotating liquid pool. The liquid pool can be set into motion (rotation) by stray magnetic fields during remelting. Freckles can be avoided by maintaining a low pool depth and by avoiding disturbing magnetic fields through the use of a coaxial current supply.

White spots are typical defects in VAR ingots. They are recognizable as light-etched spots on a macroetched surface. They are low in alloying elements, for example, titanium and niobium in Alloy 718. There are several mechanisms that could account for the formation of white spots (Ref 34, 35):

- Relics of unmelted dendrites of the consumable electrode
- Pieces of the crown that fall into the pool and are not dissolved or melted
- Pieces of the shelf region transported into the solidifying interface

All three of the above mechanisms, individually or combined, can be considered as sources of white spots. This indicates that white spots cannot be completely avoided during vacuum arc remelting. To minimize the frequency of occurrence of these defects, the following conditions should be observed during remelting:

- Use the maximum acceptable metal rate permitted by the ingot macrostructure
- Use a short arc gap to minimize crown formation and to maximize arc stability
- Use a homogenous electrode free of cavities and cracks

Process Variables

Atmosphere. The heat generated by melting of the metal in vacuum arc remelting results from the electric arc between the consumable electrode and the liquid pool on the top of the ingot. The pressure in the remelting vessel is usually of the order of 0.1 to 1 Pa (10^{-3} to 10^{-2} mbar, or 7.5×10^{-4} to 0.0075 torr). In some exceptional cases, the melting is also carried out under inert gas with a pressure up to 10 kPa (100 mbar, or 75 torr). Evaporation losses of volatile alloying elements are minimized at this pressure.

Melt Rate. As mentioned earlier, the melt rate is an important factor in the quality of the ingot macrostructure. A modern VAR furnace is therefore equipped with a load cell system to measure the weight of the electrode at a particular interval of time. The actual values of the melt rate are compared by computer with the desired set values. Any difference between the measured melt rate and the desired value is eliminated by the proper accommodation of the power input.

Figure 28 shows the melt rate and the melting current at start-up, during steady-state melting, and during hot topping. Startup and hot topping are usually controlled based on time. The melting phase is controlled based on weight.

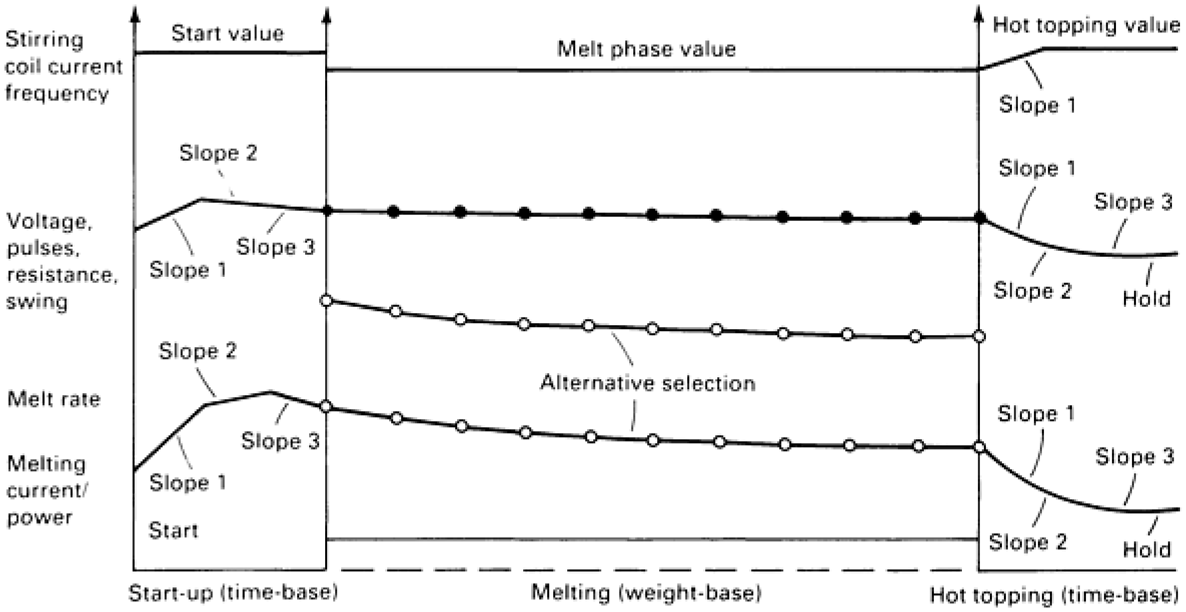

Fig. 28 Process control parameters and set point functions in vacuum arc remelting.

Hot topping begins when a preselected residual electrode weight is reached. A computer controls the melting parameters, which are stored in the form of up to 250 different recipes in the computer. Figure 29 shows a simplified version of the computer furnace control. With this, melting rate can be controlled with a precision of better than ±2%. The computer also provides documentation in the form of tables and graphs for the relevant process parameters.

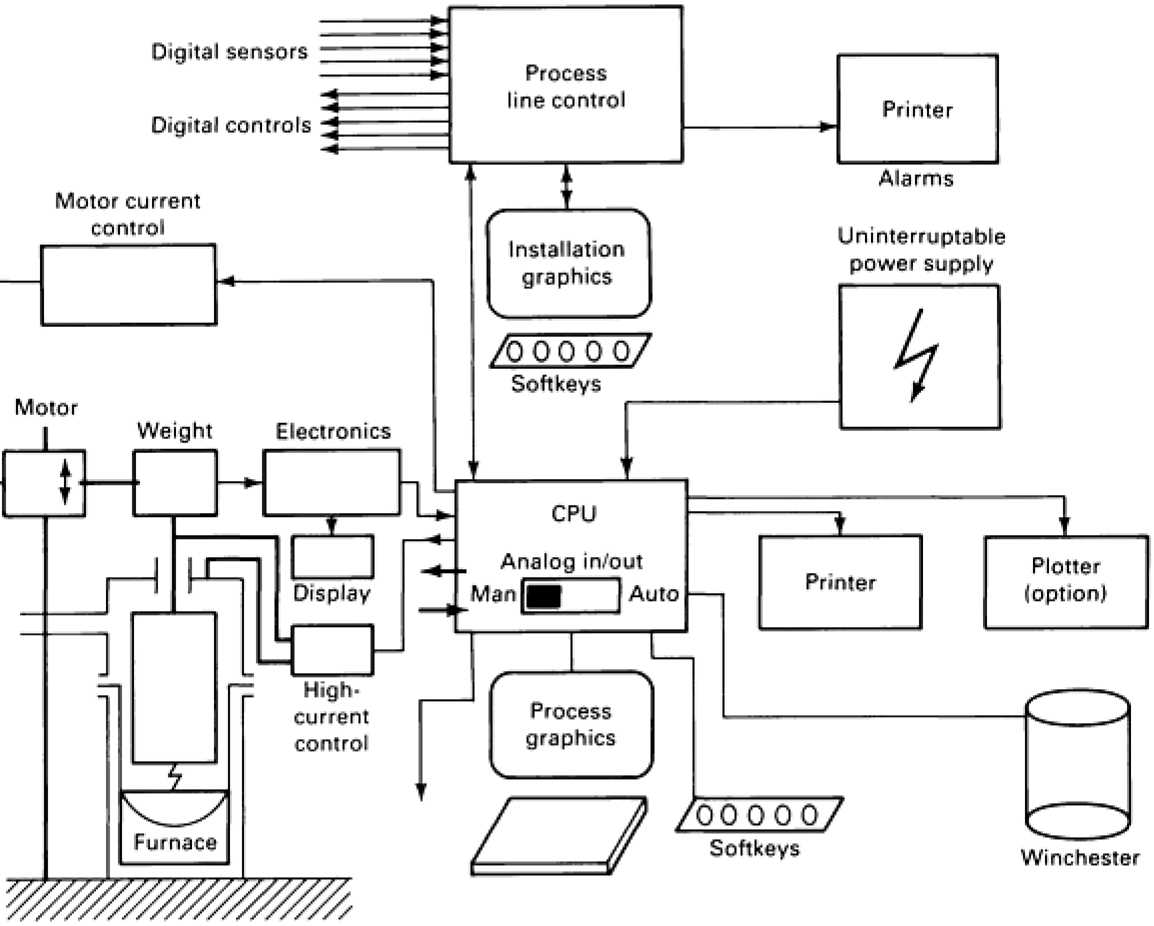

Fig. 29 Schematic of automatic melt control system.

Remelting Variations Under Vacuum

Apart from the remelting of a consumable electrode in a water-cooled copper crucible, there is a recent development of the vacuum arc remelting process, namely vacuum arc double electrode remelting (VADER). Figure 30 shows the basic design of the VADER process with a static crucible. The arc is struck between the two horizontal electrodes that are to be melted.

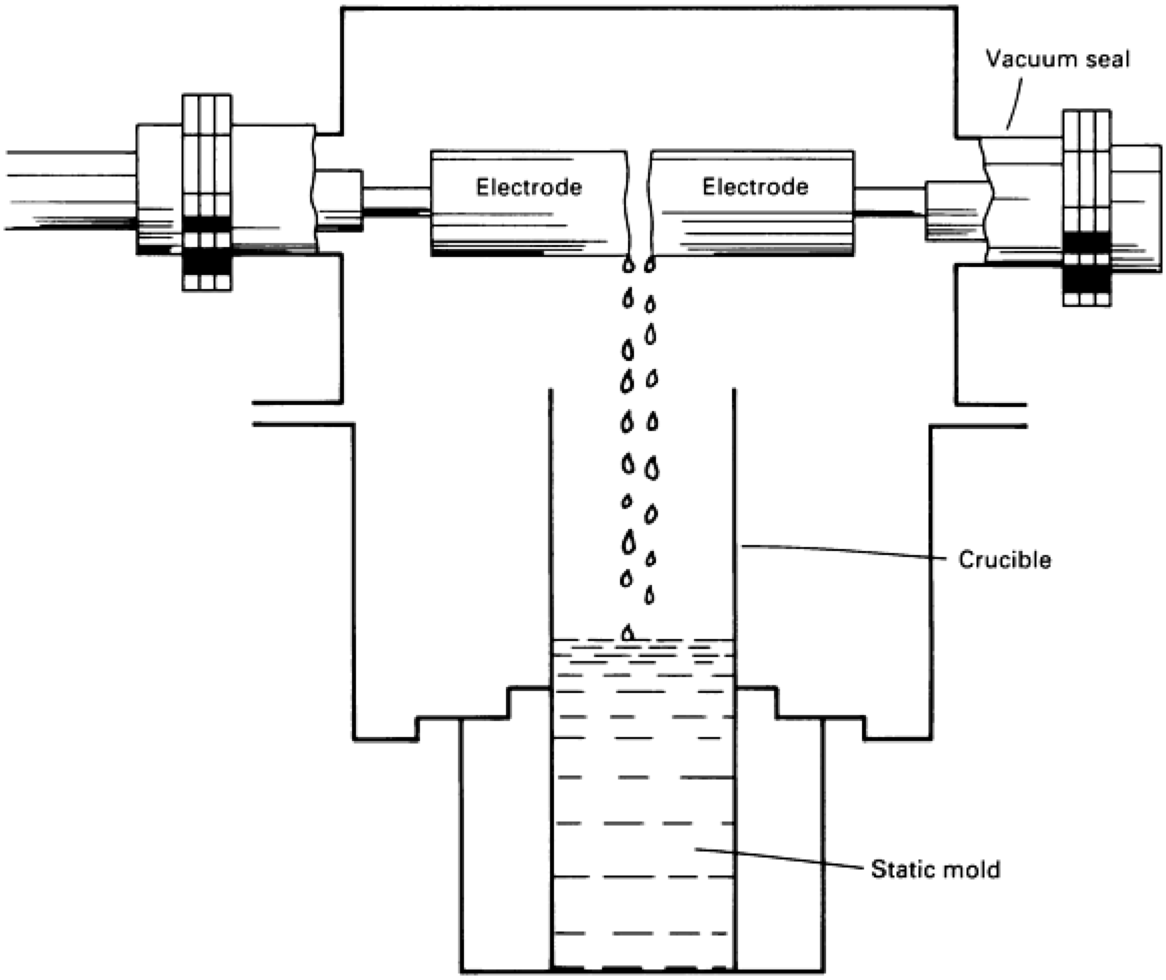

Fig. 30 Schematic of the VADER process.

As in vacuum arc remelting, the metal drops fall into a water-cooled copper mold. Bath temperature, and therefore pool depth, can be very closely controlled. Remelting can be done with minimal superheating; segregation is thus minimized. The advantages of the VADER process over vacuum arc remelting are as follows (Ref 36):

- Very low or no superheating of the pool and high rate of nucleation, producing a fine grain structure
- The lowest possible influence of magnetic fields on melting bath movement
- No condensation formation due to evaporation of liquid elements on the crucible walls
- Lower specific energy consumption
- Good ultrasonic testability due to the fine macrostructure of the ingot

Vacuum Arc Skull Melting and Casting

F. Müller and E. Weingärtner, Leybold AG, West Germany

Titanium investment casting has recently gained the same importance as the precision casting of superalloys (see the article "Titanium and Titanium Alloys" in this Volume). Titanium skull melting originated at the Bureau of Mines in Albany, Oregon. The first castings were made in 1953, although possibilities had been announced as early as 1948 and 1949. In the late 1950s, this technology was applied by research institutes, which were looking for a practical means of liquefying and pouring uranium into graphite molds, for example, to produce uranium carbide.

An early industrial vacuum arc skull melter was built in 1963 for the continuous production of uranium carbide. This furnace had a crucible volume of approximately 0.01 m^3 (0.35 ft^3) and used a nonconsumable graphite electrode to liquefy the uranium pellets fed into the crucible. The crucible tilting system was hydraulically driven. The molds were stationary. It was not until 1973 that one of the first skull melters for titanium went into operation; this furnace started production in 1974 in West Germany.

State-of-the-art titanium vacuum arc skull melting furnaces are often equipped with turntable systems for centrifugal casting (up to 350 rpm). Casting weights of more than 1000 kg (2200 lb) are possible. Vacuum arc skull melting and casting is used for many titanium investment castings for aircraft, aerospace, medical, and chemical applications. Electron beam skull melting is also used for titanium alloys (see the section "Electron Beam Melting and Casting" in this article).

Furnaces

Vacuum arc skull casting furnaces basically consist of a vacuum-tight chamber in which a titanium or titanium alloy electrode is driven down into a water-cooled copper crucible. The dc power supply provides the fusing current needed to strike an electric arc between the consumable electrode and the crucible. Because the crucible is water cooled, a solidified titanium skull forms at the crucible surface, thus avoiding direct contact between melt and crucible.

Once the predetermined amount of liquid titanium is contained in the crucible, the electrode is retracted, and the crucible is tilted to pour the melt into the investment casting mold positioned below. For optimum mold filling, the mold can be preheated and/or rotated on a centrifugal turntable.

Figure 31 shows the operating principle of a modern 50 kg (110 lb) vacuum arc skull melting furnace. At an operating pressure of approximately 1 Pa (10^{-2} mbar, or 0.075 torr), the specific working current ranges from approximately 1 kA/kg for small furnaces to about 0.2 kA/kg for large pouring weights. This batch-type skull melting furnace allows for cycle times of approximately 1 h for a full 50 kg (110 lb) pumping/melting/casting cycle, and in principle three consecutive pours can be obtained from one electrode. This furnace basically consists of a vacuum chamber, an arc voltage-controlled electrode drive system, a skull crucible, a centrifugal casting system with stepless adjustable turntable speed, an automatically sequenced vacuum pump system, a power supply, and an electrical control system with control desk.

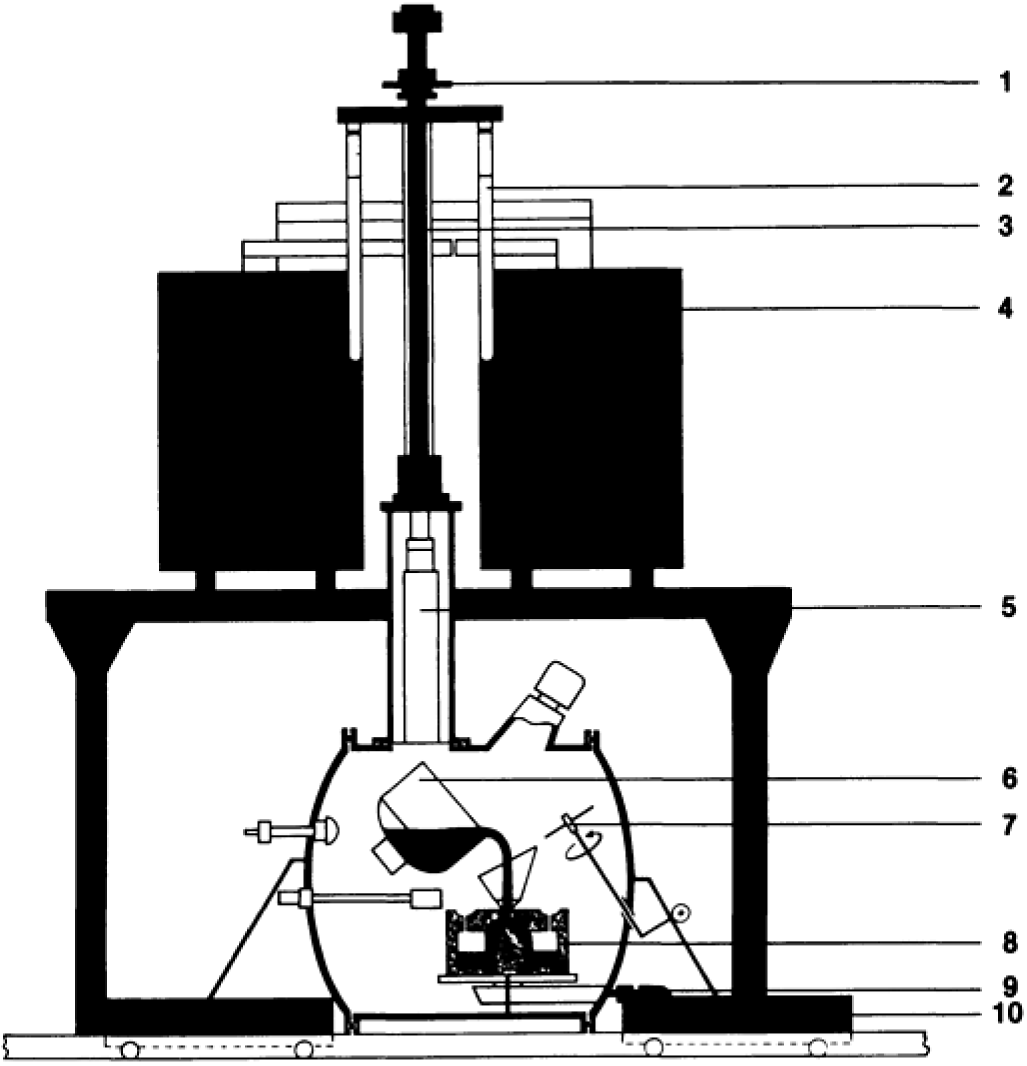

Fig. 31 Schematic of a modern 50 kg (110 lb) vacuum arc skull melting and casting furnace. 1, fast retraction system; 2, power cables; 3, electrode feeder ram; 4, power supplies; 5, consumable electrode; 6, skull crucible; 7, tundish shield; 8, mold arrangement; 9, centrifugal casting system; 10, chamber lid carriage.

The cylindrical vacuum chamber is equipped with two large dished doors that support the crucible with the tilting mechanism, the mold platform with the centrifugal casting system, and the casting tundish with its cover. The crucible support system with an additional detachable device is also used for electrode loading. The chamber is jacketed for water cooling in regions that are subject to heat radiation.

A top flange with a throat carries the electrode chamber and the electrode feeding system. Viewing ports allow for video monitoring of the melting and pouring. A vacuum pumping port is located in the cylindrical portion of the chamber.

Figure 32 shows a semicontinuously operated vacuum arc skull melter for charge weights of up to 1000 kg (2200 lb). The principal difference between this furnace and the smaller model (Fig. 31)--apart from capacity-related layout features--is the rectangular vacuum chamber. Again, the crucible and the tilting mechanism are carried by a dished door.

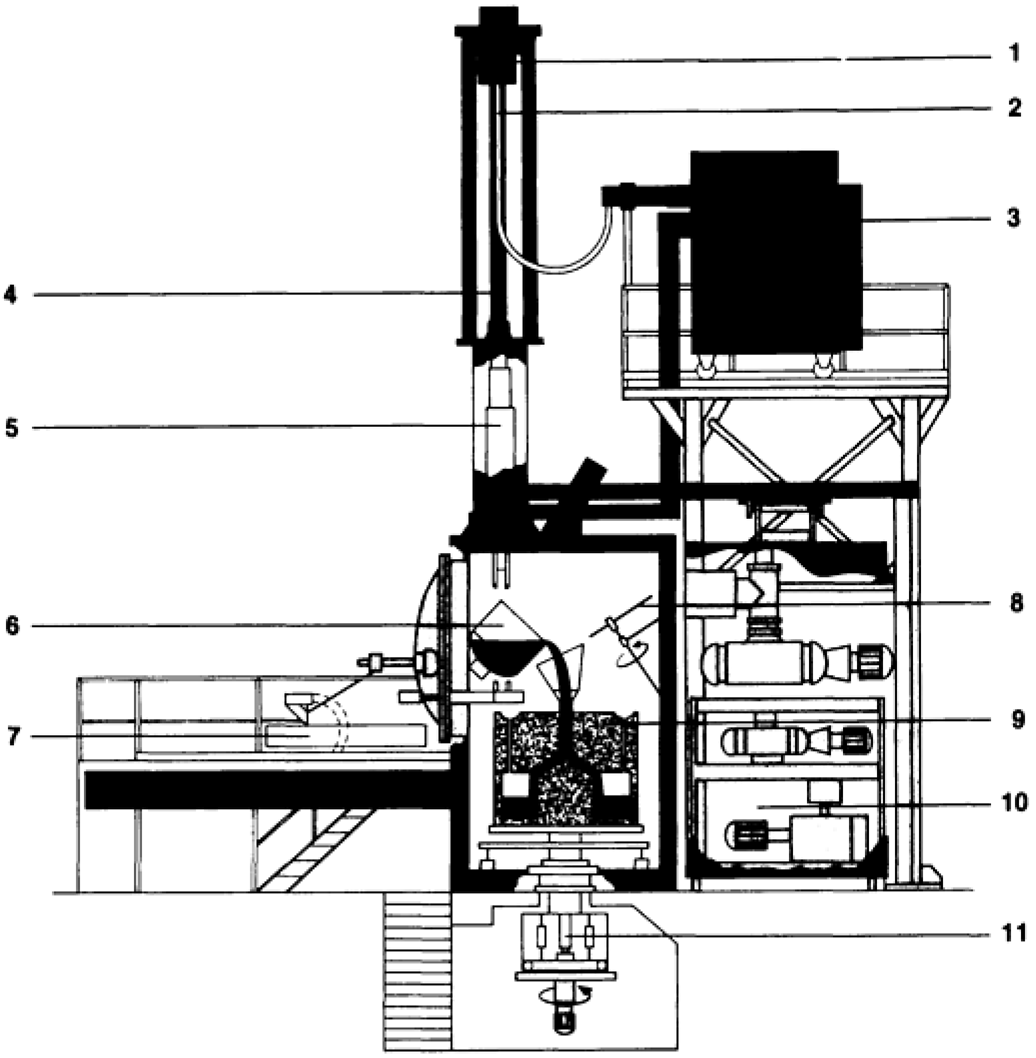

Fig. 32 Schematic of a modern semicontinuously operating vacuum arc skull melter for charge weights of up to 1000 kg (2200 lb). 1, fast retraction system; 2, power cables; 3, power supplies; 4, electrode feeder ram; 5, consumable electrode; 6, skull crucible; 7, crucible carriage; 8, tundish shield; 9, mold arrangement; 10, vacuum pumping system; 11, centrifugal casting system.

In this furnace design, the centrifugal casting system is introduced from the bottom of the chamber to allow the horizontal connection of a separate cooling chamber, if desired. Molds are loaded from the back side into the chamber and can be discharged through a front door, which also allows the use of a cooling and charging chamber with lock valves for continuous mold transport flow.

Modern vacuum arc skull melting furnaces are usually equipped with:

- Coaxial power feed directly to the skull crucible to avoid electromagnetic fields that can disturb the melt bath
- Programmable control systems for crucible tilting to allow repeatable pouring profiles for consistent parameters
- Highly accurate electrode weighing system for precise determination of pouring weights
- *XY* adjustment system for coaxial positioning of the electrode in the skull crucible
- Compact air-cooled power-supply modules of high capacity for achieving high melt rates, thinner skulls, and correspondingly increased yields above 80%
- Proven vacuum pumping and measuring systems
- Forced argon cooling systems for faster mold cooling

Electron Beam Melting and Casting

W. Dietrich and H. Stephan, Leybold AG, West Germany

Electron beam melting and casting technology is accepted worldwide for the production of niobium and tantalum ingots weighing up to 2500 kg (5500 lb) in furnaces with electron beams of 200 to 1500 kW. Another application in East Germany and other Soviet bloc countries is the production of steel ingots weighing 3.3 to 18 Mg (3.6 to 20 tons) using electron beams of up to 1200 kW. Furnaces of up to 2400 kW in electron beam power have been used since 1982 for recycling titanium scrap to produce 4.8 Mg (5.3 ton) slabs 1140 mm (45 in.) wide. Furnaces of 200 to 1200 kW are used to refine nickel-base superalloys. Other metals, such as vanadium and hafnium, are melted and refined in furnaces between 60 and 260 kW. Approximately 150 furnaces with melting powers ranging from 20 to 300 kW are in operation in research facilities. These furnaces are used in the development of new grades and purities of conventional and exotic metals and alloys, for example, uranium, copper, precious metals, rare-earth alloys, intermetallic materials, and ceramics. The total power of installed electron beam melting and casting furnaces worldwide was approximately 25,000 kW at the end of 1987.

Electron beam melting and casting includes melting, refining, and conversion processes for metals and alloys. In electron beam melting, the feedstock is melted by impinging high-energy electrons. Electron beam refining takes place in vacuum in the pool of a water-cooled copper crucible, ladle, trough, or hearth. In electron beam refining, the material solidifies in a water-cooled continuous casting copper crucible or in an investment ceramic or graphite mold. This technology can be used for all materials that do not sublimate in vacuum.

Competing processes include sintering (for example, for refractory metals), vacuum arc melting and remelting (for reactive metals and superalloys), and electroslag melting and vacuum induction melting (for superalloys, specialty steels, and nonferrous metals). Some advantages and limitations of the competing vacuum processes are given in Table 4. Additional information on some of these processes is available in the sections "Vacuum Arc Remelting (VAR)," "Electroslag Remelting (ESR)," and "Vacuum Induction Melting (VIM)" in this article.

Table 4 Comparison of characteristics of electron beam melting and competing processes

Metal	**Sintering**		**Vacuum arc melting**		Electron beam melting	
	Advantages	**Limitation**	**Advantages**	**Limitations**	**Advantages**	Limitations
Tungsten, molybdenum	Small grain size most often used	Refining limited; small batches; high energy consumption	Moderate grain size; acceptable workability large ingots; low energy consumption	Refining limited; costly electrode preparation; melting dangerous	Highest possible purity; economical feedstock preparation; large ingots; low energy consumption	**Large grain size; brittle product; very rarely applied**
Tantalum, niobium	Small grain size; good workability	Same as above; rarely applied	Alloying; moderate grain size; large ingots; low energy consumption	Refining limited; expensive electrode; melting dangerous	Same as above; most frequently used	**Alloying limited**
Hafnium, vanadium	. . .	Same as above	Alloying during remelting	Almost no refining; costly electrode preparation; melting dangerous	Good refining; economical feedstock preparation and ingot production; most often used	**High melting costs**

Zirconium, titanium	**. . .**	**Not used**	**Very low contamination; wide range of alloying possible; large ingots low energy consumption; economical melting**	**Limited refining; expensive feedstock preparation; only round ingots**	**Economical feedstock preparation; refining of high-density inclusions; melting of slabs, ingots, and rods; high production rate; low energy consumption**	**Alloying limited; material losses from splatter; high furnace investment**

Electron Beam Melting and Casting Characteristics

The characteristics of electron beam melting and casting technology are:

- The flexibility and controllability of the process temperature, speed, and reaction
- The use of a wide variety of feedstock materials in terms of material quality, size, and shape
- The different methods of material processing available
- Product quality, size, and quantity

Contamination of the product is avoided by melting in a controlled vacuum and in water-cooled copper crucibles (Fig. 33).

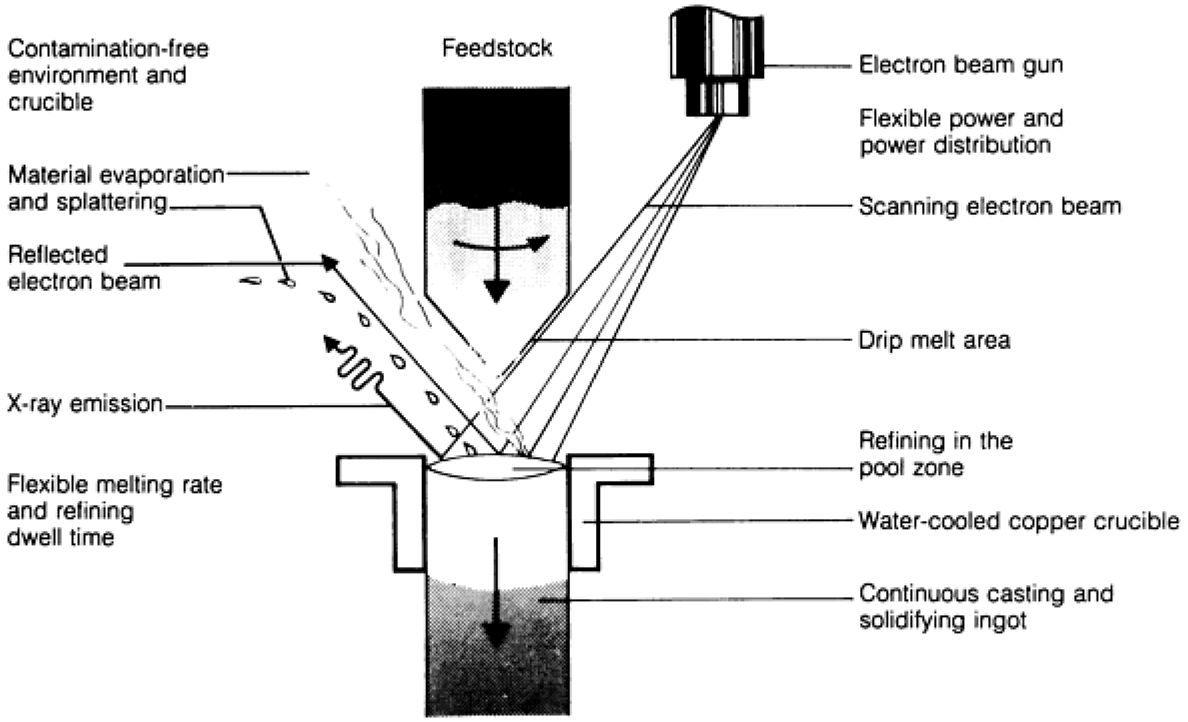

Fig. 33 Schematic of the electron beam melting process.

The energy efficiency of electron beam processing exceeds that of competing processes because of the control of the beam spot dwell time and distribution at the areas to be melted or maintained as liquid. In addition, unnecessary heating of the ingot pool, as occurs in vacuum arc remelting, for example, is avoided. Power losses of the electron beam inside the gun and between the gun nozzle and the target are very small, but approximately 20% of the beam power is lost because of beam reflection, radiation of the liquid metal, and heat conductivity of the water-cooled trough and crucible walls.

Electron Beam Melting and Casting Processes

From the large variety of electron beam melting and casting processes shown in Fig. 34 only the processes illustrated in (a), (c), (d), and (f) are related to processes used in foundry technology:

- Button melting processes for the quality control of steel and superalloy cast parts to control the content of low-density inclusions
- Drip melting process for the preparation of refractory and reactive metal feedstock material for electron beam and VAR skull melting and casting
- Continuous flow melting process for the feedstock refining of superalloys for VIM and electron beam casting
- Electron beam investment casting process

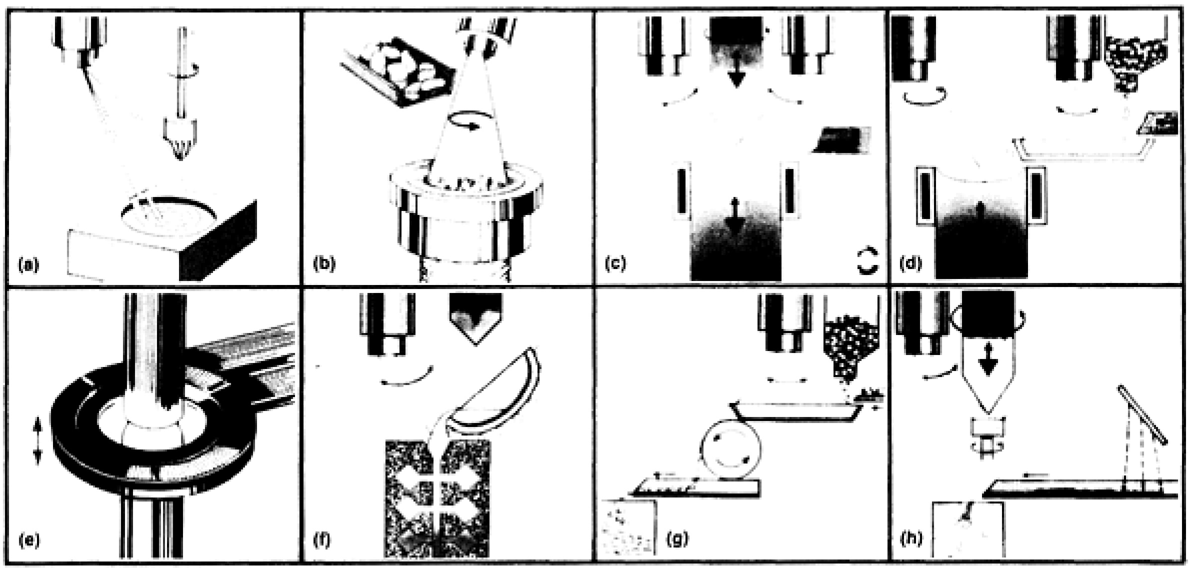

Fig. 34 Examples of electron beam melting and casting processes. (a) Button melting with controlled solidification for quantitative determination of low-density inclusions. (b) Consolidation of raw material, chips, and solid scrap to consumable electrodes for vacuum arc or electron beam remelting. (c) Drip melting of horizontally or vertically fed feedstocks. (d) Continuous flow refining/melting. (e) Floating zone melting. (f) Investment casting. (g) Pelletizing (manufacture of pellets from scrap and other materials for scrap recycling). (h) Atomization and granulation of refractory and reactive metals.

Electron Beam Heat Source Specifications

For all electron beam melting and casting processes, except for the crucible-free floating zone melting process, Pierce-type electron beam guns with separately evacuated beam generating and prefocusing rooms are the key components of the furnaces used. The essential features of these guns are:

- Large power range of 0 to 1200 kW
- Long free beam path of 250 to 1500 mm (10 to 60 in.) and the adjustable beam power distribution
- Beam deflection angle of ±45° and spot frequency up to 500 Hz
- Usable vacuum pressure range between 1 and 0.0001 Pa (10^{-2} and 10^{-6} mbar, or 7.5×10^{-3} and 7.5×10^{-7} torr)
- Reliability of the gun and cathode system

The power control and distribution system allows a very accurate distribution of beam power and energy for achieving the required heating for material melting, superheating, refining, and electrothermal effects.

Button Melting for Quality Control

The button melting process (Fig. 34a) serves to control the quality of feedstock materials for investment casting and to produce casting samples. In contrast to the conventional electron beam melting process, this process is not used for refining, but only for flotation and concentration of low-density inclusions. During the eight-step process, the sample is heated and drip melted. Low-density inclusions are floated to the surface and concentrated in the center of the pool of molten metal during controlled solidification by computer-controlled reduction of beam power and circular electrothermal stirring. The concentrated impurities can be identified and evaluated by conventional metallographic methods, but the size of the raft gives the first indication of the quantity of impurities in the metal.

Most button melting furnaces are completely automated and microprocessor controlled to guarantee process reproducibility. Melting is usually carried out in the pressure range of 1 to 0.001 Pa (10^{-2} to 10^{-5} mbar, or 7.6×10^{-3} to 7.6×10^{-6} torr).

Drip Melting

The drip melting processes (Fig. 35c and d) are primarily used for the production of clean, mostly ductile ingots of refractory and reactive metals or of specialty steels. The feedstock for the first melt (Fig. 35c) can be compacted sponge, granular, powder, or scrap, which might be presintered in a vacuum heating furnace. In some cases, loose raw materials can be consolidated in a water-cooled copper trough (Fig. 35a). The consolidated ingot can then be fed horizontally for drip melting. Raw material that is continuously consolidated in a water-cooled copper crucible with a retractable bottom plate (Fig. 35b) can be fed horizontally or vertically for drip melting. In both consolidation processes, only 20 to 80% of the material is melted. Refining and losses of material by splattering are negligible.

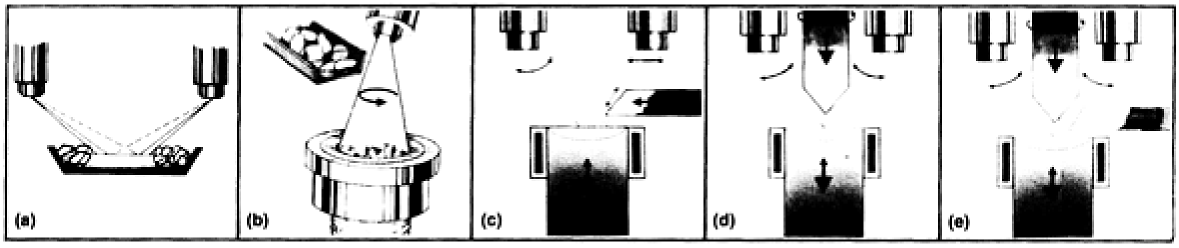

Fig. 35 Schematics of electron beam consolidation and drip melting processes. (a) Consolidation of coarse and solid scrap. (b) Continuous consolidation of raw material, chips, and solid scrap by direct feeding into a continuous casting crucible. (c) Drip melting of horizontally fed compacts, sintered bars, or consolidates for initial melting of reactive and refractory metals. (d) Drip melting of vertically fed vacuum induction melted or conventionally melted electrodes. (e) Drip melting of horizontally and vertically fed materials for the production of alloys from feedstocks with very different melting points.

Drip melting of horizontally fed compacts is the most frequently used process for the production of ingots from refractory or reactive metals. The resulting ingot is of sufficient purity, but has an area of inhomogeneity caused by the shadow of the horizontally fed bar. Two or more electron guns are used in drip melting to make use of reflected electron beams and to reduce evaporation and splattering. The end of a compact is welded to the front of the following one to avoid dropping semisolid material into the pool. Table 5 lists processing parameters that have been successfully used to electron beam melt various reactive and refractory metals and 4340 alloy steel.

Table 5 Melting and refining data of refractory and reactive metals and alloy steels gained in laboratory and pilot production furnaces

(a) The reproducibility of the refining data could not be confirmed.

Vertical Feeding of Ingots. Refractory and reactive metal ingots of high purity, homogeneity, and smooth surface are remelted by vertical feeding (Fig. 35d). The molten metal droplets run down the conical, rotating electrode tip, are refined, and then drop into the pool center. The crucible pool is normally of the same diameter as the electrode but is sometimes smaller or larger. It is kept in the liquid state to allow final refining and to guarantee ingot homogeneity. Because two or more electron guns are used, the entire pool can be equally bombarded; thus, shadow effects of the electrode can be eliminated.

Simultaneous melting of horizontally and vertically fed electrodes (Fig. 35e) can be used for the production of critical alloys. In this case, the feedstock should be of the desired purity.

Horizontally Fed Ingots. Drip melting of horizontally fed material with a single electron gun (Fig. 36) is used for refining some steel alloys in East Germany and other Soviet bloc countries. In this process, the feedstock size is smaller than the pool diameter to minimize the shadow effect of the horizontally fed bar. In production units, feeding can be carried out from two opposite sides.

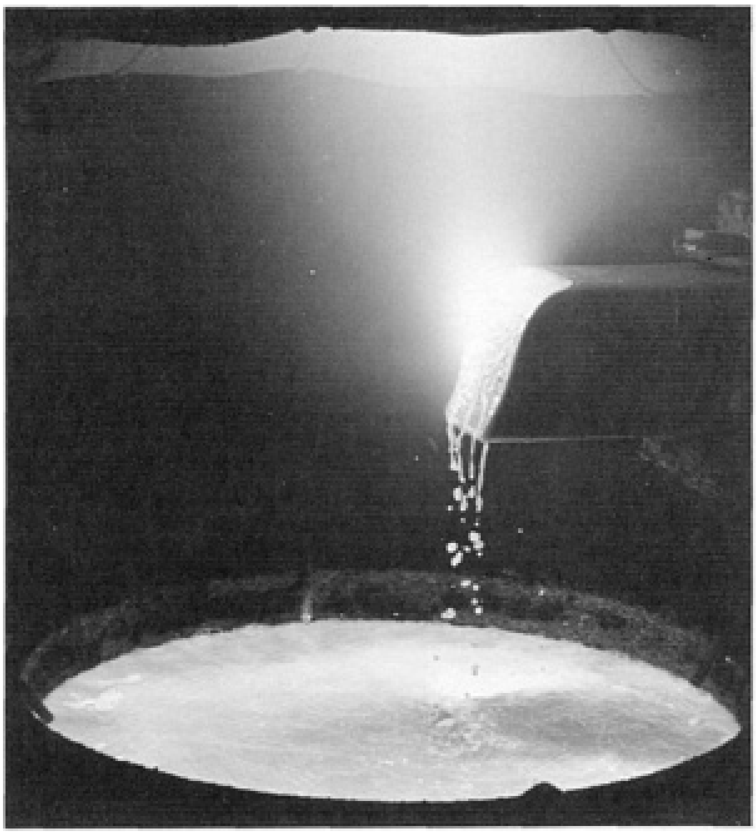

Fig. 36 Drip melting of 330 mm (13 in.) square steel billet in a 1100 kW single-gun furnace. Melt rate: 1000 kg/h (2200 lb/h). Courtesy of VEB-Edelstahlwerk, East Germany.

Other Process Considerations. To ensure the production of clean, homogeneous metals and alloys in electron beam drip melting furnaces, various aspects of material processing and handling must be controlled. Key considerations include:

- Dimensions and quality of the feedstock, and the feeding system used
- Ingot cooling and unloading during melting of another ingot
- Passivation and removal of condensates from the melt chamber
- Planning of melt sequences to minimize the number of furnace cleanings required
- Routine preventive furnace maintenance to ensure reliability
- Operator skill in operation of the furnace
- Material yield and energy consumption

Equipment for Drip Melting

The essential equipment groups required for drip melting--melting furnaces, control systems, and power supply units--are all important for achieving optimum productivity.

The melting furnace (Fig. 37) includes the electron beam gun as the heat source, material feeding and ingot withdrawal systems, a crucible for material solidification, and a vacuum system to maintain the low pressure. Process observation, both visually and with video systems, is possible through viewports. The melt chamber flanges are equipped with x-ray absorbing steel boards, and interlocking systems prevent operation failures and accidents.

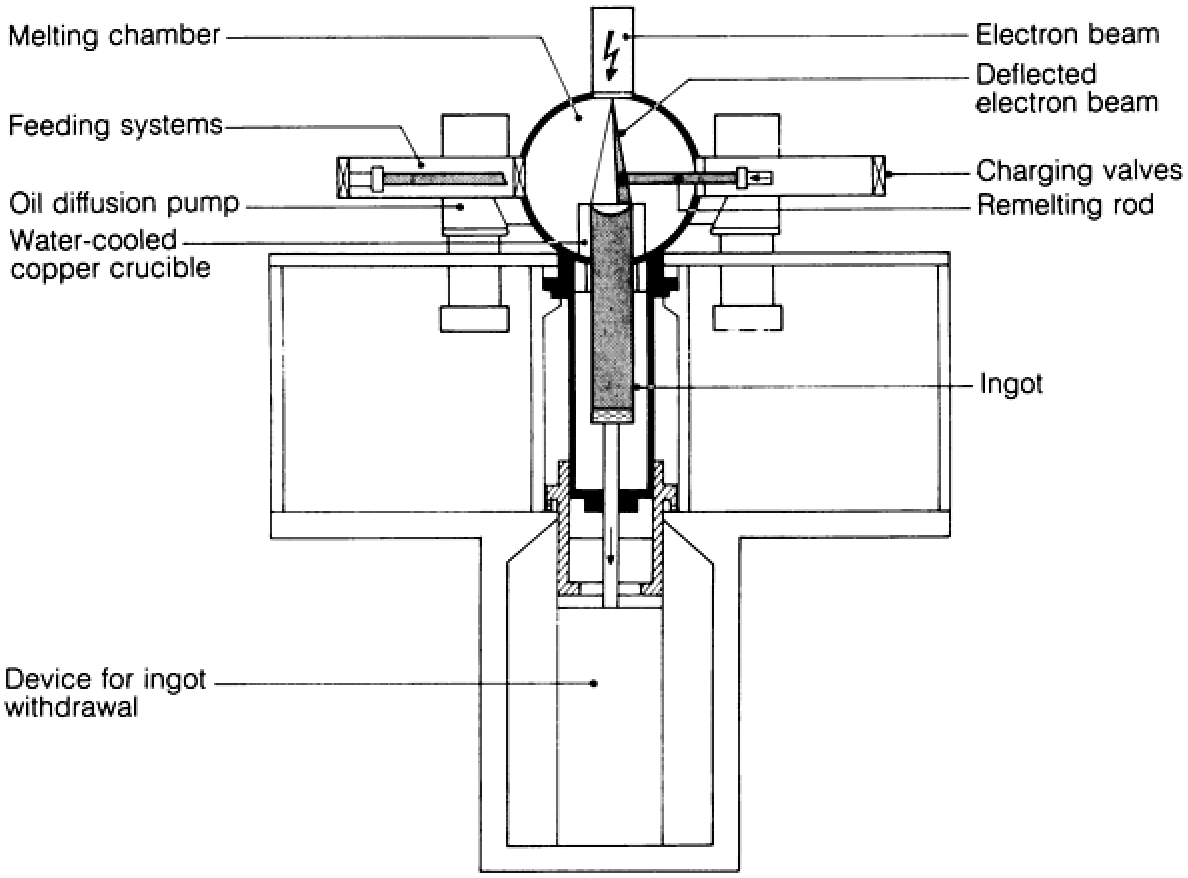

Fig. 37 Single-gun 1200 kW furnace for horizontal drip melting of steels. Melting rates of up to 1100 kg/h (2425 lb/h) are possible.

The control system allows the adjustment and control of such operating process parameters as electron beam power, operating vacuum level, material feed rate, and ingot withdraw speed. The control system also records and logs the process data.

Power Supply Units. One or more high-voltage power supply units are needed to supply the electron beam guns with the required continuous voltage (30 to 40 kV). The beam power of each gun can be adjusted between zero and maximum power with an accuracy of ±2%.

Other Equipment. Large production furnaces are equipped with lock-valve systems to allow simultaneous melting and unloading of ingots without breaking the vacuum in the melt chamber. Production is thus limited only when the condensate remaining in the melt chamber requires cleaning or when a different alloy is to be melted.

Characteristics of Electron Beam Drip Melted Metals

Electron beam melted and refined material is of the highest quality. The amount of interstitials present is very low, and trace elements of specific high vapor pressure can also be reduced to very low values (Ref 37, 38).

Reactive and Refractory Metals

Tantalum and niobium ingots have smooth surfaces and are of sufficient ductility that they can be cold worked, and sheets and wires can be produced.

Tungsten and molybdenum ingots are also of the highest possible purity, but the ingots are brittle because of the very large grain size and the concentration of impurities at grain boundaries.

Hafnium. Electron beam melted hafnium is of higher ductility than the vacuum arc remelted metal (Ref 39). The main application of electron beam melted hafnium is as control elements for submarine nuclear reactors.

Vanadium is refined by electron beam drip melting. The aluminothermically produced feedstock is drip melted in several steps. During this procedure, the ingot diameter is reduced at each step by approximately 30 to 40 mm (1.2 to 1.6 in.) to obtain an ingot 30 to 40 mm (1.2 to 1.6 in.) in diameter, regardless of the initial ingot diameter. The clean vanadium ingots are primarily used in nuclear reactor applications (Ref 40).

Applications for electron beam melted refractory and reactive metals are listed in Table 6.

Table 6 Principal applications for vacuum arc remelted (VAR), electron beam melted (EB), and powder metallurgy (P/M) reactive and refractory metal ingots

Metal	Applications
Reactive metals, VAR and EB melting	
Hafnium	Flash bulbs and glow discharge tubes for the electronics industry; control rods and breakoff elements in submarine nuclear reactors
Vanadium	Targets for high deposition rate sputtering processes in the electronics industry; breakoff elements, fixtures, and fasteners in nuclear reactors; standards for basic research; alloying element for certain high-purity alloys
Zirconium	Getter material in tubes in the electronics industry; stripes for flash bulbs; fuel claddings, fasteners, and fixtures for nuclear reactors
Titanium	Components for bleaching equipment and desalination plants in the chemical industry; superconductive wires; turbine engine disks, blades and housings, rain erosion boards, landing legs, wing frames, missile cladding, and fuel containers in the aircraft and aerospace industries shape memory alloys; biomedical fixtures and implants; corrosion resistant claddings
Refractory metals, EB melting and P/M	
Tungsten	Heating elements, punches and dies, and nonconsummable electrodes for arc melting and gas tungsten arc welding for metal processing equipment; targets for x-ray equipment and high sputtering rate devices such as very large-scale integrated circuits, cathodes and anodes for electronic vacuum tubes in the electronics industry; radiation shields in the nuclear industry; cladding and fasteners for missile and reentry vehicles

Tantalum	Condensers, autoclaves, heat exchangers, armatures, and fittings for the chemical industry; electrolytic capacitors for the electronics industry; surgical implants; fasteners for aerospace applications
Molybdenum	Dies for conventional and isothermal forging equipment; electrodes for glass melting; targets for x-ray equipment; cladding and fasteners for missile and reentry vehicles
Niobium	Superconductive wire for energy transmission and large magnets for the electrical and electronics industries; heavy ion accelerators and radio frequency cavities for nuclear applications; components for aircraft and aerospace applications

Steels

The purity and properties of electron beam melted steels are in some respects better than those of vacuum arc and electroslag remelted steels, but the processing costs are higher. The electron beam melting of steel is primarily used in East Germany and other Soviet bloc countries. The resulting ingots are up to 1000 mm (40 in.) in diameter and weigh up to 18 Mg (20 tons). The furnaces used have been in operation since 1965, and have beam powers of up to 1200 kW. Larger furnaces for the production of ingots weighing up to 30 to 100 Mg (33 to 110 tons) are under construction (Ref 41).

The essential advantage of the electron beam melting of steel is the drastic reduction of metallic and nonmetallic impurities and interstitial elements (Ref 42, 43). The principal applications for electron beam melted steels are in the machinery industry for parts for which high wear resistance and long service life are required. The extended service lives of the parts and the reduced manufacturing time (for example, less surface polishing is required for electron beam melted steel) can justify the higher material costs.

The electron beam melting of steel and superalloys can become much more economical when melting and refining are done by continuous flow melting or cold hearth refining. These melting and refining methods reduce energy costs and minimize material losses.

Continuous Flow Melting

The continuous flow melting process (cold hearth refining process) (Fig. 38) was developed approximately 10 years after drip melting (Ref 44). Continuous flow melting is mainly used for refining specialty steels and superalloys and for refining and recycling reactive metal scrap, especially Ti-6Al-4V from high-density tungsten carbide tool tips (Ref 45).

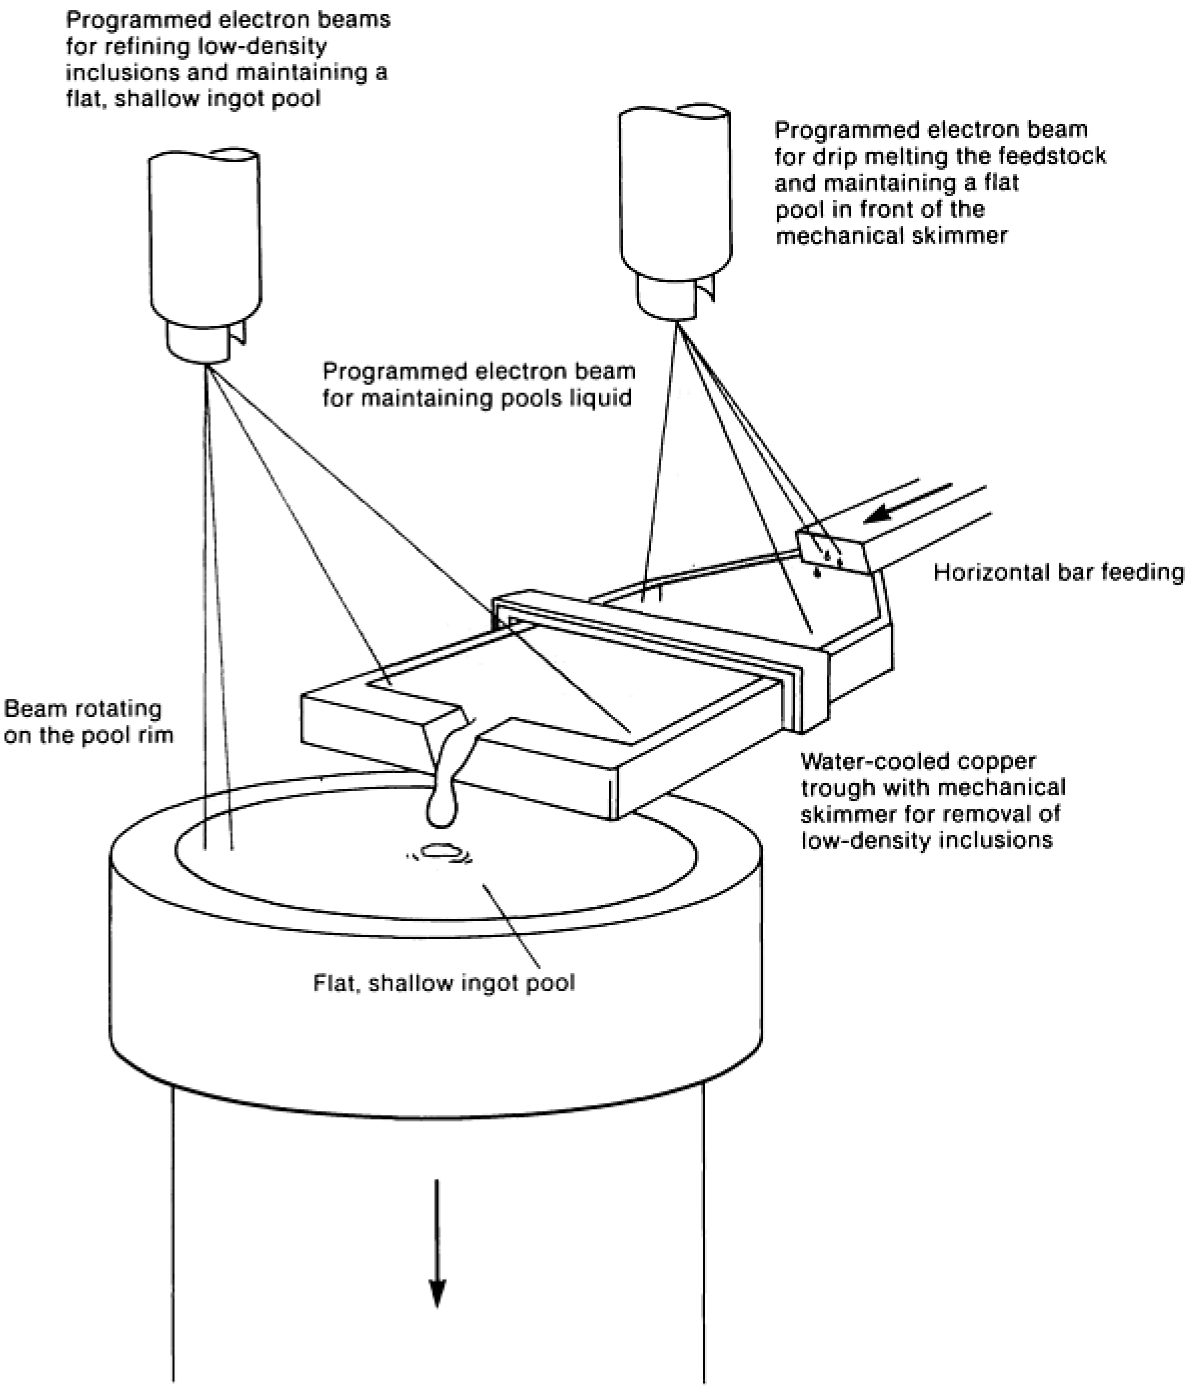

Fig. 38 Schematic of the continuous flow melting process.

Principles of Continuous Flow Melting

Continuous flow melting (Fig. 39) is the most flexible vacuum metallurgical melting process. It is a two-stage process in which the first step (material feeding, melting, and refining) takes place in a water-cooled copper trough, ladle, or hearth. In the second step, solidification occurs in one of several round, rectangular, or specially shaped water-cooled continuous copper crucibles. Both process steps are nearly independent from each other; they are linked only by the continuous flow of the liquid metal stream. The major refining actions are carried out in the hearth, but some postrefining takes place in the pool of the continuous casting crucible, similar to the drip melting of horizontally fed billets. Refinement in continuous flow melting occurs by vacuum distillation in the hearth pool, superheating, and stirring of the molten metal pool.

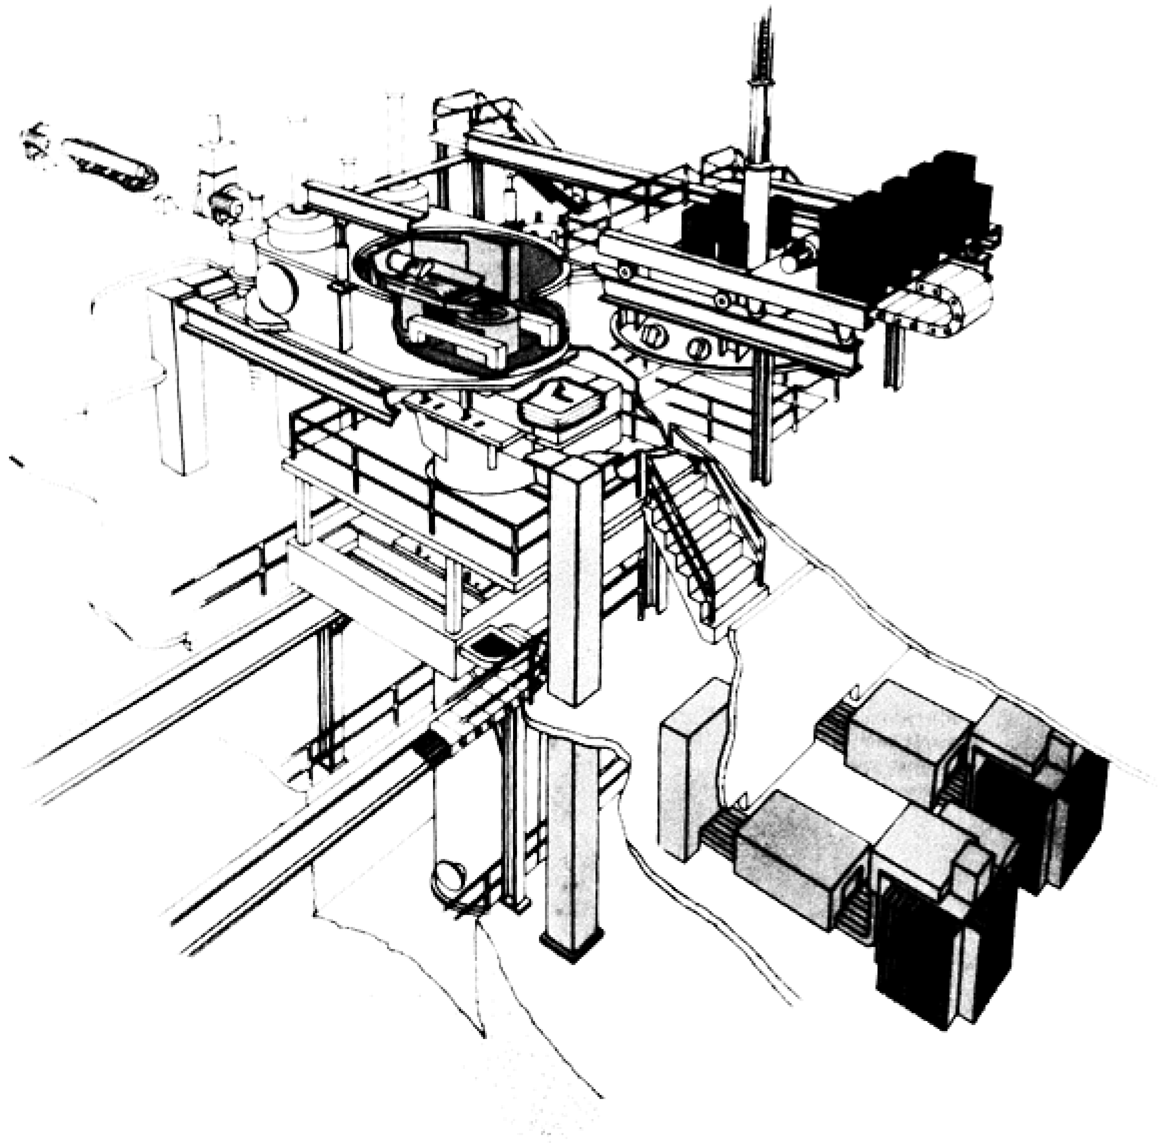

Fig. 39 Four-gun 1200 kW combined electron beam drip melting and continuous flow melting furnace.

Removal of Impurities. Most impurities with densities lower than that of the melt (for example, metalloids in steels and superalloys) can be segregated by flotation and formed into a slag raft. The raft is then held in place by either mechanical or electrothermal means. Impurities denser than the melt, such as tungsten carbide tool tips in titanium, are removed by sedimentation. Inclusions with densities such that efficient flotation or sedimentation does not occur can be partially removed by adhesion to the slag raft.

Hearth dimensions are based on the type and amount of refining required. For example, hearths for vacuum distillation should be nearly square and relatively deep to allow sufficient melt stirring. For flotation refining, the hearth should be long and narrow (for superalloys, approximately 10 mm, or 0.4 in., of hearth length for each 100 kg/h, or 220 lb/h, of melt rate is recommended). Hearths for titanium alloy scrap recycling can be relatively short if all the materials can be transported to the pool of the hearth rather than to the ingot pool.

Feeding. Material feeding criteria include 100% homogenous material transportation to avoid uncontrolled evaporation of alloying elements and correct feeding into or above the hearth pool. Horizontal feeding of compacted, premelted, or cast material is most often used. Loose scrap and raw material are used only when compaction is too expensive. Feeding of liquid metal was used in one of the first continuous flow melting furnaces to produce a ferritic steel in a vacuum induction furnace (Ref 46). Postrefining was carried out in a cascade of five hearths 1.5 m (60 in.) long and 1 m (40 in.) wide.

Casting and Solidification. The criteria for material casting and solidification include the shape of the final product and the solidification rate required to avoid ingot tears or other defects and to ensure a homogeneous ingot structure. The multiple casting of small ingots is sometimes used, especially when forging is impossible because of the brittleness of the solidified material (for example MCrAly wear-resistant coating alloys). The casting of round and rectangular ingots and slabs is common practice, and the continuous casting of hollow ingots is also being used (Ref 47). The casting of segregation-free ingots and ingots with a fine grain size is under development to improve the workability of superalloys (Ref 48, 49).

Continuous Flow Versus Drip Melting

Table 7 compares the essential features of drip melting and continuous flow melting. Generally, continuous flow melting is used for all refractory metals, superalloys, and specialty steels, especially when flotation or sedimentation of inclusions is required. Drip melting is used for refractory metals because of their high melting points and the resulting high heat losses to the water-cooled copper crucible. Depending on production quantity, double or triple drip melting may require less energy than a single continuous flow melt of some materials, such as niobium.

Table 7 Comparison of the characteristics of drip melting and continuous flow melting

Characteristic	**Refractory metals**	Reactive metals, superalloys, and specialty steels
Power density	High	**Soft; smoothly distributed**
Inclusions	Irrelevant	**Must be removed**
Ingot shape and structure	Round; coarse grain	**Round or flat; fine grain, segregation-free**
Mass production	Low	**High**

Refining and Production Data

Data on continuous flow electron beam melting and refining in laboratory and pilot production furnaces are given in Table 8. The data demonstrate the effectiveness of the process in reducing impurities and interstitial elements. It can also be seen that the selective evaporation of chromium from superalloys can be controlled by the distribution of beam power at the trough pool and by controlling trough pool area and melt rate. The selective evaporation of aluminum from Ti-6Al-4V alloy is much more difficult to control; additional aluminum must be used to compensate for the aluminum evaporated.

Table 8 Refining and production data for the continuous flow melting of reactive and refractory metals and stainless steels in laboratory and pilot production furnaces

Equipment for Continuous Flow Electron Beam Melting

The equipment required for continuous flow melting is different from that used in drip melting mainly because of the trough and the somewhat larger melting chamber. In addition, because of the materials often melted in the continuous flow process (superalloys and titanium alloys), additional instrumentation is often provided. This may include an ingot pool level control system, metal vapor and partial pressure analyzers, a two-color temperature control system, and a data logging system.

Accurate beam power distribution is achieved in two- or three-gun furnaces by microprocessor control, which allows the splitting of a single beam to 64 locations and the adjustment of dwell time at each location between 0.01 and 1000 s. The beam spot at each of the 64 locations can be scanned over an elliptical or rectangular area. With such systems, the required refining can be achieved without unnecessary power consumption and evaporation of alloying elements (Ref 51).

Process observation is accomplished with a video monitoring system. Samples can be obtained from both the trough pool and the ingot pool for nearly continuous control of material quality.

Feeding systems for continuous flow furnaces must maintain homogeneity along the length of the feed material. The trough and crucible should be easily accessible for convenient maintenance, especially when different alloys are to be melted in the same furnace.

Characteristics of Continuous Flow Melted Materials

Titanium ingots and slabs can be produced from titanium scrap contaminated with tungsten carbide tool tips. The electron beam melted product contains tungsten carbide particles no larger than 0.7 mm (0.028 in.) in diameter. Oxygen content can be reduced by fitting titanium sponge compacts around a forged ingot or slab. Continuous flow melted titanium ingots can be directly remelted in a VAR furnace.

Superalloys. Continuous flow electron beam melted superalloy ingots 150 to 200 mm (6 to 8 in.) in diameter are often used in VIM investment casting furnaces. Such ingots are nearly free of nonmetallic inclusions and trace elements (Ref 52). The simultaneous continuous casting of twin, triple, or multiple ingots is under development in a 200 kW pilot

furnace. Multi-ingot casting can become economical when 90 Mg (100 tons) or more of an alloy is being produced annually (Ref 53).

Investment Casting Using Electron Beam Melting

Investment casting with electron beam heat sources from water-cooled copper skull crucibles has been used for the production of superalloy turbine parts with directionally solidified or monocrystal structures and for titanium parts with equiaxed structures. In both applications, the feedstock is clean material that is melted with no major refining effect and without picking up any contamination. The process competes for superalloys with vacuum induction melting and investment casting and for titanium with vacuum arc skull melting and casting.

Characteristics of Electron Beam Investment Casting

With electron beam melting, it is possible to superheat the casting material just before and during pouring to increase the fluidity of the metal. This is not possible with vacuum arc skull melting. The extremely short metal flow path between the crucible spout and the mold funnel reduces erosion of the mold, and the controllable pouring speed allows the use of small mold funnels for reducing revert material. An essential advantage of electron beam titanium casting is the possibility of using premelted VAR ingots and solid, clean in-house recycling scrap separately or simultaneously to reduce material costs. The decisive advantage of electron beam casting technology is the possibility of process automation, which guarantees reproducibility of quality and a high production rate. Therefore, electron beam melting is used only when a high production rate is demanded. The obvious disadvantage is the decreasing metal temperature during pouring caused by the temperature gradient of the melt in the water-cooled copper crucible; for this reason, the process cannot be used for the production of superalloy cast parts with very specific equiaxed structures.

Process Technology and Equipment for Superalloy Castings

For the economical mass production of superalloy turbine parts, the electron beam casting process and equipment shown in Fig. 40 and described in Table 9 meet the required process and product specifications. The pool temperature before casting can be adjusted between 1650 and 1900 °C (3000 and 3450 °F), depending on part requirements. The adjusted temperature can be reproduced with an accuracy of 0.3%.

Table 9 Processing data for the mass production of directionally solidified and monocrystal superalloy castings in 120 and 300 kW electron beam casting machines

E	Pool superheating	12	100	0.74	0.33
F	Pouring with simultaneous pool superheating	0.7	100	0.04	0.33
G	Washing of crucible for reduction of skull weight	6.0	60	0.22	0.10
H	Cleaning of the spout lip to obtain reproducible pouring streams; tilting back of crucible	1.0	60	0.04	0.02

Fig. 40 Procedure and process data for the electron beam melting and casting of 0.45 kg (1 lb) superalloy parts. Cycle time: 60 s; total electron beam energy: 3.01 kW · h/s.

The accuracy of the part weight was 1.8% for small parts (450 g, or 1 lb) and 1.5% for larger parts (8 kg, or 18 lb). The cycle time for smaller parts was 58 ± 1.5 s; for larger parts, 300 ± 10 s.

Reduction in chromium content was less than 0.1%. Feedstock load is twelve electrodes 125 mm (5 in.) in diameter and 1600 mm (63 in.) long. The electrode magazine can be reloaded without venting the melt chamber. Exchange of water-cooled copper crucibles, for changing alloys or part weight, can also be accomplished without venting the melt chamber.

More than 50% of the evaporating and splattering material can be condensed and collected at the condensate plate. This plate can be replaced through a lock-valve system.

Vacuum pressure during melting and pouring is in the range of 0.001 to 0.0001 Pa (10^{-5} to 10^{-6} mbar, or 7.5×10^{-6} to 7.5×10^{-7} torr). Leak and wall degassing rates are below 2×10^{-4} mbar · L/s.

Melting and pouring within one electrode cycle can be done automatically. Movement of an electrode from the storage position to the melting position is semiautomatic.

The distance between the copper crucible pouring spout and the mold funnel was less than 40 mm (1.6 in.) during pouring. The mold funnel cross section was 20 to 30 mm (0.8 to 1.2 in.) for casting small parts.

These results can be achieved with a computer-controlled electron beam melting furnace using the process data given in Table 9. The fundamental equipment groups are the means for accurate beam power distribution at the electrode tip and

crucible pool and its programmable power level during the many steps of process procedure, and integrated droplet counter and balance to control the material to be drip melted, and the weight of the remaining skull, which will be remelted again and again at each step. The high degree of process reproducibility is achieved by controlling pool surface temperature, crucible washing, and crucible spout lip cleaning. Crucible washing and spout lip cleaning minimize the skull weight remaining in the crucible and ensure a reproducible beam pattern for pouring in a small mold funnel. A computer-controlled production casting system that uses electron beam melting is described in detail in Ref 54.

Process Technology and Equipment for Titanium Castings

The production of titanium castings in electron beam furnaces is economical when large quantities of the same size and weight must be manufactured and when the entire specification range of alloy compositions can be used. Electron beam casting is economical and superior to the competing VAR skull melting and nonconsumable arc melting processes; a blend of solid scrap and consumable electrodes can be used because the crucible spout can be cleaned by electron beam melting after each pour. Figure 41 illustrates the beam control possible with microprocessor control. Another advantage of this process is the possibility of superheating the pool just before pouring and the metal stream during pouring. During the melting and casting process, the feedstock can be loaded into the scrap feeder or into the electrode lowering device without influencing the process cycle. Mold loading, transportation, positioning below the crucible spout, spinning there with up to 500 rpm, and unloading of the cooled casting are completely automated.

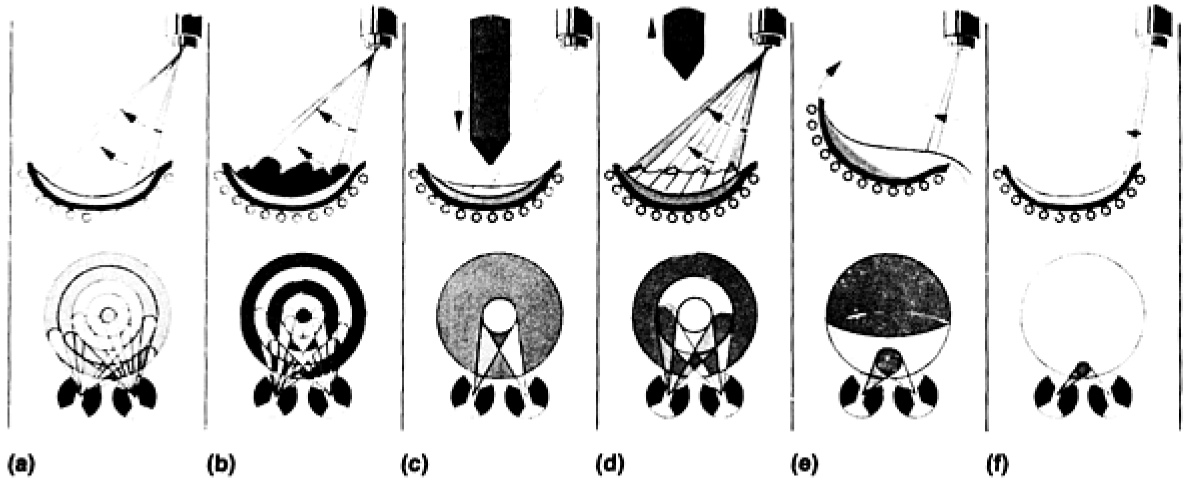

Fig. 41 Procedure and process data for the electron beam melting and casting of titanium and titanium alloy parts starting from scrap and consumable electrodes. (a) Melting of skull with two beams, each scanning and jumping on two circles (500 kW, 7 min). (b) Melting of scrap with two beams, each scanning and jumping on different circles (500 kW, 7 min). (c) Melting of consumable electrode with two concentrated beams (500 kW, 6 min). (d) Superheating of the pool with two beams, each scanning and jumping on two different circles (500 kW, 3 min). (e) Superheating of the metal stream during pouring with two concentrated beams (500 kW, 10 s). (f) Cleaning of the mold spout with two slightly scanning beams (10 kW, 2 min).

Plasma Melting and Casting

H. Pannen and G. Sick, Leybold AG, West Germany

Plasma melting is a material processing technique in which the heat of a thermal plasma is used to melt the feed material. A thermal plasma is considered a suitable heat source if high temperature and a defined gas atmosphere are needed to

melt the material before subsequent processing, such as solidification or atomization. The products are usually ingots, slabs, castings, or powders.

Plasma Torch

Plasma Generation. An electric current passing through an ionized gas leads to a phenomenon known as gaseous discharge. To generate this kind of plasma, electrical breakdown of the gas must be accomplished. Breakdown (that is, the creation of charge carriers) establishes a conducting path between a pair of electrodes in gases that are insulators at room temperature. Other plasmas can be created by electrodeless radio frequency (RF) discharges, microwaves, shock waves, lasers, or high-energy particle beams.

In this section, only thermal (hot) plasmas will be considered. The term thermal differentiates these plasmas from cold (nonequilibrium) plasmas, which are characterized by high electron temperatures and low sensible temperatures of the heavy particles. Cold plasmas are produced in various types of glow discharges, low-pressure RF discharges, and corona discharges. Cold plasmas are not suitable for melting processes.

Most plasma generators (plasma torches) for melting processes use an electric arc to produce gaseous discharges. The characteristics of an electric arc include relatively high current densities, low cathode fall, and high luminosity of the column.

A typical potential distribution along an arc is shown in Fig. 42 (Ref 55). The column cross section at the cathode is smaller than at the anode, with contrary current and power densities. This fact influences the design principle of plasma torches.

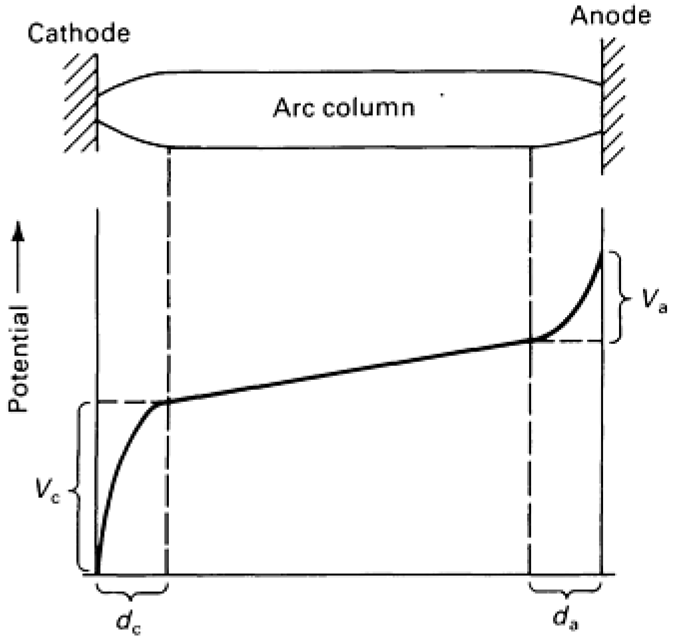

Fig. 42 Typical potential distribution along a plasma arc. V_a, anode voltage; V_c, cathode voltage; d_a, anode current density; d_c, cathode current density.

Torch Design. Plasma torches can be used in either the transferred or the nontransferred mode. In the nontransferred mode, the cathode and the anode are inside the torch. This mode is generally suitable only for the melting of nonconductive materials and has the disadvantage of lower efficiency compared to the transferred mode. In the transferred mode, one electrode is inside the torch, and the counter-electrode is the material to be melted. Figure 43 shows two typical design principles for torches in the transferred mode: the tungsten tip design and the hollow copper electrode design.

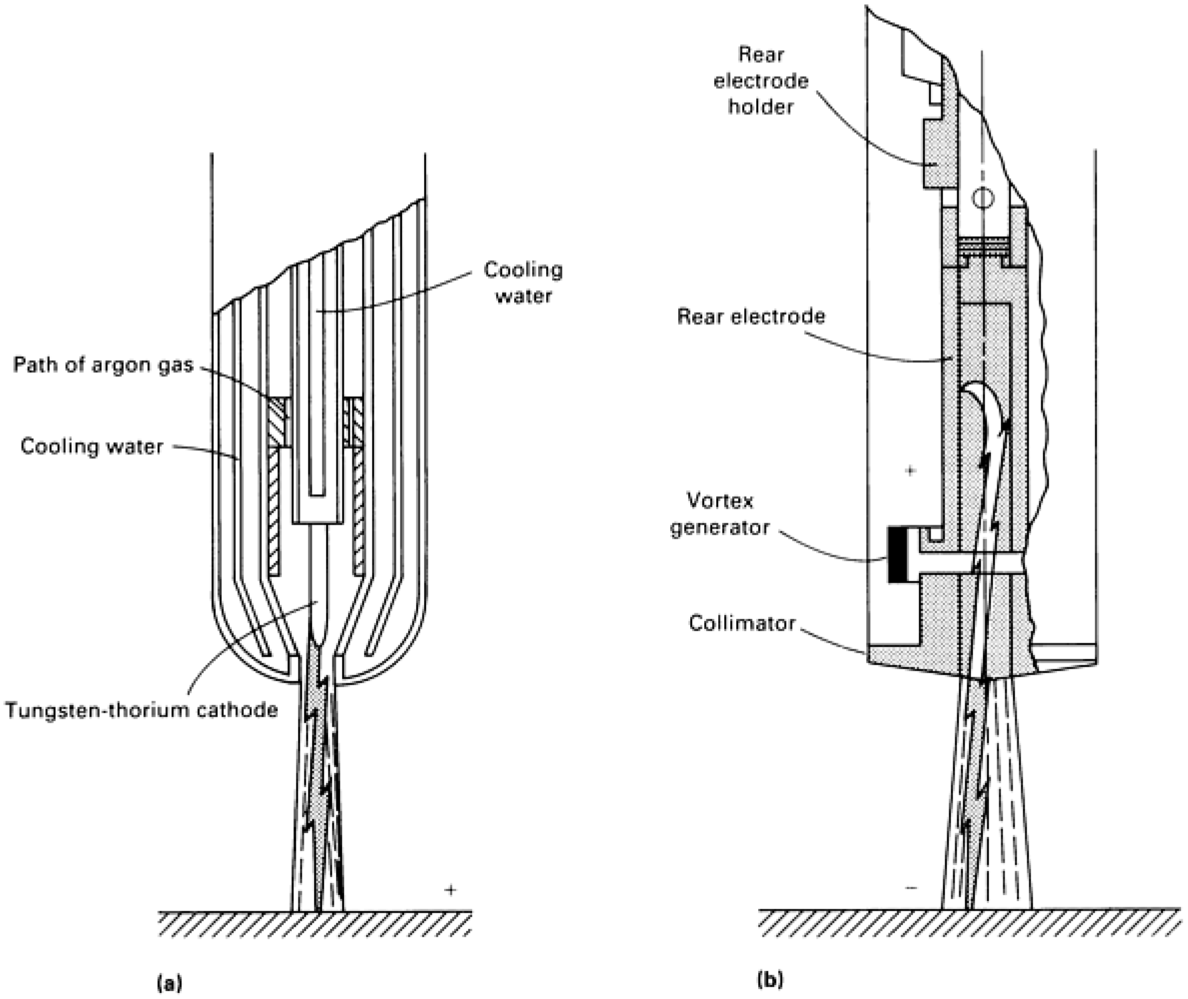

Fig. 43 Design concepts for plasma arc torches in the transferred mode. (a) Torch with tungsten tip and concentric gas flow. (b) Torch with hollow copper electrode and vortex generator.

In the tungsten tip design (Fig. 43a), the torch electrode is connected as the cathode because high current densities are required. The cathodes are usually made of tungsten, along with small additions of thoria to lower the thermionic work function of tungsten. Still, electron emission requires high electrode temperatures (3500 to 6000 K) at the attachment of the arc. Therefore, the cathode material is liquid at the arc attachment point even with water cooling at the rear of the cathode. For this reason, oxidizing gases generally cannot be used in direct contact with the tungsten tip. Argon shielding is one solution. Further, it should be kept in mind that portions of the small liquid pool at the cathode tip are ejected into the material being melted. The high melting point of tungsten can result in inclusions in the product; such defects are not tolerable in high-strength metals such as titanium alloys and superalloys for aircraft applications.

With argon as the plasma gas, the service life of the cathode in the tungsten tip design is typically between 30 and 150 h. The inert gas consumption and plasma column stabilization of such torches are low.

The hollow copper electrode design is shown in Fig. 43(b). The electrode material, usually copper alloyed with chromium or zirconium, is intensively water cooled. Copper is a field emitter of electrons (as opposed to tungsten, a thermionic emitter) because its boiling point is substantially below that required for thermionic electron emission. Current densities at the attachment points on cold cathodes are double those for thermionic emission on hot cathodes. Cathode spots are of high intensity, rapidly moving on the surface of the cold cathode and causing erosion by locally vaporizing copper. For this reason, the polarity is usually reversed in plasma torches with cold electrodes. The rear electrode acts as the anode, and the workpiece or melt is the cathode. The anodic arc attachment is smoother, and erosion is reduced. The plasma-forming gas is blown in tangentially between the rear electrode and the nozzle to create a swirl or vortex to stabilize the arc and to rotate the arc attachment in the rear electrode. With the movement of the arc attachment, a substantially lower power density can be achieved in the rear electrode.

Electrode life of 1000 h has been demonstrated in torches using argon as the plasma gas. All inert and reactive gases, or mixtures of these, can generally be used in such torches, but the influence of the gases on electrode erosion varies. The gas consumption of vortex-stabilized torches is higher than that of other designs.

The efficiency of plasma torches is less affected by design principles than by process parameters and by the type of plasma gas used. Efficiency is defined as P_w/P_t, where P_t is the electrical power input of the torch and P_w is the thermal power applied to the workpiece or melt. The efficiency of a 650 kW torch measured in a cold furnace ranges from approximately 20 to 40%, depending on the plasma gas used, furnace pressure, and the distance between torch and workpiece.

The highest efficiency is obtained with helium as the plasma gas and a short distance between material and torch. The power loss in torches with hollow water-cooled electrodes is approximately 20%. Remaining losses are due to radiation and convection of the plasma column between torch and workpiece. These losses are primarily a function of the distance between torch and workpiece, but radiative losses of the plasma column also increase with pressure.

Furnace Equipment

Plasma melting furnaces usually consist of double-wall, vacuum-tight, water-cooled constructions that can withstand the radiative and convective heat transfer from the plasma column. Furnaces also usually have material feeding systems. These can consist of vibratory or rotary feeders with bins (for bulk materials) or bar feeding systems. If the furnace is to operate continuously, the feed material must be "locked in" to prevent disturbance of the furnace atmosphere.

The furnace must also have a vacuum pump so that it can be evacuated before backfilling. If the furnace is operated under reduced pressure, an offgas pump with an on-line gas control valve is required.

Atmosphere Control

Plasma melting furnaces are usually operated under slightly positive pressure to prevent the potential atmospheric contamination by oxygen and nitrogen. However, state-of-the-art furnaces are vacuum tight and can be operated at pressures between 5 and 200 kPa (50 and 2000 mbar, or 38 and 1500 torr). Vacuum tightness is essential because the back diffusion of oxygen, nitrogen, and moisture through small leaks can be easily demonstrated even with positive pressure in the furnace. Plasma torches are normally operated with argon plasma gas. A typical gas purity of 99.999% indicates 10 ppm gaseous impurities and corresponds to an absolute pressure of 1 Pa (0.01 mbar, or 0.0075 torr) in a vacuum process.

Additional sources of atmospheric contamination are the moisture and gases in the feed material, desorption of the furnace wall, and leaks in the furnace construction. In the case of metals with high affinities for oxygen or nitrogen, these gases are totally absorbed by the melt and will be found as oxide or nitride inclusions in the product.

To obtain a clean initial furnace atmosphere, the vacuum-tight plasma furnace is evacuated with a mechanical pump to final pressure (typically about 1 Pa, or 0.01 mbar, or 0.0075 torr). The furnace walls can be degassed with the help of warm water running between the double walls of the furnace to enhance moisture desorption. The furnace is then backfilled with high-purity inert gas up to 1 kPa (10 mbar, or 7.5 torr), evacuated again to 1 Pa (0.01 mbar, or 0.0075 torr), and backfilled to operating pressure. This procedure dilutes residual gas impurities by a factor of 1000.

Processes

Application of Plasma Melting Processes. The selection of a suitable heat source for melting, remelting, casting, and atomizing reactive metals, titanium, and superalloys is of great interest to the manufacturer and user of plasma furnace equipment. Skull melting processes in water-cooled copper crucibles are often the only melting technology for these metals (see the section "Vacuum Arc Skull Melting and Casting" in this article). Plasma torches, however, are the only nonconsumable heat sources for melting under high inert gas pressures in skull crucibles. High pressure is an

essential requirement for preventing the selective evaporation of alloying elements that are characterized by high activity coefficients and/or vapor pressures, such as chromium and manganese in superalloys and aluminum in titanium alloys.

Various plasma melting processes have been developed, including plasma consolidation, plasma arc remelting, plasma cold hearth melting, and plasma casting. Plasma cold hearth melting and plasma cold crucible casting are thought to have the most potential for industrial application. Table 10 lists data on feed materials, operating parameters, and products of furnaces for some of these processes.

Table 10 Characteristics and operating parameters of furnaces for plasma melting processes

Plasma Consolidation. Consolidation implies that low-density feed material is converted into a high-density product. Plasma consolidation is used for titanium scrap and sponge to produce an electrode for further remelting in vacuum arc remelting (VAR) furnaces. The material is usually fed directly into a water-cooled copper crucible and melted by plasma heat from one or several plasma torches. The water-cooled copper baseplate of the crucible is continuously withdrawn. The shape and depth of the liquid pool in the crucible depend on feed rate and power input. Under these conditions, 100% melting cannot be ensured; some material can be trapped at the liquid/solid interface before melting. Figure 44 shows two typical plasma consolidation furnaces.

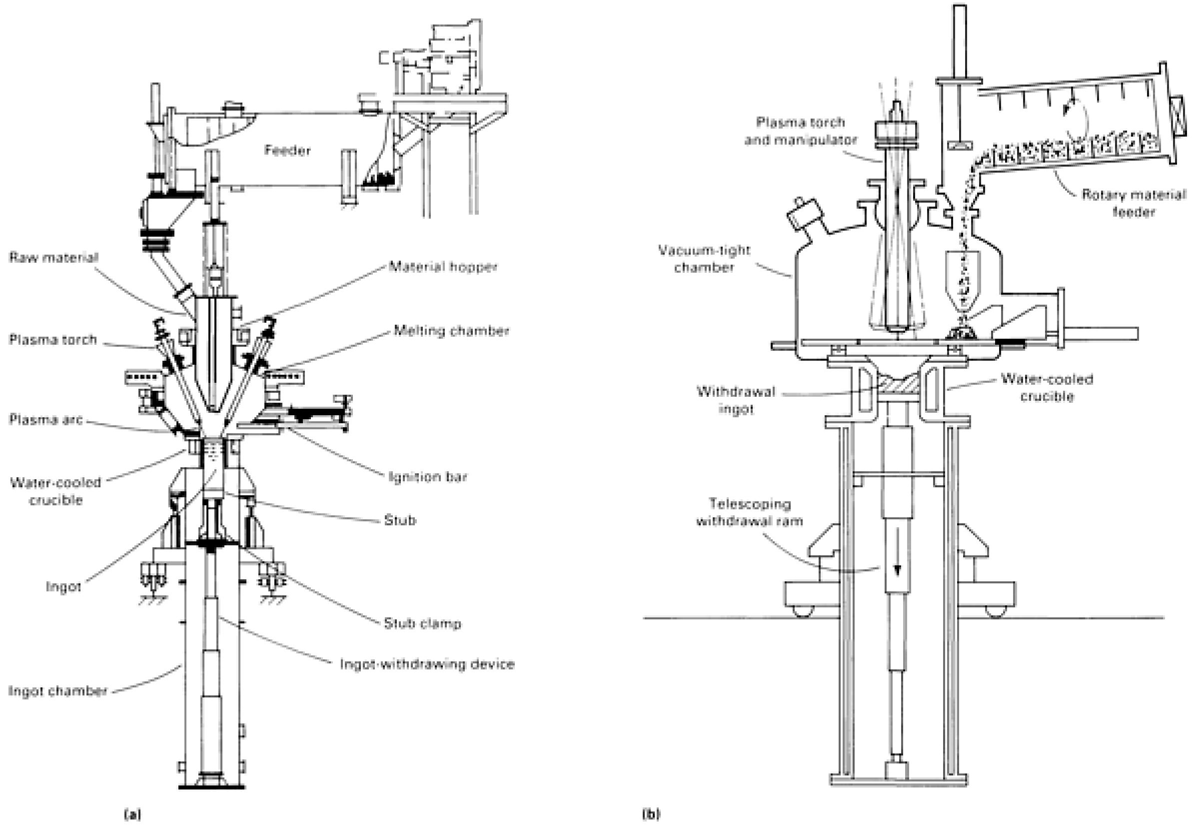

Fig. 44 Plasma consolidation furnaces. (a) Japanese furnace with six torches and total power of 540 kW. Source: Ref 60. (b) Retech furnace in the United States with one torch. Source: Ref 57.

Figure 45 shows ingot density as a function of the raw material feed rate and power consumption in the plasma consolidation of titanium. Plasma consolidation processes can reduce manufacturing costs for the preparation of titanium VAR electrodes, which are usually plasma melted from pressed sponge or chip compacts.

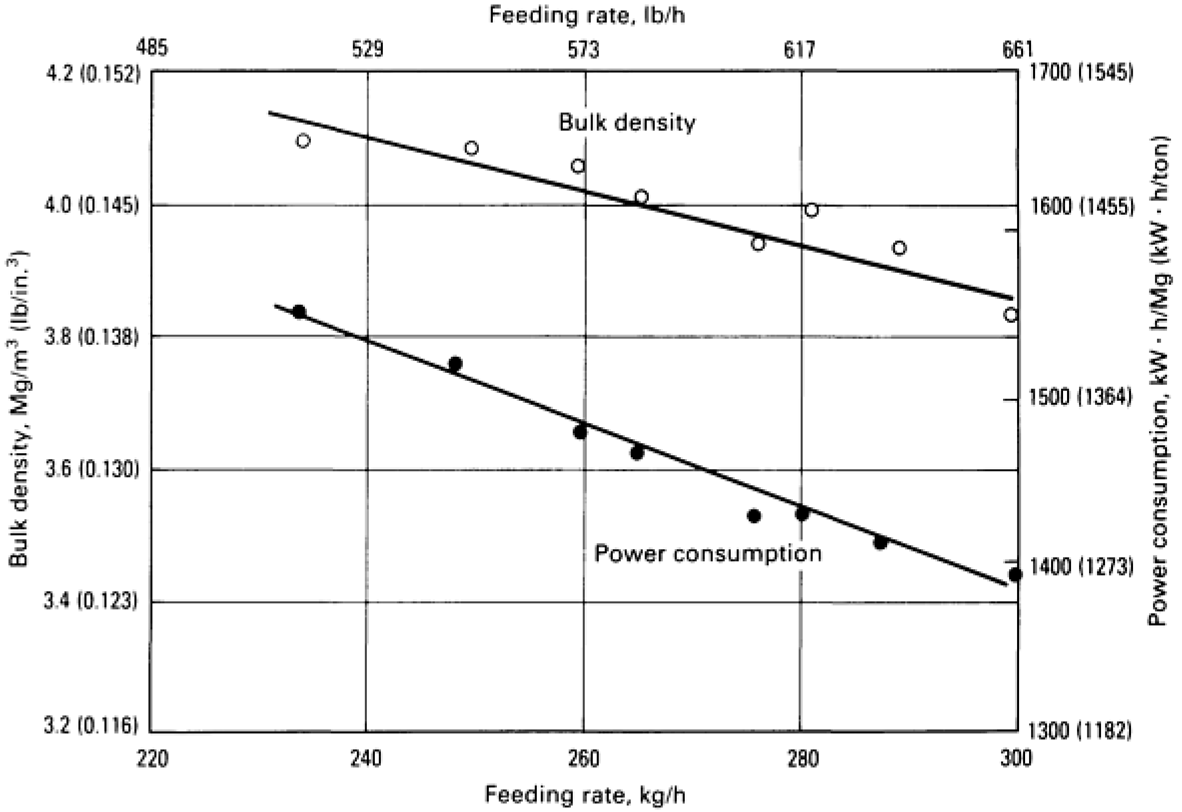

Fig. 45 Relationship among raw material feeding rate, ingot bulk density, and specific power consumption in the plasma consolidation of titanium. Source: Ref 56.

With plasma consolidation, metal chlorides can be removed from titanium sponge to sufficiently low levels. Tungsten carbide tool tips in titanium chips cannot be removed and eventually form high-density inclusions in the product. Therefore, the conventional x-ray inspection of scrap is still necessary. Low-density inclusions such as titanium nitride particles have not been found after plasma consolidation of contaminated titanium scrap and subsequent VAR remelting (Ref 57). Plasma consolidation has also been successfully applied to the processing of titanium aluminide (TiAl), a low-density alloy with excellent high-temperature service properties (Ref 57).

Plasma Arc Remelting. An electrode that has already been melted by a primary melting process such as electric arc or induction melting can be plasma arc remelted into a water-cooled withdrawal crucible. The major objectives for plasma arc remelting are:

- To obtain directional solidification without changing the chemical composition of the feed material
- To improve cleanliness by removal, size reduction, shape control, and redistribution of inclusions
- To lower gas impurity content
- To alloy with nitrogen

Plasma arc remelting is used most frequently in the Soviet Union to produce high-temperature alloys, bearing steels, superalloys, and titanium alloys. Plasma arc remelting can be advantageous for the nitrogen alloying, deoxidation, or desulfurization of nonreactive alloys. An example of successful reactive melting is the nitrogen alloying of steel during plasma arc remelting with argon-nitrogen mixtures as the plasma gas (Ref 58). Figure 46 shows nitrogen concentrations in various metals as a function of nitrogen partial pressure in the gaseous phase after plasma arc remelting. The data indicate that excited molecules of nitrogen in the plasma react with the metal (Ref 58).

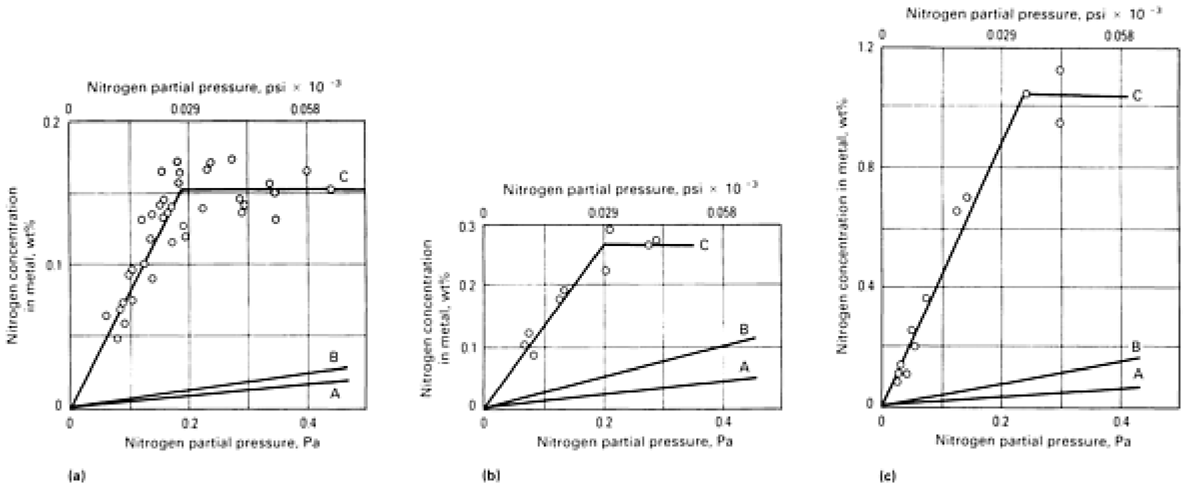

Fig. 46 Nitrogen concentrations in various metals as a function of the partial pressure of nitrogen after plasma arc remelting. (a) Iron. (b) 16-25-6 stainless steel. (c) Austenitic stainless steel. Curves A and B, induction heating; minimum and maximum nitrogen concentrations, respectively. Curve C, plasma arc remelting. Source: Ref 58.

In plasma cold hearth melting, bars, sponge, or scrap can be continuously fed into a water-cooled copper trough, usually called a hearth, and melted by means of plasma heat. The liquid metal flows over the lip of the hearth into a withdrawal mold. The plasma cold hearth melting process is adapted from the electron beam cold hearth refining process, which is a well-developed refining and casting method for superalloys. Plasma heat, instead of an electron beam, is employed to minimize selective evaporative losses that occur during electron-beam melting in the pressure range of 0.01 to 1 Pa (10^{-4} to 0.01 mbar, or 7.5×10^{-5} to 0.0075 torr).

In the hearth, high-density inclusions from tungsten carbide tool tips will sink down to the skull. Low-density inclusions can be dissociated or dissolved in the base metal during interaction with the superheated melt and the plasma jet.

Process optimization is necessary to prevent short circuiting of the hearth by unmelted particles and to establish sufficient dwell time at high melting rates. The power distribution of one or more plasma torches required for smooth melting and fluid flow can be ensured by automated torch-moving devices.

Figure 47 shows a pilot plasma cold hearth furnace (Fig. 47a) and the only industrial-scale plasma cold hearth melting furnace currently in operation (Fig. 47b). The plasma heat source of the industrial furnace is unconventional in that there is no mechanism provided for torch movement. The torches, called plasma electron beam guns, use hollow tantalum cathodes and operate at pressures of 1 to 10 Pa (0.01 to 0.1 mbar, or 0.0075 to 0.075 torr). The unusually high specific power consumption of this furnace reflects the relatively low efficiency of the heat source used.

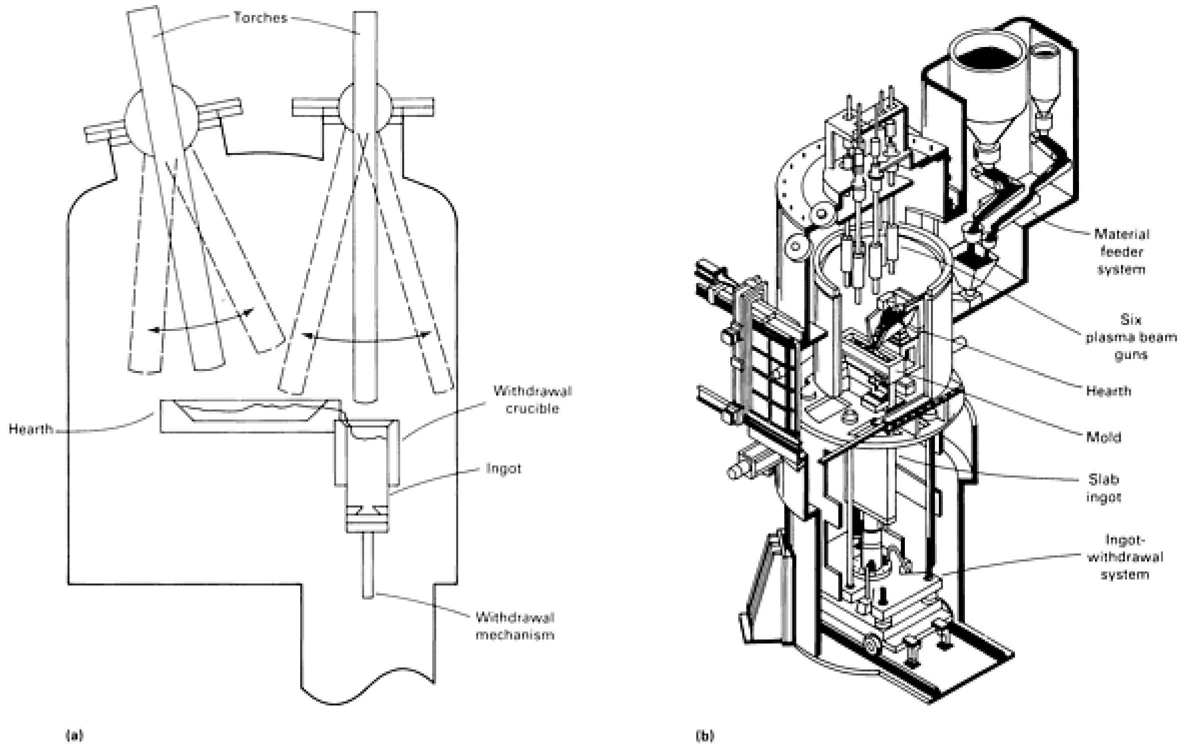

Fig. 47 Two plasma cold hearth melting furnaces. (a) Pilot-scale furnace with two tiltable plasma torches. Total power: 400 kW. (b) ULVAC plasma beam furnace with six fixed plasma beam guns. Total power: 2000 kW. Source: Ref 57.

Figure 48 shows a modern plasma cold hearth melting furnace concept with a double-wall, water-cooled, vacuum-tight furnace chamber and three plasma torches for the production of ingots 710 mm (28 in.) in diameter. Two torches serve the hearth, and the third the ingot mold. The torches use hollow water-cooled copper electrodes. The high gas consumption of this torch design means that an effective gas recycling system must be provided, especially if helium is used as the plasma gas.

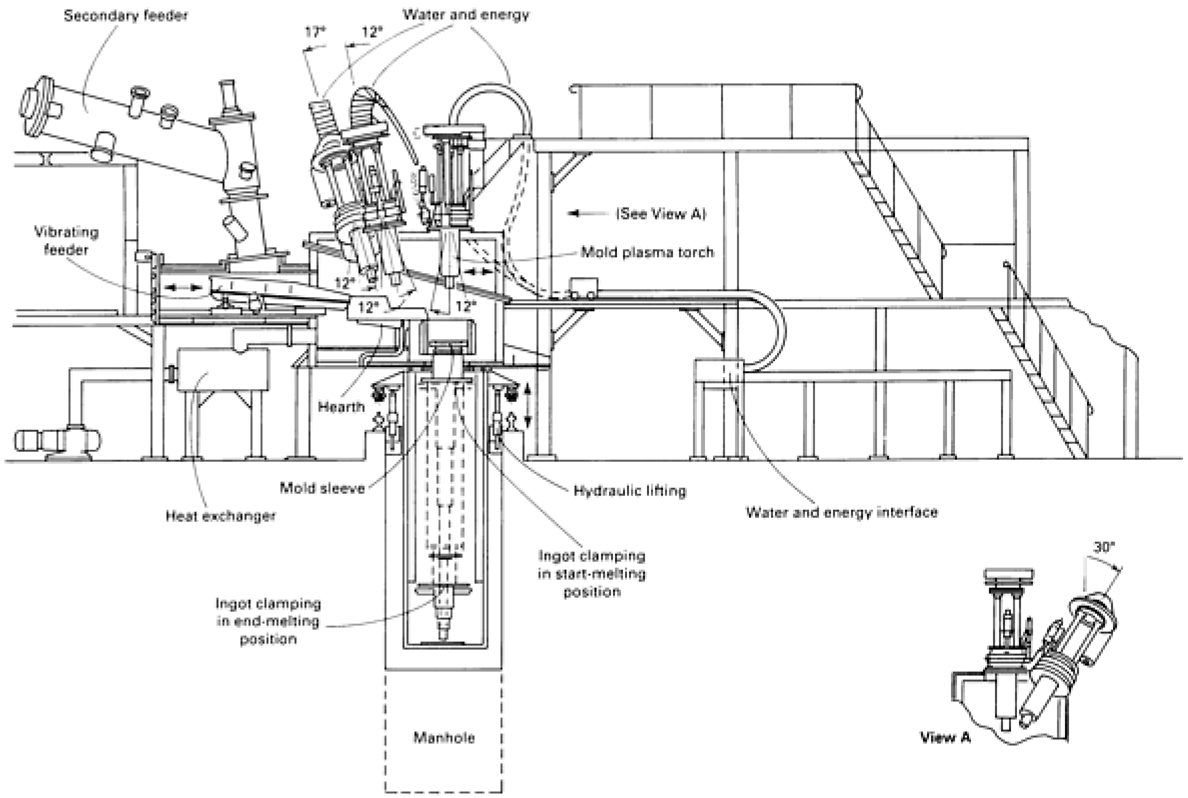

Fig. 48 Plasma cold hearth melting concept for the recycling of titanium scrap.

The operating principle of a gas-recycling system is shown in Fig. 49. Key technology in this system includes reactive filters, oil-free high-capacity pump sets, and compressors. If necessary, the recycling system can be supplemented with cleaning systems for oxygen, carbon dioxide, nitrogen, hydrogen, and moisture.

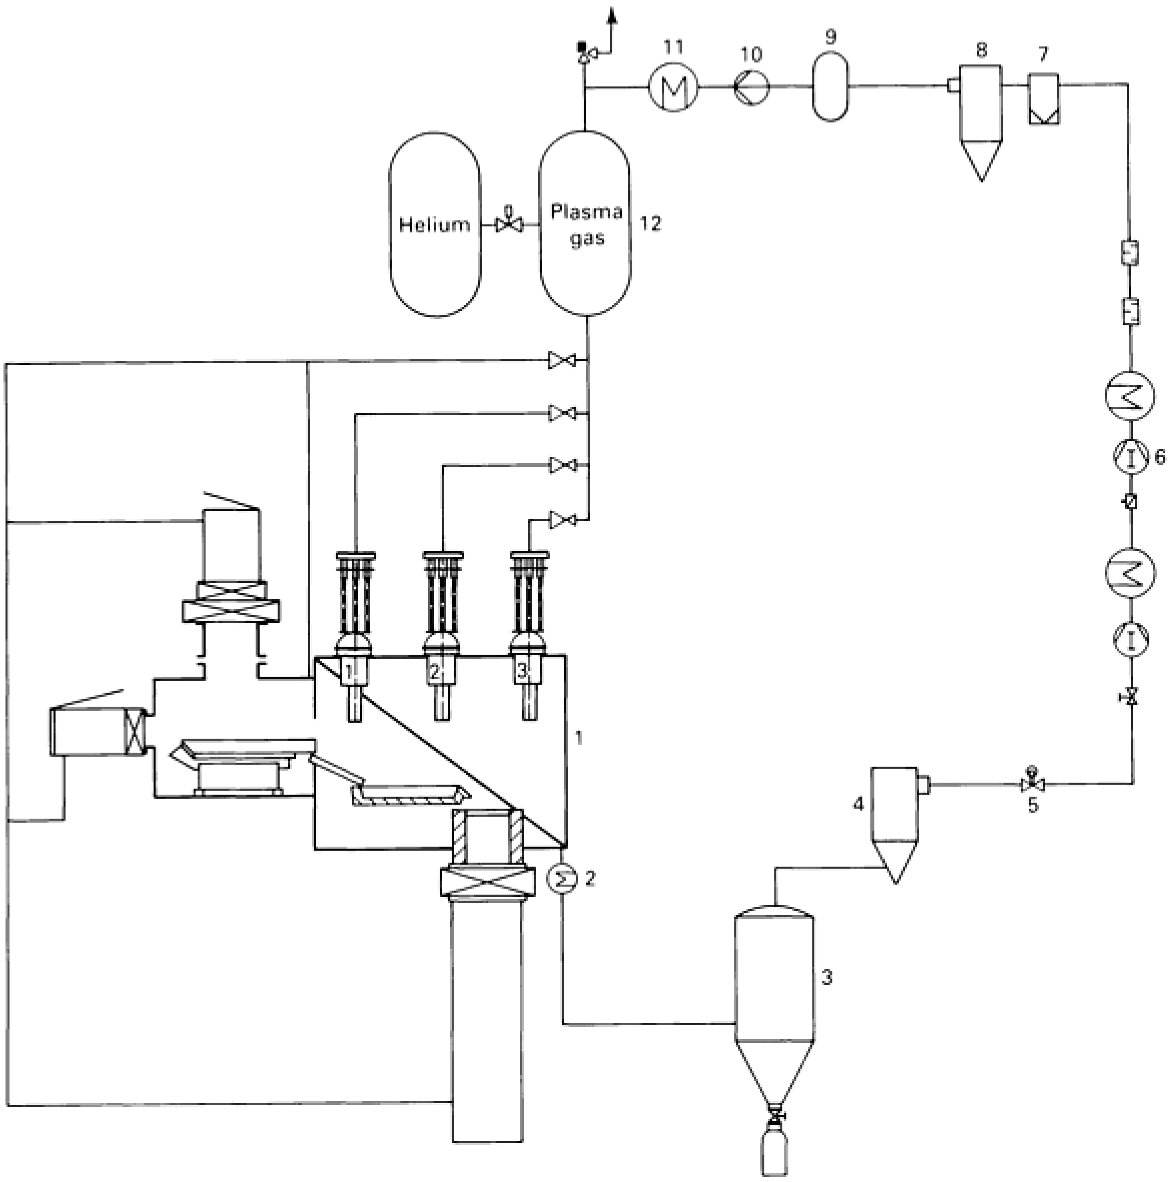

Fig. 49 Schematic of plasma gas-recycling system. 1, plasma furnace; 2, off-gas heat exchanger; 3, cyclone separator; 4, mechanical filter; 5, motor-actuated valve; 6, vacuum pump set; 7, chemical filter; 8, fine filter; 9, buffer; 10, compressor; 11, heat exchanger; 12, gas storage tank.

Plasma cold crucible casting is an alternative process to vacuum arc skull melting and casting or electron beam skull melting and casting, and it can overcome some of the disadvantages of these processes. The disadvantages of vacuum arc skull melting in the melting and casting of titanium and superalloys are:

- Control of superheating is not possible; increased power results in increased melting rate instead of superheating
- Expensive electrodes must be used instead of the high-quality unconsolidated revert material that can be used for plasma cold crucible casting

For small batches of superalloys (up to 8 kg, or 18 lb), electron beam skull casting is a well-established technique. Electron beam melting and casting is rarely used for large castings of either superalloys or titanium alloys. This is because of the shallow melt pool in the crucible due to lack of stirring action and the potential for selective evaporation of alloying elements during melting.

Figure 50 shows a sectional view of an industrial-size plasma cold crucible casting furnace. The furnace consists of a cylindrical, horizontally installed mold chamber with lockchambers at both sides and the melt chamber on top of the mold chamber. A programmable torch-moving device is installed on top of the melt chamber.The pressure in the furnace during the melting operation can be preselected; pressures typically range from 30 to 50 kPa (300 to 500 mbar, or 225 to 375 torr). The melting operation can be started at every pressure in this range. Solid material can be charged continuously into the water-cooled copper crucible, and additional material can be fed into the crucible during melting. The melt is poured into stationary molds or centrifugal casting molds situated in the mold chamber. The pouring stream can be superheated during casting.

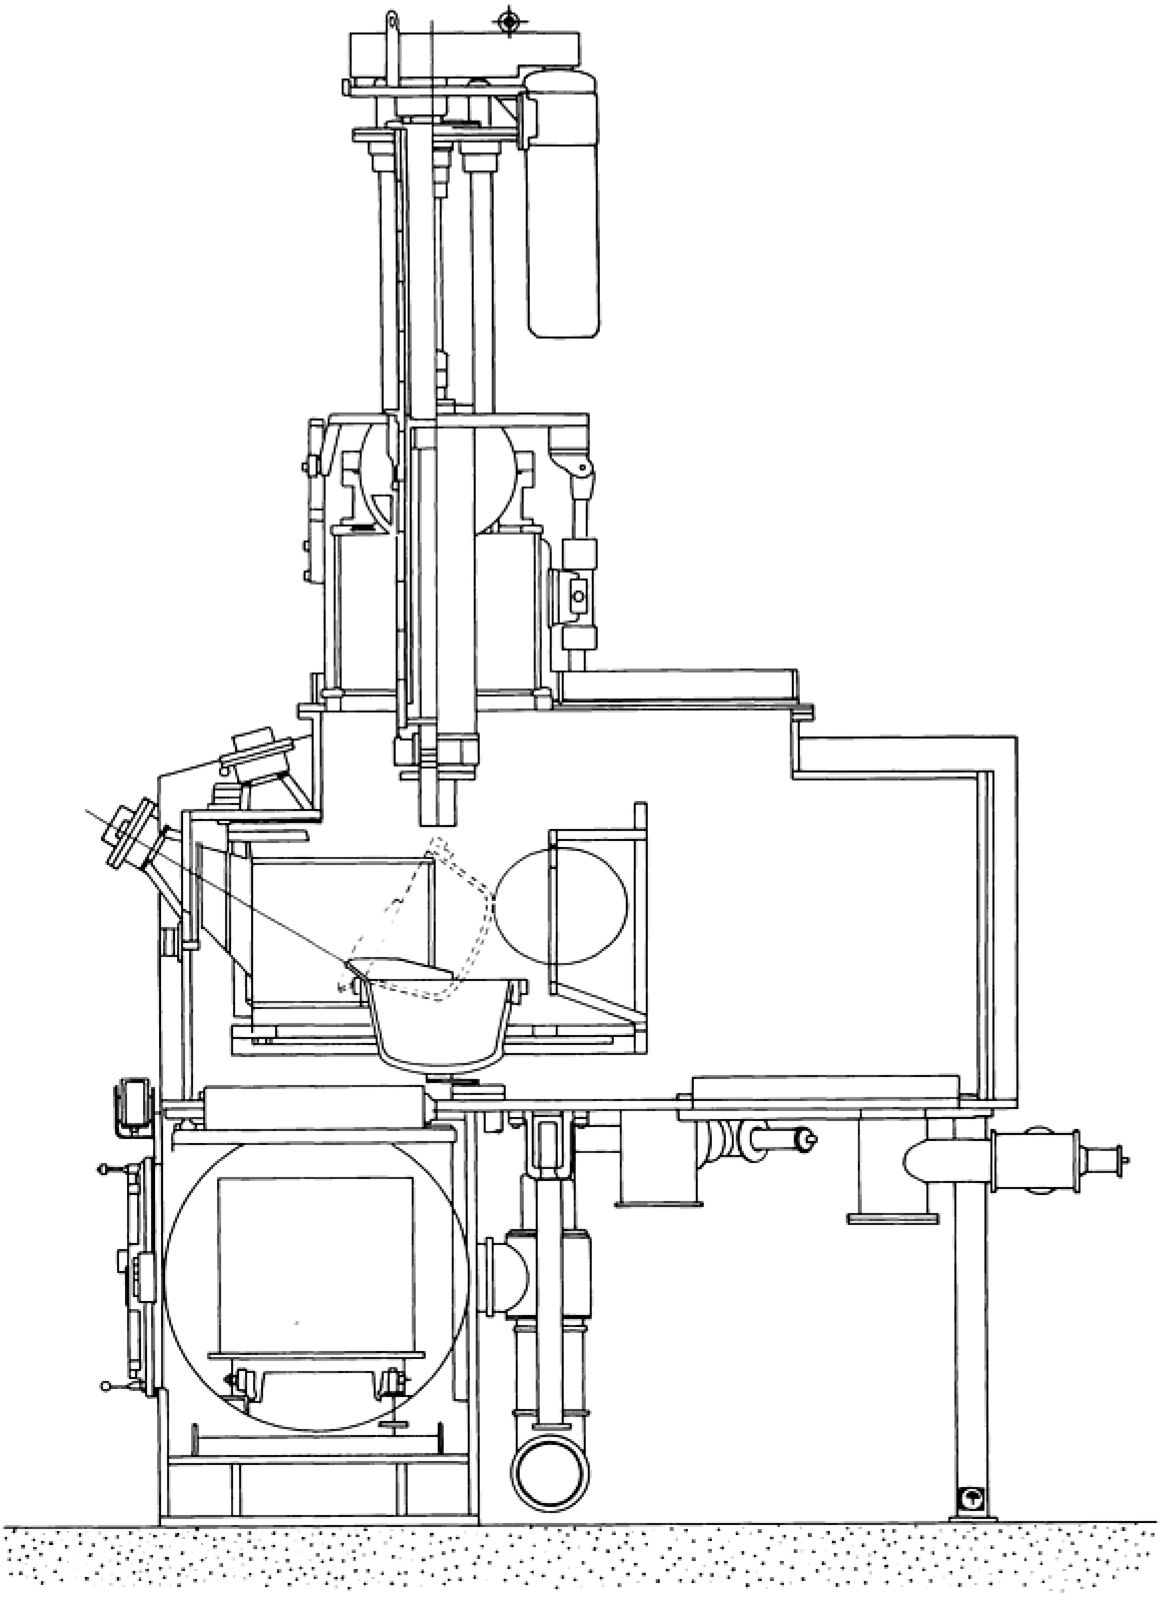

Fig. 50 Industrial-size plasma cold crucible casting furnace with 650 kW torch power.

The typical casting weight of this furnace is 27 kg (60 lb) of titanium with a 650 kW plasma torch. To achieve a deep molten pool, a high heat flow from the plasma torch to the melt must be established in combination with high stirring velocity in the melt to enhance the effective heat transfer coefficient. The stirring action in the melt can be regulated by controlling current, gas flow, and torch-to-melt distance. Continuous feeding of the metal to be melted is required in order to achieve a deep pool.

In contrast to vacuum arc skull melting, the crucible need not be inspected after each melt. The power densities in the plasma attachment area are adjusted to avoid damaging the crucible if it is inadvertently exposed to the plasma for short periods of time.

Degassing Processes (Converter Metallurgy)

Chairman: Gerhard Kienel, Leybold AG, West Germany

Introduction

CONVERTERS are used in secondary metallurgy to refine melts outside the primary metallurgical melting unit. Various converters are available that apply the bottom blowing of oxygen-inert gas mixtures. These bottom-blowing converters use different types, numbers, and arrangements of injection nozzles and the following gases:

- Argon as a cooling inert gas with a purity ranging from 85 to 99.99%
- Nitrogen as a cooling inert gas with a purity of 99 to 99.9%
- Argon-oxygen and nitrogen-oxygen mixtures in the case of the argon oxygen decarburization converter
- Dry air as a diluted reactive gas
- Oxygen as a reactive gas with a purity of 80 to 99.5%
- Steam as a cooling reactive gas
- Carbon dioxide as a diluted reactive gas

This article will review three converter designs. These are the argon oxygen decarburization vessel; the oxygen top and bottom blowing converter, which is an extension of argon oxygen decarburization technology; and the vacuum oxygen decarburization converter. Additional information on degassing processes can be found in the article "Degassing Processes (Ladle Metallurgy)" in this Volume.

Argon Oxygen Decarburization (AOD)

Ian F. Masterson, Union Carbide Corporation--Linde Division

Argon oxygen decarburization (AOD) is a secondary refining process that was originally developed to reduce material and operating costs and to increase the productivity of stainless steel production. In addition to its economic merits, argon oxygen decarburization offers improved metal cleanliness, which is measured by low unwanted residual element contents and gas contents; this ensures superior mechanical properties. The AOD process is duplexed, with molten metal supplied from a separate melting source to the AOD refining unit (vessel). The source of the molten metal is usually an electric arc furnace or a coreless induction furnace. Foundries and integrated steel mills utilize vessels ranging in nominal capacity from 1 to 160 Mg (1 to 175 tons).

Although the process was initially targeted for stainless steel production, argon oxygen decarburization is used in refining a wide range of alloys, including:

- Stainless steels
- Tool steels
- Silicon (electrical) steels
- Carbon steels, low-alloy steels, and high-strength low-alloy steels
- High-temperature alloys and superalloys

Fundamentals

In the AOD process, oxygen, argon, and nitrogen are injected into a molten metal bath through submerged, side-mounted tuyeres. The primary aspect of the AOD process is the shift in the decarburization thermodynamics that is afforded by blowing with mixtures of oxygen and inert gas as opposed to pure oxygen. References 1, 2, and 3 contain detailed discussions of the thermodynamics and the dilution principle and its influence on the refining of chromium-bearing steel.

To understand the AOD process, it is necessary to examine the thermodynamics governing the reactions that occur in the refining of stainless steel, that is, the relationship among carbon, chromium, chromium oxide (Cr_3O_4), and carbon monoxide (CO). The overall reaction in the decarburization of chromium-containing steel can be written as:

$$\frac{1}{4} Cr_3O_4 + \underline{C} \;\; \boldsymbol{f} \;\; \frac{3}{4} \underline{Cr} + CO(g) \qquad \textbf{(Eq 1)}$$

The equilibrium constant, *K,* is given by:

$$K = \frac{(a_{cr})^{3/4}(P_{CO})}{(a_{Cr_3O_4})^{1/4}(a_c)} \qquad \textbf{(Eq 2)}$$

where *a* and *P* represent the activity and partial pressure, respectively.

At a given temperature, there is a fixed, limited amount of chromium that can exist in the molten bath that is in equilibrium with carbon. By examining Eq 2, one can see that by reducing the partial pressure of CO, the quantity of chromium that can exist in the molten bath in equilibrium with carbon increases. The partial pressure of CO can be reduced by injecting mixtures of oxygen and inert gas during the decarburization of stainless steel. Figure 1 illustrates the relationship among carbon, chromium, and temperature for a partial pressure of CO equal to 1 and 0.10 atm (1000 and 100 mbar, or 760 and 76 torr). The data shown in Fig. 1 indicate that diluting the partial pressure of CO allows lower carbon levels to be obtained at higher chromium contents with lower temperatures.

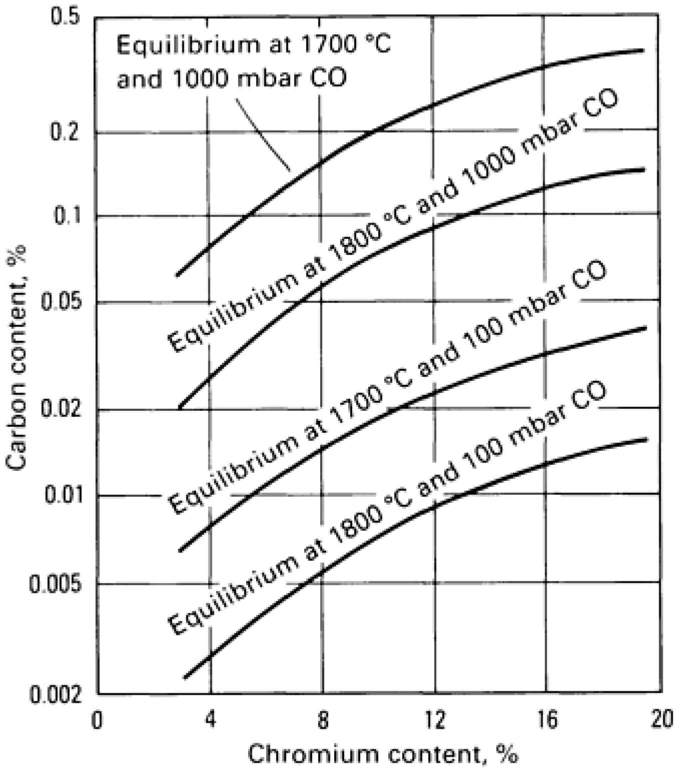

Fig. 1 Carbon-chromium equilibrium curves

In refining stainless steel, it is generally necessary to decarburize the molten bath to less than 0.05% C. Chromium is quite susceptible to oxidation; therefore, prior to the introduction of the AOD process, decarburization was accomplished by withholding most of the chromium until the bath had been decarburized by oxygen lancing. After the bath was fully decarburized, low-carbon ferrochromium and other low-carbon ferroalloys were added to the melt to meet chemical specifications.

Dilution of the partial pressure of CO allows the removal of carbon to low levels without excessive chromium oxidation. This practice enables the use of high-carbon ferroalloys in the charge mix, avoiding the substantially more expensive low-carbon ferroalloys. Figure 2 compares the refining steps in the two processes.

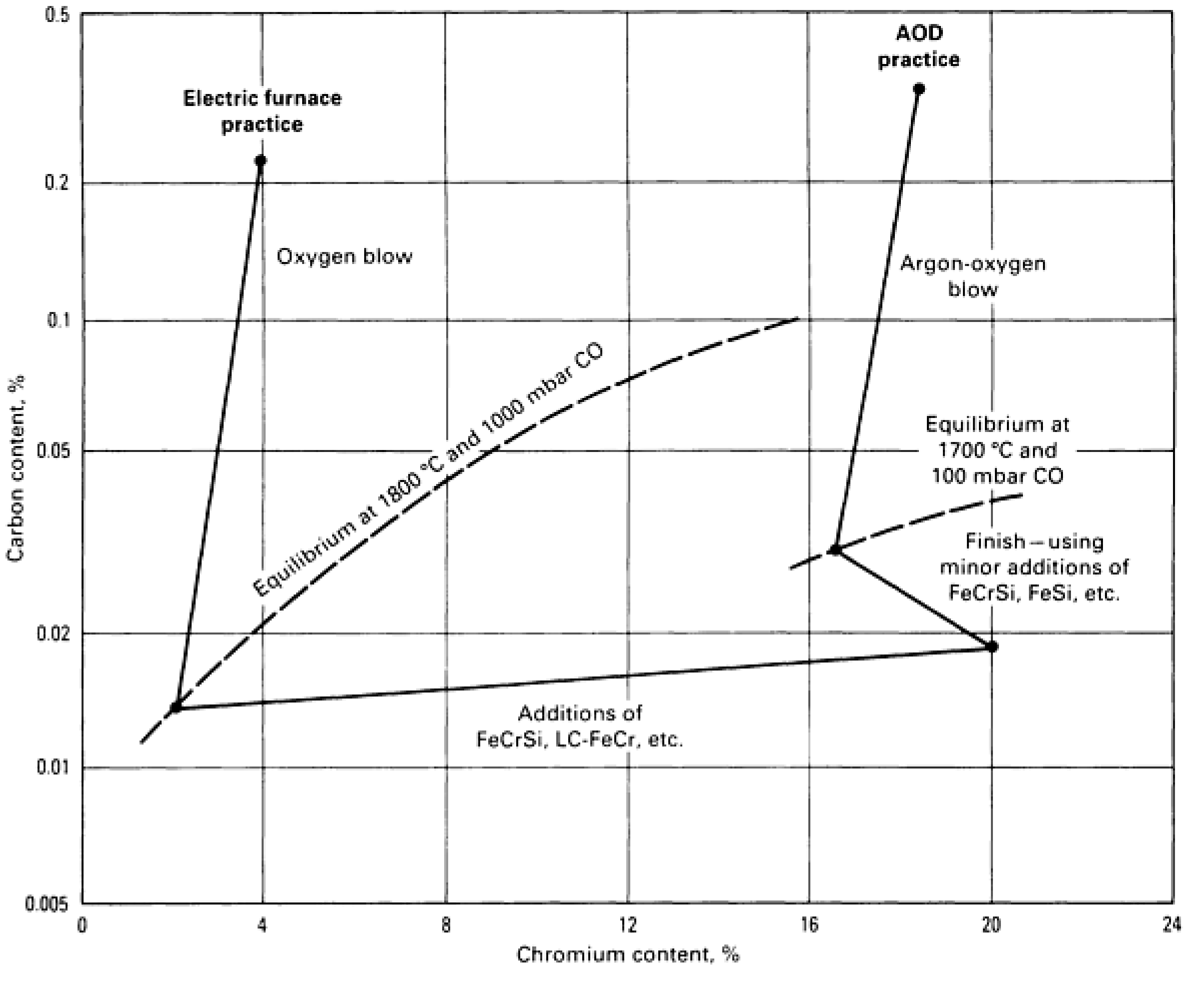

Fig. 2 Composition changes in refining type 304-L stainless steel using electric arc furnace practice and argon oxygen decarburization

Equally important, however, are the processing advantages offered by submerged blowing. These include excellent slag/metal and gas/metal contact, superior decarburization kinetics, and 100% utilization of the injected oxygen by reaction with the bath. In addition, submerged injection allows the accurate control of end point nitrogen and the removal of dissolved gases (nitrogen and hydrogen) and nonmetallic inclusions.

Equipment

The processing vessel consists of a refractory-lined steel shell mounted on a tiltable trunnion ring (Fig. 3). With a removable, conical cover in place, the vessel outline is sometimes described as pear shaped. Several basic refractory types and various quality levels of the refractories have gained widespread acceptance (Ref 4, 5). Dolomite refractories are used in most AOD installations; magnesite chromium refractories are predominant in small (<9 Mg, or 10 ton) installations and are used almost exclusively in Japan.

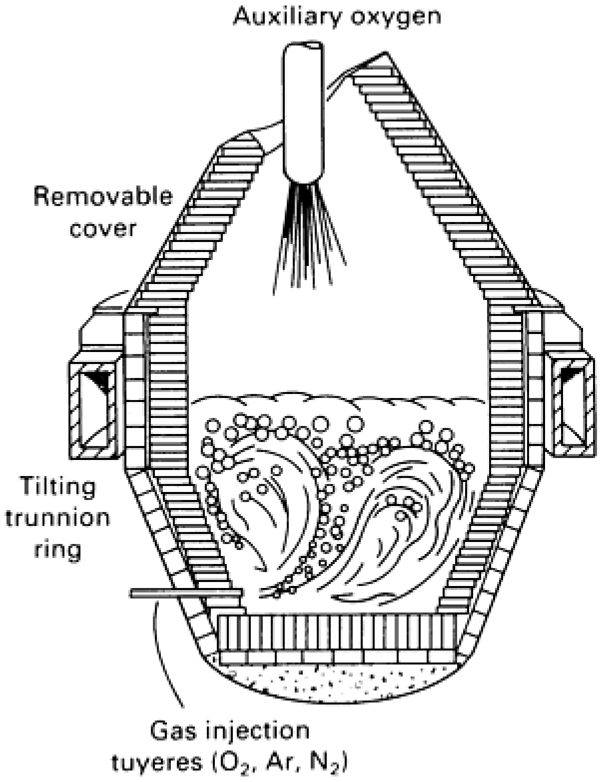

Fig. 3 Schematic of argon oxygen decarburization vessel

As seen in Fig. 3, process gases are injected through submerged, side-mounted tuyeres. The number and relative positioning of tuyeres are determined in part by vessel size, range of heat sizes, process gas flow rates, and the types of alloys refined. Process gases are oxygen, nitrogen, argon, and in some cases carbon dioxide (CO_2). The most recent AOD installations include the use of top-blown oxygen (one-third of all AOD installations have this capability). Oxygen top- and bottom-blowing converters are described in the discussion "Oxygen Top and Bottom Blowing" in this section.

The specific volume of AOD vessels ranges from 0.4 to 0.8 m^3/Mg (16 to 32 ft^3/ton). The gas control system supplies the process gases at nominal rates of 0.5 to 3 m^3/min/Mg (15,000 to 6000 ft^3/h/ton). The system accurately controls the flow rates and monitors the amount of gas injected into the bath to enable the operator to control the process and keep track of the total oxygen injected.

Normally, a shop has three interchangeable vessels. At any given time, one of the vessels is in a tiltable trunnion ring refining steel, a second vessel is at a preheating station, and the third vessel is being relined. The vessel in the trunnion ring can be replaced with a preheated vessel in less than 1 h.

The control of process gases, vessel activities, and ancillary equipment can range from manual to fully automated. Most installations are equipped with a computer to assist in process control by calculating the required amount of oxygen as well as alloying additions. Some installations have computer control systems capable of sending set points and flow rates to the gas control systems.

Processing

Stainless Steels. Charge materials (scrap and ferroalloys) are melted in the melting furnace. The charge is usually melted with the chromium, nickel, and manganese concentrations at midrange specifications. The carbon content at meltdown can vary from 0.50 to 3.0%, depending on the scrap content of the charge. Once the charge is melted down, the heat is tapped, and the slag is removed and weighed prior to charging the AOD vessel.

In the refining of stainless steel grades, oxygen and inert gas are injected into the bath in a stepwise manner. The ratio of oxygen to inert gas injected decreases (3:1, 1:1, 1:3) as the carbon level decreases. Once the aim carbon level is obtained, a reduction mix (silicon, aluminum, and lime) is added. If extra-low sulfur levels are desired, a second desulfurization can be added. Both of these steps are followed by an argon stir. After reduction, a complete chemistry sample is usually taken and trim additions made following analysis. Figure 4 illustrates the relationships among carbon, chromium, temperature, and the various processing steps for refining a typical type 304 stainless steel using argon oxygen decarburization.

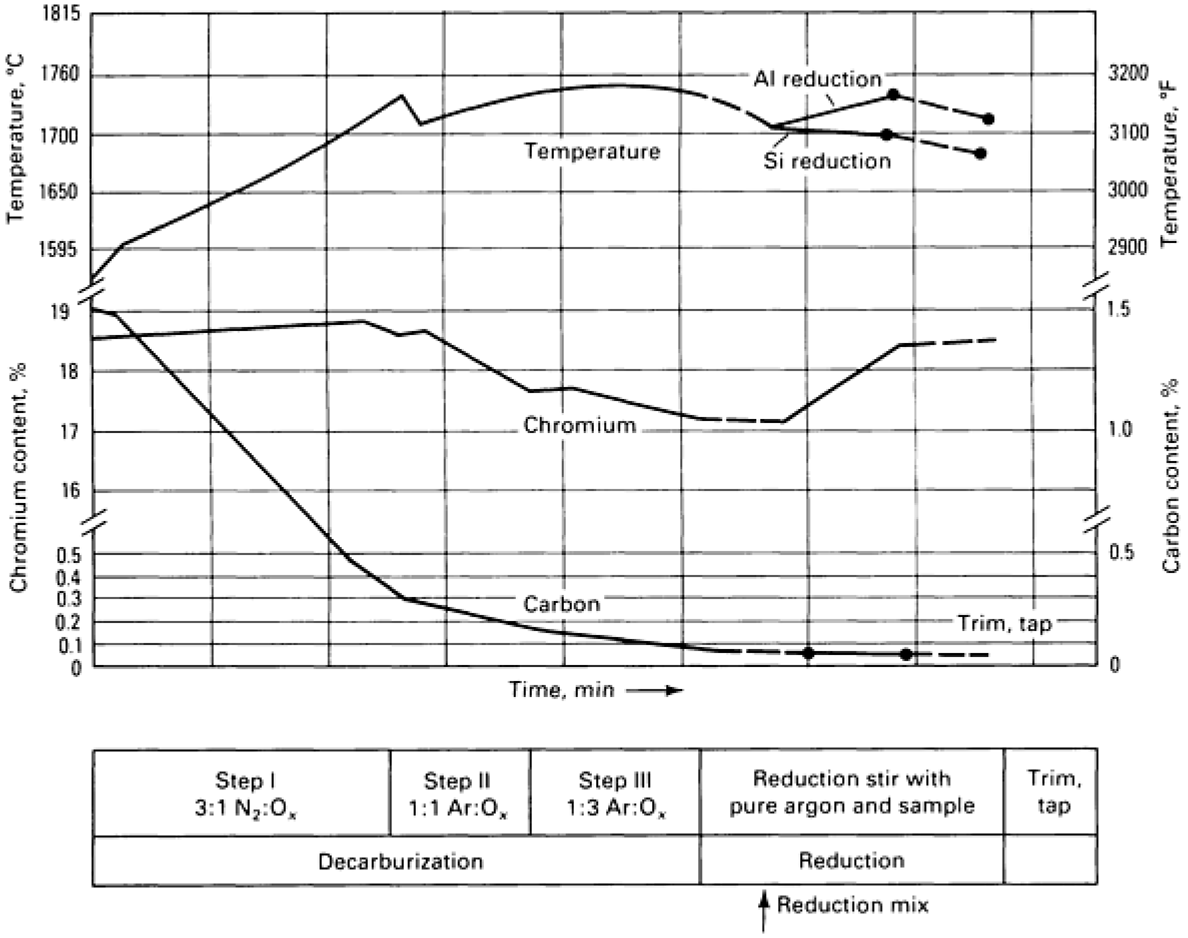

Fig. 4 Schematic of stainless steel refining cycle for small (<27 Mg, or 30 ton) vessels showing the relationship

between carbon and chromium contents as a function of time and temperature

Another critical aspect of AOD refining is the ability to predict when to change from nitrogen to argon to obtain the aim nitrogen specification. Table 1 lists the process parameters, carbon removal efficiencies, and carbon removal rates for the AOD refining of type 304 stainless steel. The point during refining when the oxygen-to-inert-gas ratio is lowered is based on carbon content and temperature. The ratios and carbon switch points are designed to provide optimum carbon removal efficiency without exceeding a bath temperature of 1730 °C (3150 °F).

Table 1 Processing parameters for AOD refining of type 304 stainless steel

Total gas flow rate: ~1.5 m^3/min/ton (3500 ft^3/h/ton)

Carbon level, %	Gas ratios			Partial pressures, atm			CRE[a], %	CRR[b], ppm/min	Temperature	
	O_2	N_2	Ar	Ar	N_2	CO			°C	°F
3.0-0.7	4	1	. . .	. . .	0.14	0.86	80	1200	1510	**2750**
1-0.25	3	1	. . .	. . .	0.20	0.80	65	830	1700	**3100**
0.25-0.12	1	1	. . .	. . .	0.53	0.47	45	430	1700	**3100**
0.12-0.04	1	. . .	3	0.83	. . .	0.17	30	133	1730	**3150**

(a) CRE, carbon removal efficiency.

(b) CRR, carbon removal rate

Carbon and Low-Alloy Steels. The refining of carbon and low-alloy steels involves a two-step practice: a carbon removal step, followed by a reduction/heating step. The lower alloy content of these steels eliminates the need for injecting less than a 3:1 ratio of oxygen to inert gas. Once the aim carbon level is obtained, carbon steels are processed similarly to stainless steels. Figure 5 illustrates carbon content and temperature relationship for the AOD refining of carbon and low-alloy steels. Because the alloy content of these grades of steel is substantially lower than that of stainless steel and because the final carbon levels are generally higher, there is no thermodynamic or practical reason for using an oxygen, inert-gas ratio of less than 3:1.

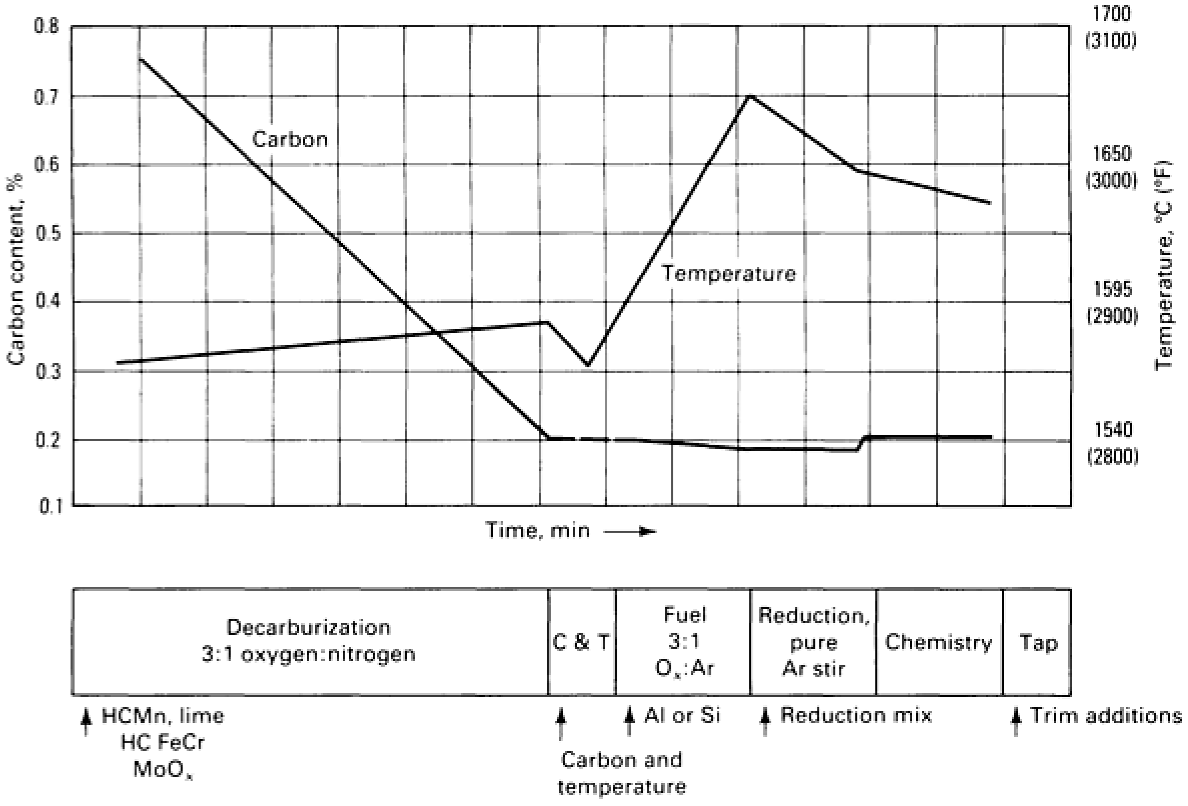

Fig. 5 Schematic of carbon and low-alloy steel argon oxygen decarburization refining

Oxidation measurements indicate that all of the oxygen reacts with the bath and that none leaves the vessel unreacted. By monitoring and recording the oxygen consumption during refining, very close control of end point carbon is achieved. Because the oxygen and inert gases are introduced below the bath and at sonic velocities, there is excellent bath mixing and intimate slag/metal contact. As a result, the reaction kinetics of all chemical processes that take place within the vessel are greatly improved.

Decarburization. In both stainless and low-alloy steels, the dilution of oxygen with inert gas results in increased carbon removal efficiencies without excessive metallic oxidation. In stainless grades, carbon levels of 0.01% are readily obtained.

Chemistry Control. The excellent compositional control of AOD-refined steel is indicated in Table 2 for a ten-heat series of high-strength low-alloy steel. The injection of a known quantity of oxygen with a predetermined bath weight enables the steelmaker to obtain very tight chemical specifications.

Table 2 Composition control of AOD-refined high-strength low-alloy steel

Element	Aim	Mean	Standard deviation
Carbon	0.27	0.264	0.006
Manganese	0.80	0.83	0.03
Silicon	0.50	0.49	0.04

Phosphorus	. . .	0.019	0.002
Sulfur	. . .	0.002	0.001
Molybdenum	0.28	0.28	0.01
Chromium	0.50	0.56	0.07
Nickel	. . .	0.13	0.03
Aluminum	0.05	0.043	0.009

Desulfurization. Sulfur levels of 0.01% or less are routinely achieved, and levels less than 0.005% can be achieved with single slag practice. When extra-low sulfur levels are required, a separate slag treatment for 3 min is sufficient.

Slag Reduction. During oxygen injection for carbon removal, there is some metallic oxidation. Efficient slag reduction with stoichiometric amounts of silicon or aluminum permits overall recoveries of 97 to 100% for most metallic elements. Chromium recovery averages approximately 97.5%, and the recovery of nickel and molybdenum are approximately 100%.

Nitrogen Control. Degassing in argon oxygen decarburization is achieved by inert gas sparging. Each argon and CO bubble leaving the bath removes a small amount of dissolved nitrogen and hydrogen. Final nitrogen content can be accurately controlled by substituting nitrogen for argon during refining. Nitrogen levels as low as 25 to 30 ppm can be obtained in carbon and low-alloy steels, and 100 to 150 ppm N can be obtained in stainless steels. The ability to obtain aim nitrogen levels substantially reduces the need to use nitrided ferroalloys for alloy specification, and this also minimizes the use of argon. Hydrogen levels as low as 1.5 ppm can be obtained.

Property Improvements. It has been well documented that AOD-refined steels exhibit significantly improved ductility and toughness, along with impact energy increases of over 50% (Ref 6, 7, 8). These improved properties result from a decrease in the number and size of inclusions. The capability to produce low gas content steel with exceptional microcleanliness, along with alloy savings, is the primary factor for the growth of the AOD process for refining stainless, carbon, and low-alloy steels.

Oxygen Top and Bottom Blowing

Oxygen top and bottom blowing (OTB), also referred to as combined blowing, is an extension of AOD technology for refining steel. During OTB, oxygen is injected into the molten steel through a top lance during carbon removal, and inert gases, such as argon, nitrogen, or carbon dioxide, are injected with oxygen through submerged tuyeres or alternate forms of gas injectors such as canned bricks, porous bricks, or thin pipes set in the refractory brick. The top-blown oxygen can react with the bath, reducing refining times, or with CO. The combustion of CO above the surface of the bath increases the thermal efficiency of the refining process and decreases the quantity of silicon and aluminum required for reduction of metallic oxides.

If the top-blown oxygen system is designed so that more than 65% of the oxygen reacts with the bath, the system is referred to as hard blown; if less than 65% of the oxygen reacts with the bath, it is referred to as soft blown. As a general guideline, a top-blown oxygen system installed in AOD vessels with a nominal capacity greater than 45 Mg (50 tons) will be hard blown, smaller vessels will be soft blown. In hard-blown top oxygen systems, the flow rate of oxygen through the top lance will be between 50 and 150% of the oxygen injected through tuyeres or injectors. In soft-blown systems, the top oxygen flow rate is between 50 and 100% of the oxygen flow through the tuyeres or injectors.

Because foundry AOD vessels have a nominal capacity less than 45 Mg (50 tons) the top-blown oxygen systems are designed to be soft blown. This design maximizes the thermal efficiency of the smaller AOD vessels, reducing the quantity of fuel and reduction material required during refining. Top-blown oxygen flow rates in foundry AOD vessels range from 50% of the bottom oxygen flow rate to 120%.

More detailed information on OTB technology can be found in Ref 9 and 10. Figures 8 and 9 in the following section "Vacuum Oxygen Decarburization (VODC)" compare OTB with various refining processes.

Vacuum Oxygen Decarburization (VODC)

Wilhelm Burgmann, Leybold AG, West Germany

Vacuum oxygen decarburization can be carried out in a converter vessel (VODC) or in the ladle (VOD). The parameters that favor the choice of ladles as reaction vessels include the following:

- Tapping, treatment, and teeming are done in the same reaction vessel. Thus, there are no temperature losses due to any final transfer of the melt, and the high level of cleanliness achieved during the treatment can be preserved up to teeming
- The use of electric power as an inexpensive energy source permits the highest flexibility in the melt shop. The ladle unit can act as a time buffer between the melting unit and the casting stand

Information on VOD ladle technology can be found in the article "Degassing Processes (Ladle Metallurgy)" in this Volume.

The primary reasons for selecting the converter as the VOD reaction vessel are as follows:

- Initial carbon contents are as high as possible, together with high oxygen blow rates
- Ease of deslagging and strong stirring action
- Shop restrictions such as a limited number of ladles, prohibited use of slide gates, and restricted crane capacity in the casting bay make converter technology more attractive

This section will review both the equipment and the processing parameters for vacuum oxygen decarburization, which is used for the production of low-alloy steels, stainless steels, and superalloys.

Equipment and Processing Parameters

Equipment. Vacuum oxygen decarburization converters are similar to argon oxygen decarburization (AOD) and oxygen top blown (OTB) converters in terms of design and the tilting device used. (AOD and OTB converters were discussed in the previous section "Argon Oxygen Decarburization (AOD)" in this article.) Bottom blowing is, however, restricted to the introduction of small amounts of inert gas through simple pipes, thus avoiding the special erosion-resistant refractory material used around tuyeres. Flue gas handling is easier and is incorporated into the vacuum system. In terms of vessel design, the conical converter top is closed by a vacuum hood with an oxygen lance feed through and vacuum addition lock (Fig. 6).

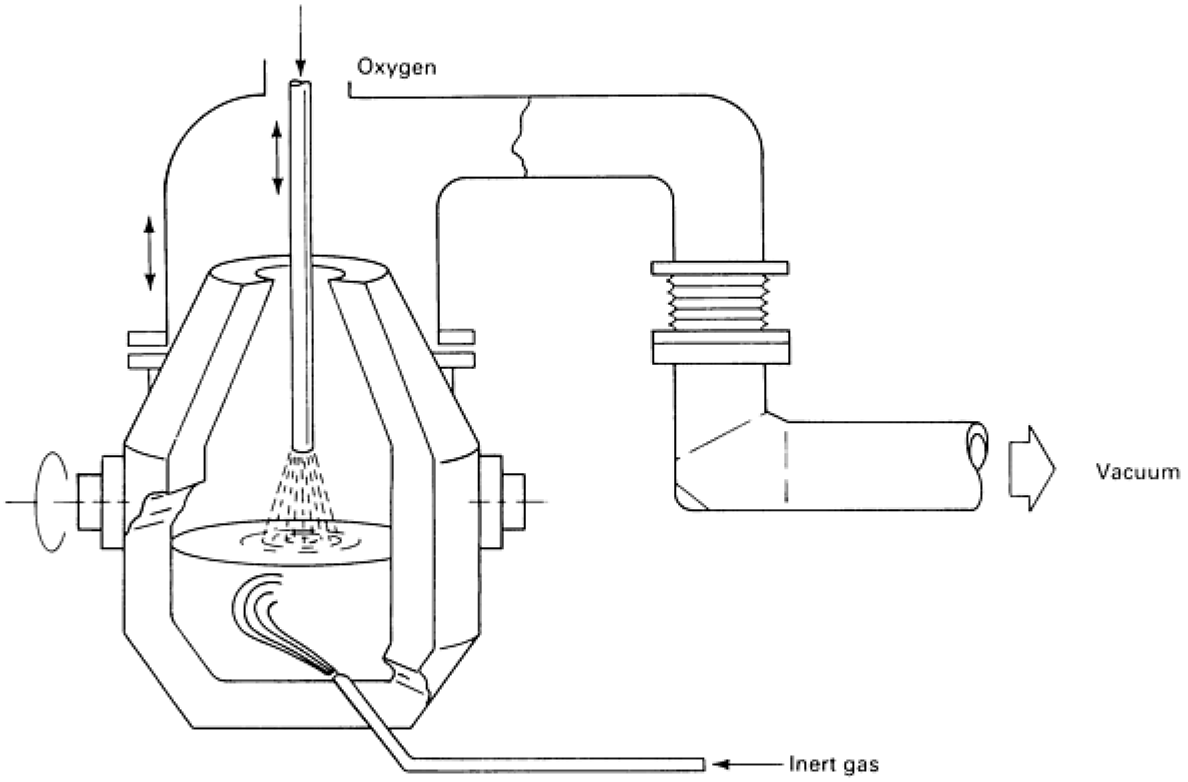

Fig. 6 Schematic layout of a vacuum oxygen decarburization converter

Because the VODC system is closed and no air enters the vessel, permanent control of the decarburization rate and the carbon level in the bath can be maintained and monitored with a flue gas analyzing device (Ref 11, 12). Pollution control for carbon monoxide (CO) and dust is also incorporated into the system.

Processing Parameters. Figures 7 and 8 show the relationship among CO partial pressure, gas blow rates, and carbon and chromium oxidation rates for the VODC, VOD, AOD, and OTB processes. As shown, low chromium losses and high carbon removal rates are possible using vacuum oxygen decarburization converters. The high carbon removal rates are due to the higher oxygen yield of the vacuum oxygen decarburization converter and the fact that oxygen dilution is not required. The amount of bottom blown inert gas is only about 2 to 5% of the oxygen volume.

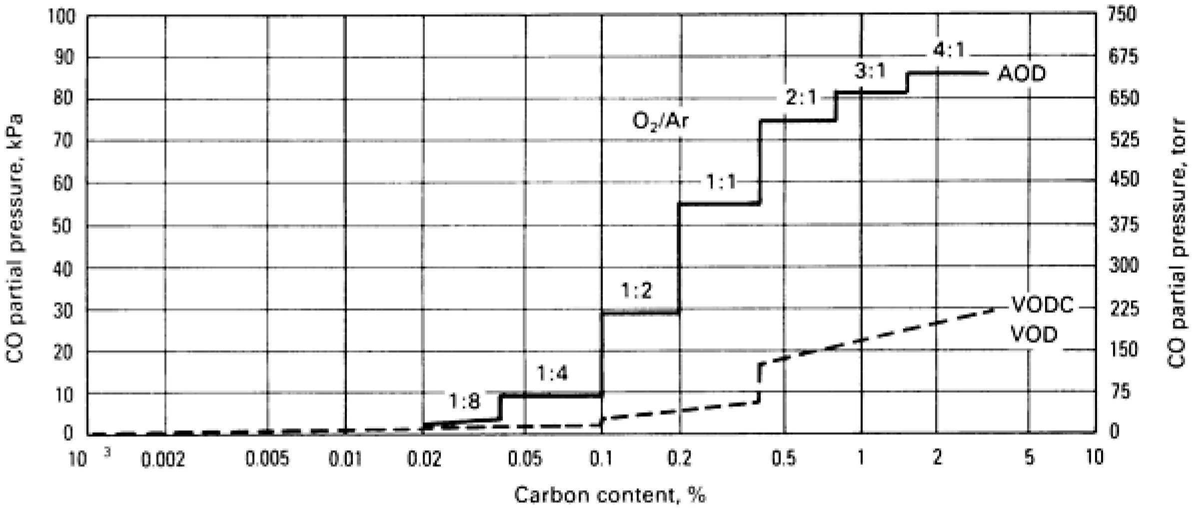

Fig. 7 Comparison of CO partial pressure for the AOD, VODC, and VOD processes

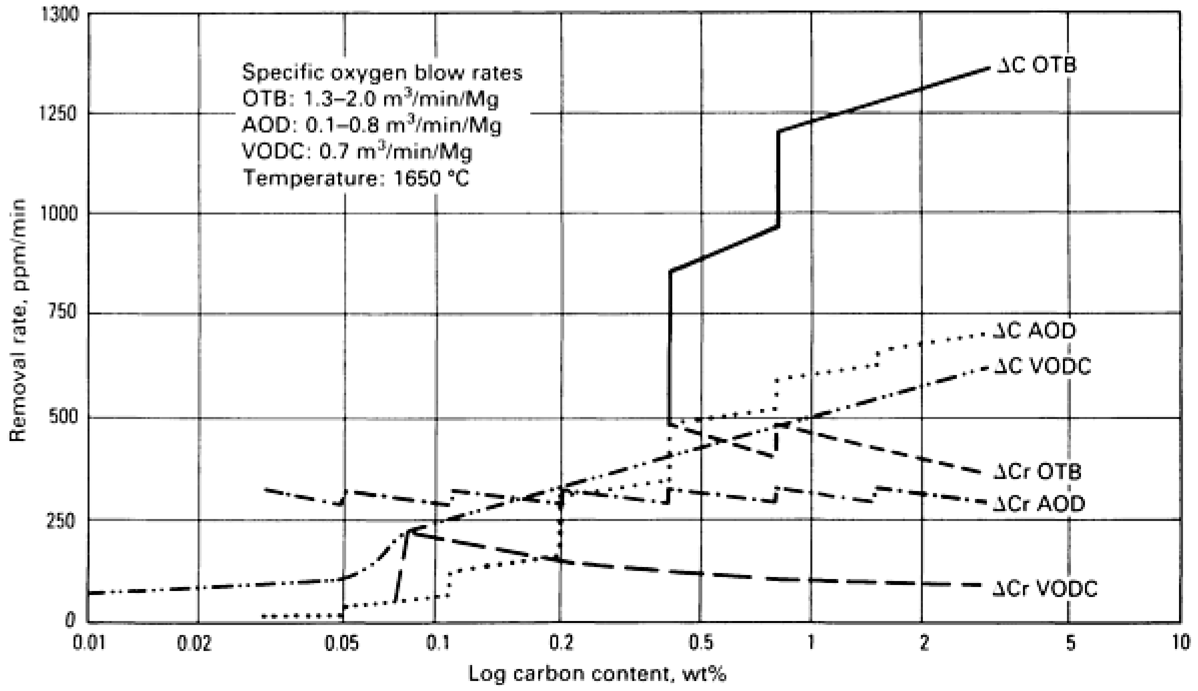

Fig. 8 Carbon removal rates and chromium oxidation rates for the VODC, OTB, and AOD processes

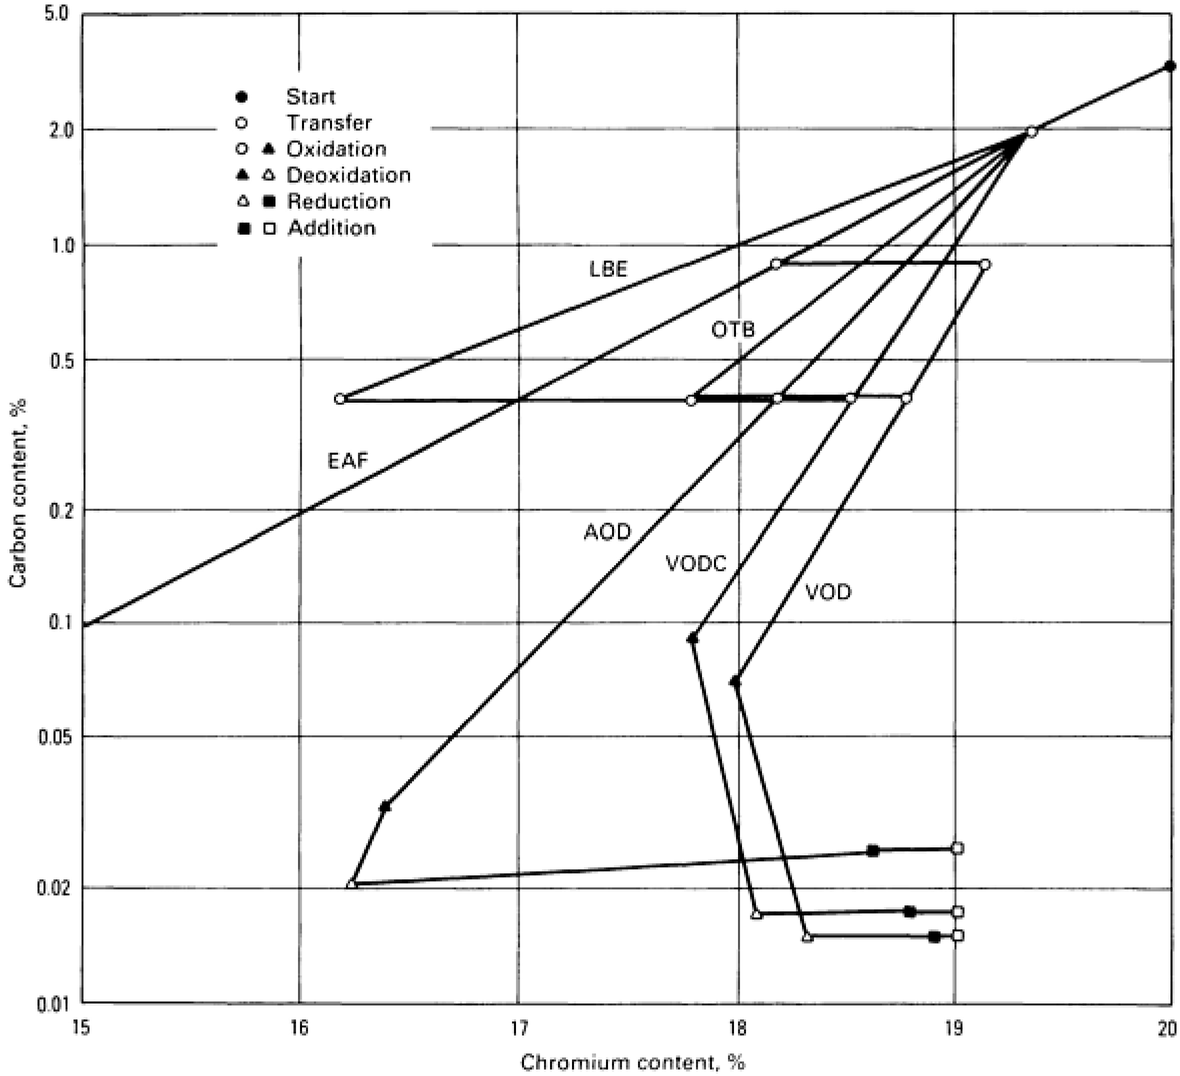
With a specific oxygen blow rate of 0.7 m^3/min/Mg (~25 ft^3/min/ton), the decarburization rate exceeds 600 ppm/min at high carbon levels (Fig. 8). In smaller VODC heats, higher blow rates of the order of 10 m^3/min (~350 ft^3/min) are maintained, leading to a carbon removal of 1500 ppm/min in 5 Mg (5.5 ton) units.

Figures 7 and 8 demonstrate clearly the low chromium losses and the high ratio of carbon-to-chromium removal rate due to the very low CO partial pressure achieved in the VODC process. As in any vacuum process, the lowest carbon levels (from 50 to 500 ppm) are reached in stainless steel heats very quickly (6 to 10 times the carbon removal rate of AOD) without applying excessive heat and excessive amounts of inert gas. As shown in Fig. 8, temperatures of about 1650 °C (3000 °F) are common. Inert gas volumes are generally less than about 40 L/min/Mg (1.5 ft^3/min/ton).

Figure 9 shows the relationship between the oxygen blow rates and the inert gas addition for various refining techniques, as well as the resulting chromium and carbon levels achieved at specific process steps. Figure 9 also shows the extent to

which decarburization is accompanied by chromium oxidation. Carbon and nitrogen levels below 100 ppm are achieved with corresponding chromium yields of over 95% before reduction and 98% after reduction (Ref 13, 14). Sulfur levels are at 10 to 30 ppm for any grade of steel without any sacrifice in the degassing effect. Hydrogen levels are below 2 ppm.



Technique	Total gas flow		Inert gas, %
	m^3/min/Mg	ft^3/min/ton	
Electric arc furnace (EAF)	1.2	46	0
Lance bubbling equilibrium (LBE)	2.5	95	1
Oxygen top blowing (OTB)	2.0	77	10
Argon oxygen decarburization (AOD)	1.0	40	20-90

Vacuum oxygen decarburization converter (VODC)	0.7	27	2-5
Vacuum oxygen decarburization (VOD-ladle)	0.4	15	0.5-4

Fig. 9 Processing steps for achieving proper chromium and carbon levels in stainless steel using various refining techniques with varying gas blow rates and inert gas additions

The operating conditions necessary for achieving low levels of sulfur and oxygen are the same as those in all strong stirring converter processes (AOD, OTB, VODC). A disadvantage of the vacuum oxygen decarburization converter, as with all converter processes, is that gas pickup of the melt is encountered during tapping into the teeming ladle. Optimum cleanliness and castability therefore require a subsequent ladle treatment, as described in the article "Degassing Processes (Ladle Metallurgy)" in this Volume.

Degassing Processes (Ladle Metallurgy)

Chairman: Gerhard Kienel, Leybold AG, West Germany

Vacuum Ladle Degassing (VD)

Wilhelm Burgmann, Leybold AG, West Germany

THE DEVELOPMENT OF ARGON INJECTION devices and the progress in ladle metallurgy regarding porous plugs, tuyeres, refractory material, heating technologies, slide gates, and so on, have significantly contributed to static ladle vacuum degassing technology. This section will review the equipment associated with vacuum ladle treatment, along with some processing results.

Equipment and Processing

Two basic setups can be utilized during ladle degassing in vacuum. The ladle, containing argon injection or induction coils, can be placed into an independent vacuum vessel (Ref 1), or if argon injection/induction coils are needed to stir the melt (Fig. 1), a vacuum ladle with a directly applied vacuum hood can be used. The vacuum vessel can be either stationary with a vacuum connection (Fig. 2a) or movable on a buggy (Fig. 2b).

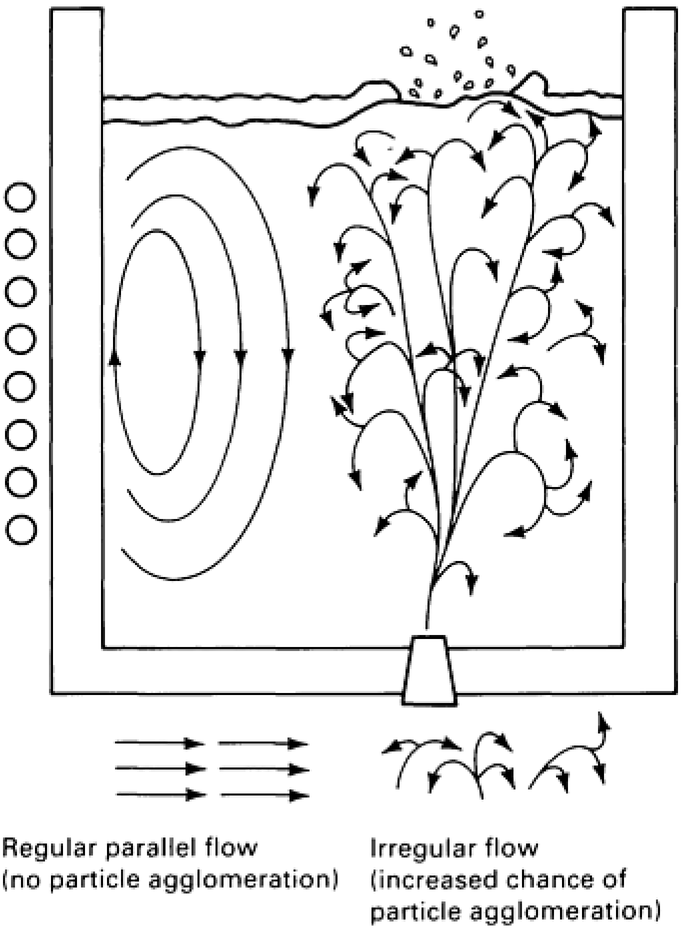

Fig. 1 Flow pattern of inductive and inert gas injection stirring in ladles. Left: regular flow (no particle agglomeration). Right: irregular flow (increased particle agglomeration)

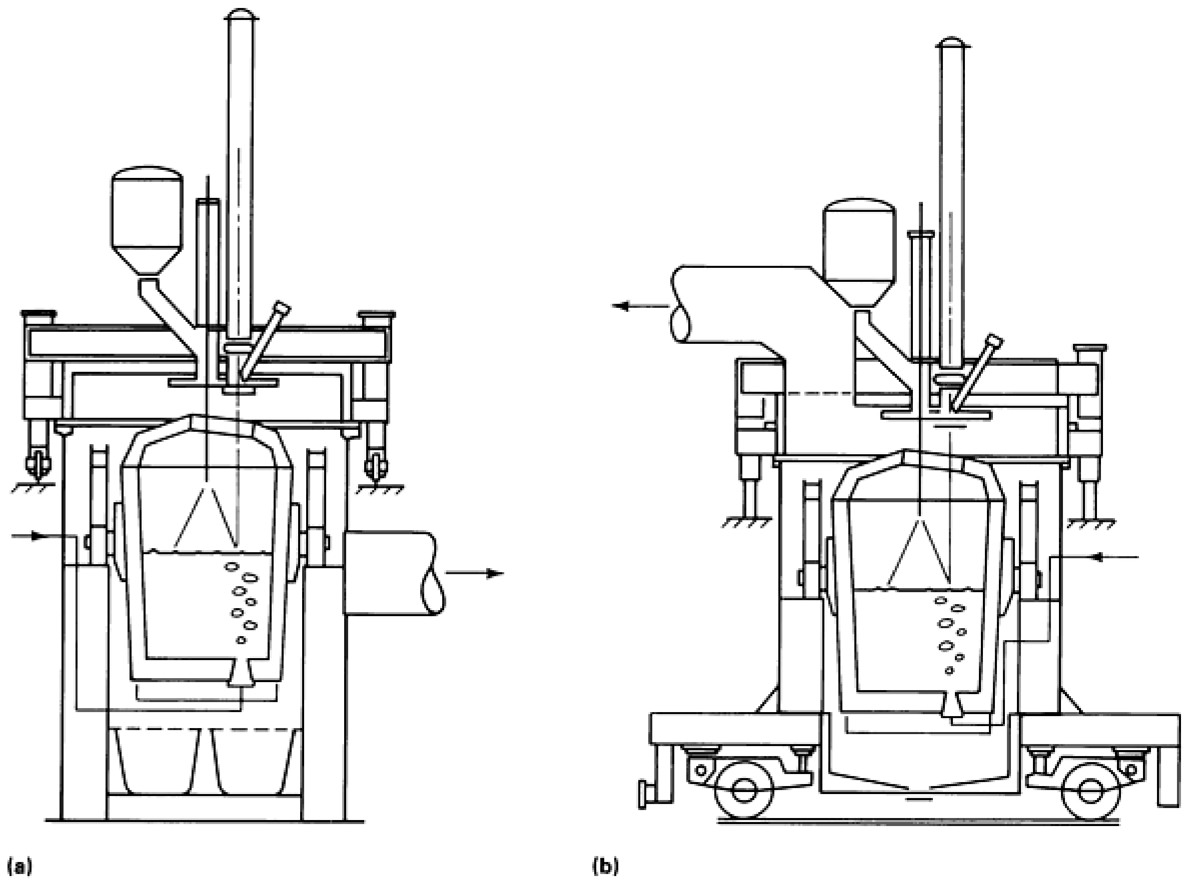

Fig. 2 Schematics of stationary (a) and movable (b) vacuum vessels

The vessel is equipped with a ladle stool for quick and safe placement of the ladle into the vessel. The vessel also has an inert gas connecting device for the ladle. The ladle has the required freeboard (Fig. 3) and is covered by a ladle hood, which retains metal splashes and heat. There is enough space left below the ladle bottom to receive the molten metal in the event of a breakthrough of the ladle.

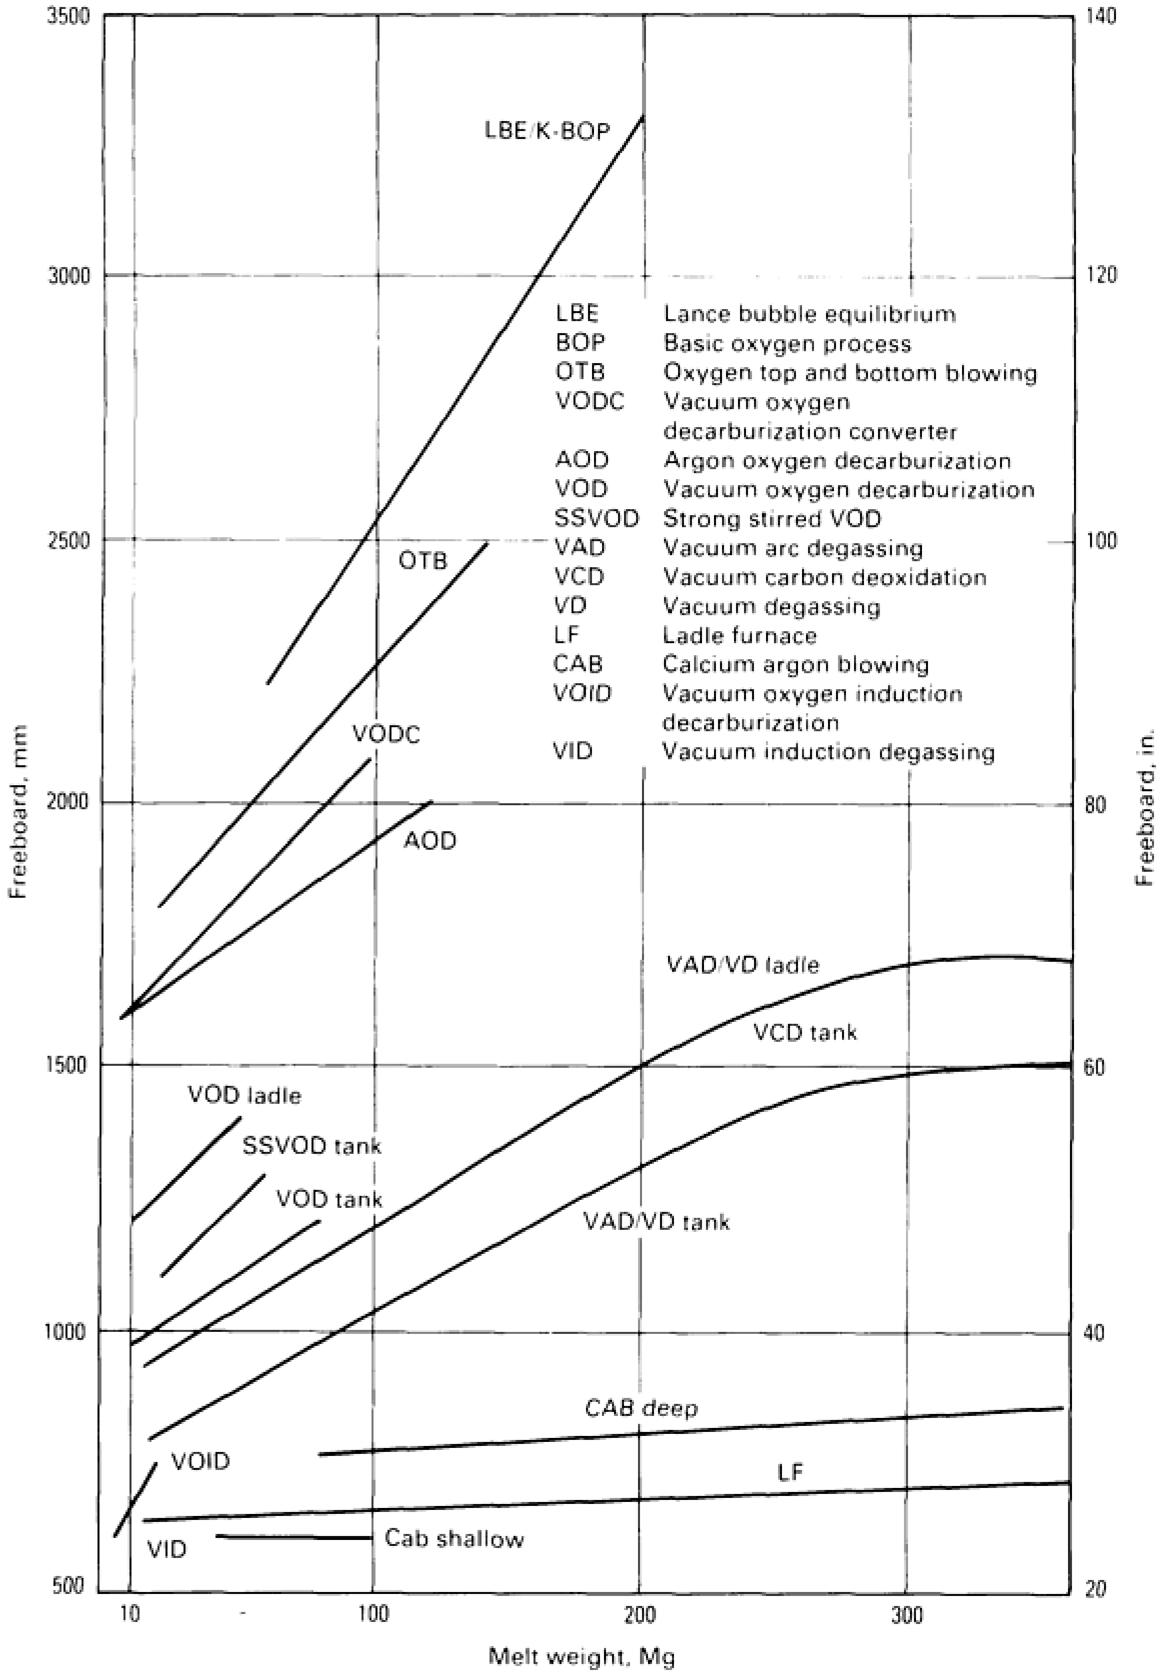

Fig. 3 Freeboard requirements in secondary metallurgy

The vacuum vessel cover is equipped with the necessary control devices for adding slag constituents and alloying and cooling material and for conducting temperature measurement, sampling, and observation to ensure uninterrupted molten

metal processing. For optimum metallurgical results, all of these activities must be executed without breaking the vacuum. Devices are also available for the addition of bulky cooling material and for the injection of aluminum, calcium, calcium-silicon, graphite, and ferroalloys.

Vacuum degassing is used to melt heats ranging in weight from 15 to 350 Mg (16.5 to 390 tons). Its success depends on treatment time, which in turn depends on the previous soaking of the ladle lining and the surface-to-volume ratio of the melt. The mean temperature decrease during vacuum treatment varies from 6 °C/min (11 °F/min) for 15 Mg (16.5 ton) heats to 0.7 °C/min (1 °F/min) for 300 Mg (330 ton) heats during the time the ladle lining is in thermal equilibrium.

It has not been possible to achieve satisfactory degassing results with the presence of slag. However, this has changed because of:

- The progress made in the fabrication of basic linings and in the corresponding lining and heating technology
- The availability of low-silica active slag mixtures
- The development of vacuum technology that prohibits foaming of the slag and permits the injection of large quantities of inert gas up to 10 L/min/Mg (0.3 ft^3/min/ton) to optimize stirring

Such improvements have led to simultaneous desulfurization rates of 95%, hydrogen removal of over 85%, nitrogen removal of 60%, and aluminum contents below 200 ppm. Figure 4 shows the removal of sulfur, hydrogen, and nitrogen as a function of gas circulation rate for a 180 Mg (200 ton) VD treatment. Vacuum treatment results for several low-alloy steel heats are given in Table 1.

Vacuum Degassing Procedures. There are two vacuum degassing stirring procedures. In the first, hydrogen, nitrogen, and sulfur are eliminated by strong stirring, that is, with 5 to 10 L/min/Mg (0.15 to 0.3 ft^3/min/ton). In this case,

the oxygen level is decreased only to 30 to 50 ppm total oxygen, with the major portion of this being the suspended oxidic inclusions. In the second procedure, the total oxygen level is reduced to 10 to 25 ppm by a soft stirring phase in combination with a previously conducted aluminum deoxidation procedure. This requires a very low stirring rate, a strongly basic slag, and sufficient temperature reserve for an extended treatment. If the thermal reserve is not adequate, an additional heat supply, for example, in the form of electric arcing at low voltage, is necessary. Additional heating by electric arcing is described later in this article (see the sections "Ladle Furnace and Vacuum Arc Degassing (LF/VD-VAD)" and "Plasma Heating and Degassing").

The distribution of stirring energy should be uniform. For strong stirring, inductive stirring combined with inert gas stirring is required. Inductive stirring alone is sufficient for gentle stirring if the flow pattern is irregular enough to create turbulences that will produce inclusion agglomeration. The differences in the flow patterns created by inductive and inert gas stirring are shown in Fig. 1.

Vacuum Oxygen Decarburization (VOD)

Wilhelm Burgmann, Leybold AG, West Germany

Vacuum oxygen decarburization differs from vacuum degassing, which is conducted under reducing conditions, in that decarburization is an oxidizing process that not only increases dissolved oxygen content in the melt by solid oxygen carriers but also introduces gaseous oxygen through a top-blowing lance that permits higher decarburization rates. The VOD process is primarily used for decarburizing stainless steel melts or other high-chromium bearing alloys; however, a VOD plant can be used for all types of steel grades and alloys when decarburization, degassing, desulfurization, or chemical heating with oxygen is required (Ref 4, 5, 6). Chemical heating with oxygen is also called vacuum oxygen heating.

The VOD process is based on the fact that decarburization is strongly favored under reduced pressure with respect to other oxidizing reactions. Thus, chromium is protected against oxidation, as discussed in the section "Argon Oxygen Decarburization" of the article "Degassing Processes (Converter Metallurgy)" in this Volume. This applies to a limited extent to manganese and silicon if the oxidation rates are kept sufficiently low.

Equipment and Processing

A modern VOD plant for heats ranging in weight from 15 to 90 Mg (16.5 to 100 tons) consists of the following equipment:

- Basic-lined ladle with a freeboard of 1 to 1.5 m (3 to 5 ft), a porous plug in the bottom for inert gas injection, a slide gate, and refractory-lined ladle hood tightly sealed on the ladle
- Vacuum vessel with ladle stool, an inner lining, a safety basin for receiving a metal breakthrough, a vacuum connection, and a vessel cover with accessories and water-cooled splash protection
- Top-blowing oxygen lance
- Probing device for in-process temperature measurement and sampling
- Movable guide pipe for feeding either aluminum wire or wire filled with such materials as calcium, calcium-silicon, titanium, graphite, and fluxes
- Observation port with television camera
- Vacuum pump set (steam ejectors, water ring pump, or mechanical pumps) with a suction capacity such that during oxygen blowing the vacuum is held below 10 kPa (100 mbar, or 75 torr), and oxidizing as well as reducing vacuum treatments can be performed below 0.1 to 1 kPa (1 to 10 mbar, or 0.75 to 7.5 torr). The pump must also be adjusted to handle carbon monoxide gas safely and to remain operational under a heavy dust load of the carried gas of up to 0.4 kg/m^3 (0.4 oz/ft^3).

Oxygen blow rates vary from 5 to 25 m^3/min (175 to 900 ft^3/min), depending on heat size and initial carbon content. The specific blow rate ranges from 0.2 to 1.4 m^3 O_2/min/Mg (6 to 45 ft^3 O_2/min/ton); the highest specific blow rates are achieved with the smallest heat sizes.

The inert gas blow rates vary strongly with the process and the desired results; that is, absolute rates range from 0.1 to 1.2 m^3/min (3.5 to 45 ft^3/min), and specific rates are 2 to 7% of oxygen flow.

According to equilibrium data for the Fe-Cr-C-O system, the lower the chromium losses, the lower the partial pressure of the formed CO + CO_2 (equilibrium conditions for chromium-containing steels are described in the section "Argon Oxygen Decarburization" of the article "Degassing Processes (Converter Metallurgy)" in this Volume). However, the main oxygen-blowing period of the VOD process is performed at an intermediate vacuum pressure range of 3 to 8 kPa (30 to 80 mbar, or 20 to 60 torr), which is governed by the suction capacity of the installed vacuum pump and the freeboard available in the ladle. The chromium loss at given carbon levels and temperatures depends on the prevailing kinetic conditions at the blowing spot. With an intense inert gas stirring from the ladle bottom, the chromium loss can be reduced to nearly zero by the strong stirring VOD process, as described in Ref 7.

In most VOD plants, the chromium yield at the end of blowing is 90 to 95% and is increased to 98 to 99% during the subsequent reducing phase by the combination of low vacuum pressure and the addition of reducing agents such as aluminum and silicon. The yield of chromium also depends on the initial and the final carbon contents of the melt.

The limited freeboard of VOD ladles and the strongly exothermic effect of the process dictate that the starting carbon content and the oxygen blow rate be limited. A typical sequence of operations during a VOD treatment is shown in Fig. 5. Achievable results reported from several plants that utilize VOD capability are summarized in Table 2.

Ladle Furnace and Vacuum Arc Degassing (LF/VD-VAD)

Wilhelm Burgmann, Leybold AG, West Germany

Secondary metallurgy techniques are energy consuming, and any extended ladle treatment leads to heat losses. As a result, the goal has always been to perform such operations as vacuum degassing, desulfurization, and alloying with simultaneous heating so that the ladle treatment could be carried out with no evident heat loss. Simultaneous heating and degassing is difficult and previously was possible only by vacuum induction degassing or partially by vacuum arc degassing (VAD); however, the combination of an arc-heating Ladle Furnace (LF) with a vacuum-degassing (VD) station meets operational requirements and produces excellent metallurgical results, as will be summarized in this section.

Equipment and Processing

Several types of LF/VD-VAD layout designs are possible. Although vacuum ladles do not provide the best operational reliability (Ref 8), they are essential if induction coils are needed for stirring. In this case, the ladle and coil are placed on a tiltable ladle car that moves from the open loading position underneath the vacuum hood and/or underneath the three-phase arc-heating ladle furnace. With the incorporation of an induction coil, this design is also known as the ASEA/SKF process.

For vacuum vessels, there are two principal designs. The first is the stationary vessel, and the second is the track-mounted movable vessel.

The stationary vessel is enclosed in a mobile vacuum cover or a swiveling ladle furnace cover. For tandem stationary vessels, each is enclosed in a moving vacuum cover, while both are served by a common swiveling ladle furnace, a common vacuum pump, and common alloying equipment. This design permits brief tap-to-tap times of about 30 to 45 min. A schematic of a combined LF/VD plant is shown in Fig. 6.

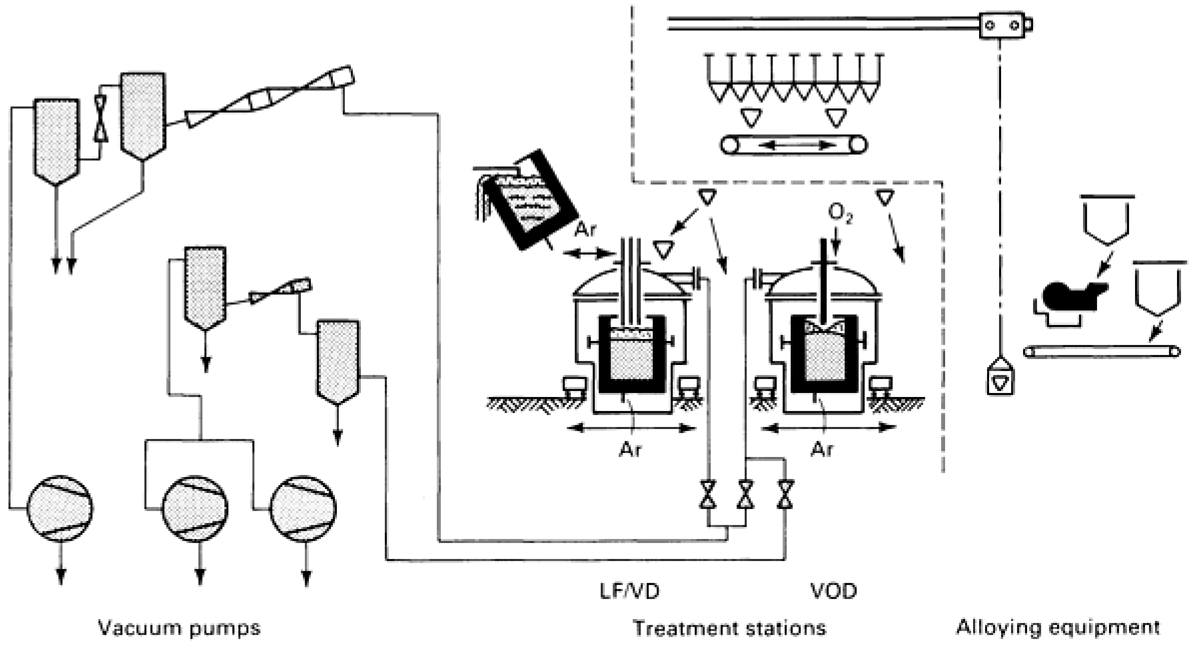

Fig. 6 Schematic of a combined ladle furnace and vacuum degassing plant

The movable vacuum vessel moves with the vacuum ladle car to several treatment platforms that contain the vacuum cover, arc-heating ladle furnace, plasma torches (in the case of ladle plasma heating units), injection stands, and alloying and wire feeding station. There are single-stand layouts that permit both arc heating and vacuum degassing in addition to other secondary metallurgy treatments, such as alloying, injection, and stirring, at the same treatment station. The movable vacuum vessel is transported to this treatment station, where arc heating and vacuum degassing can be performed by ladle furnace vacuum degassing or vacuum arc degassing.

For combined ladle furnace and vacuum degassing, arcing is carried out at the pressure created by a pollution control device; this underpressure is ~0.5 kPa (~5 mbar, or 3 torr). The protective atmosphere is created under a partially closed vessel lid, leaving only the openings for three electrodes, alloying, sampling, process control, and flue gas suction. The atmosphere composition is controlled by the carbon monoxide formed by the reaction of graphite electrodes with oxidic slag and the inert gas introduced through porous plugs in the ladle bottom or under the ladle furnace roof. For vacuum treatment, the electrodes are lifted above the vessel lid, and the lid opening is closed by a vacuum cover.

When vacuum arc degassing is used, complete protection of the electrodes is provided by telescopic water jackets and inflatable top seals that permit simultaneous arcing, vacuum treatment, and inert gas stirring. However, arcing under reduced pressure is restricted to about 30 kPa (300 mbar, or 225 torr). Below this pressure, the gas atmosphere would be ionized, resulting in severe damage to the equipment. It should be noted that 30 kPa (300 mbar, or 225 torr) arcing is feasible only if the arc voltage is kept below 100 V and the electrode regulation is reliable.

The arc length increases with the arc voltage and with the reduced pressure. Therefore, pressures are not applied below 80 kPa (800 mbar, or 600 torr), because the extreme arc length cannot be fully immersed in the slag. Submerged arcing is one precondition for the high thermal efficiency of this process. Therefore the VAD process is also divided into two steps: one arcing step at 60 to 90 kPa (600 to 900 mbar, or 450 to 700 torr), followed by a vacuum procedure carried out at below 100 Pa (1 mbar, or 0.7 torr) with the electrodes lifted.

Ladle Furnace Design. The basic design and equipment of any arc-heated ladle furnace are similar to those of electric arc melting furnaces, except that no tilting movement is required and ladle furnaces are frequently in a gantry design (Fig. 7). Electrode regulation is accomplished by either electromechanics or hydraulics. The hydraulic fluid is a water emulsion, water glycole, or oil. Direct current ladle furnaces are not manufactured, but if very small ladle furnace units are required, a monophase alternating current design with two electrodes is available. Such units are similar to those described in the article "Vacuum Melting and Remelting Processes" (see the section "Electroslag Remelting") in this Volume.

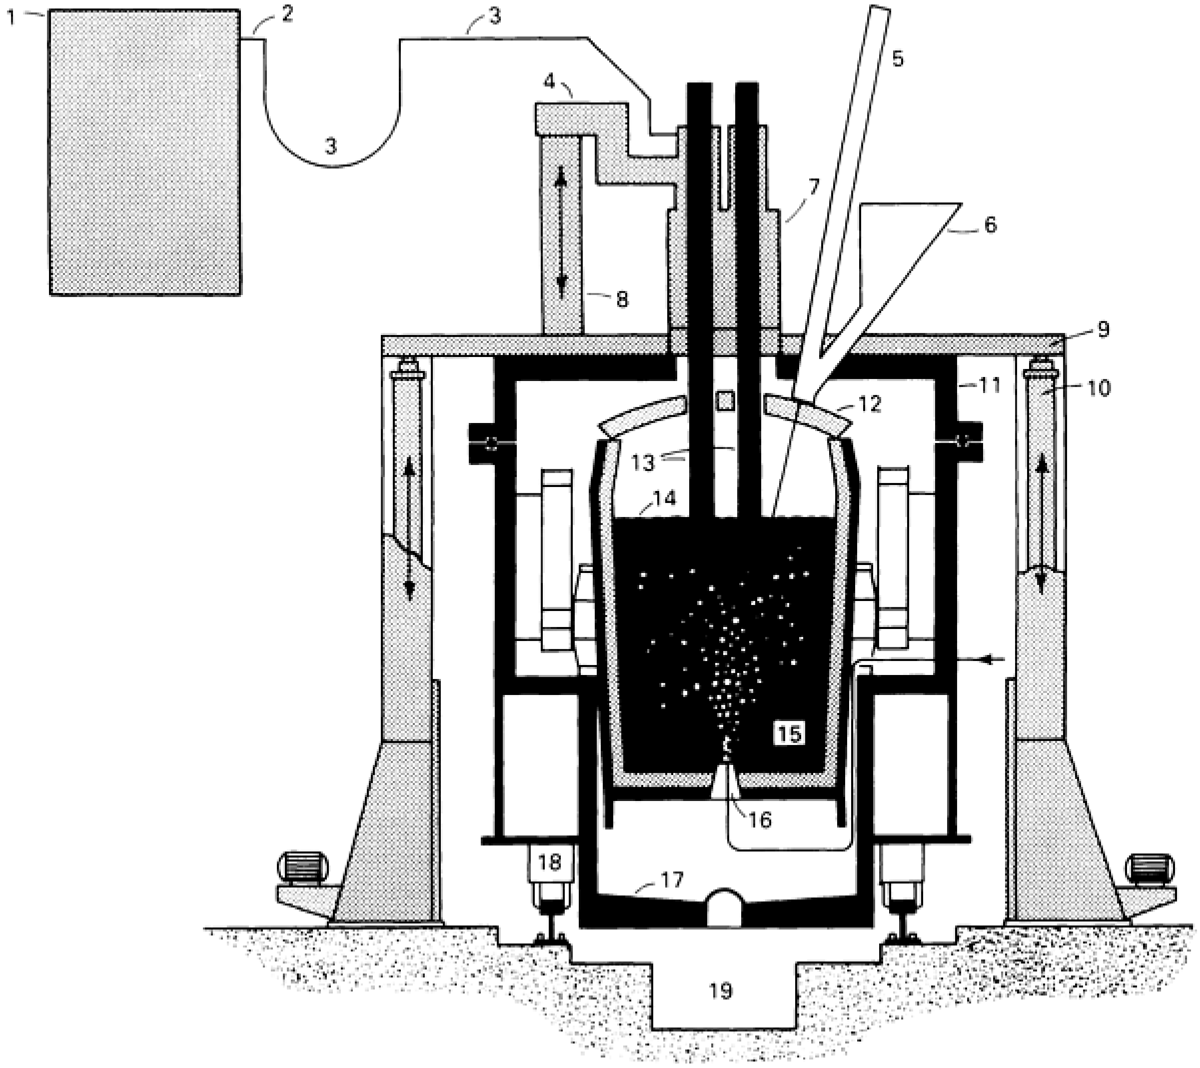

Fig. 7 Schematic of a vacuum arc degassing plant layout. 1, transformer; 2, bus bars; 3, flexible cables; 4, electrode arms; 5, temperature-measuring and sampling device; 6, alloying lock; 7, electrode housing; 8, electrode masts; 9, operating platform; 10, lifting device for platform; 11, vacuum cover; 12, ladle heat shield; 13, electrodes; 14, slag; 15, melt; 16, argon plug; 17, vacuum vessel; 18, vessel drive; 19, emergency pit

Stirring, by inductive coils or inert gas, is necessary in any ladle furnace design. However, the ladle furnace has requirements that are very different from those of the electric arc melting furnace. Ladle furnace requirements include the following:

- Controls governing electrode movement must be more sensitive because of the inert gas bubbling through the ladle bottom
- The arc must be immersed in the foaming slag; this requires short arcs and therefore a low voltage, a low voltage-to-current ratio, and a low total inductivity

The refractory wear of immersed arcing is concentrated at the wall/slag zone. It is proportional to the amount of specific arc power brought into the slag and the intensity of slag cooling during treatment.

For ladle furnaces, secondary voltages of 180 to 280 V, combined with a 2 to 3 mΩ furnace plus transformer reactance, leads to arc voltages below 100 V. The resulting relatively high current density is 10 A/mm^2 (6500 A/in.^{2}) in rigid bars and pipes, 7 A/mm^2 (4500 A/in.^{2}) in flexible water-cooled cables, and 0.40 A/mm^2 (250 A/in.^{2}) in graphite electrodes.

The response time resulting from electrode control is defined as the time required to dissolve a short circuit by lifting the electrode about 10 mm ($\frac{3}{8}$ in.). This response time may vary between 100 and 400 ms, according to the electrode control system applied. This value is important because shorter response times result in less carbon pickup and higher thermal yields.

The heating rate is also affected by heat transfer, particularly during the first 10 to 30 min of treatment. Heat losses from the melt to the different furnace components are illustrated in Fig. 8, which shows that the heating rate depends on the heat flow from the arc (area 1) to the different parts surrounding the melt (area 2). Even in the case of thermal equilibrium with the lining (area 3), permanent thermal and electrical losses (area 4) are present such that the best thermal yield under a steady state of heat transfer is only 50 to 60%. The thermal balance reached at a near steady state for arc heating (VAD/LF) and induction heating (vacuum induction melting and degassing, VIM/VID) is shown in Fig. 9. Figure 10 shows a typical treatment cycle and associated parameters for a 75 Mg (80 ton) VAD-heated melt.

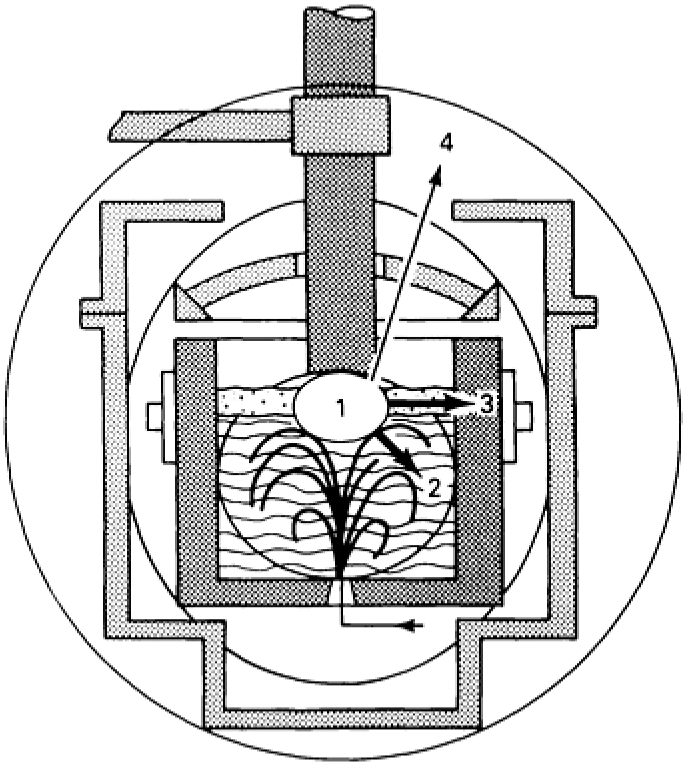

Fig. 8 Thermal flow pattern of a ladle furnace. 1, arc; 2, melt; 3, slag, electrode tip, and lining; 4, vessel, cover, busbars, and environment

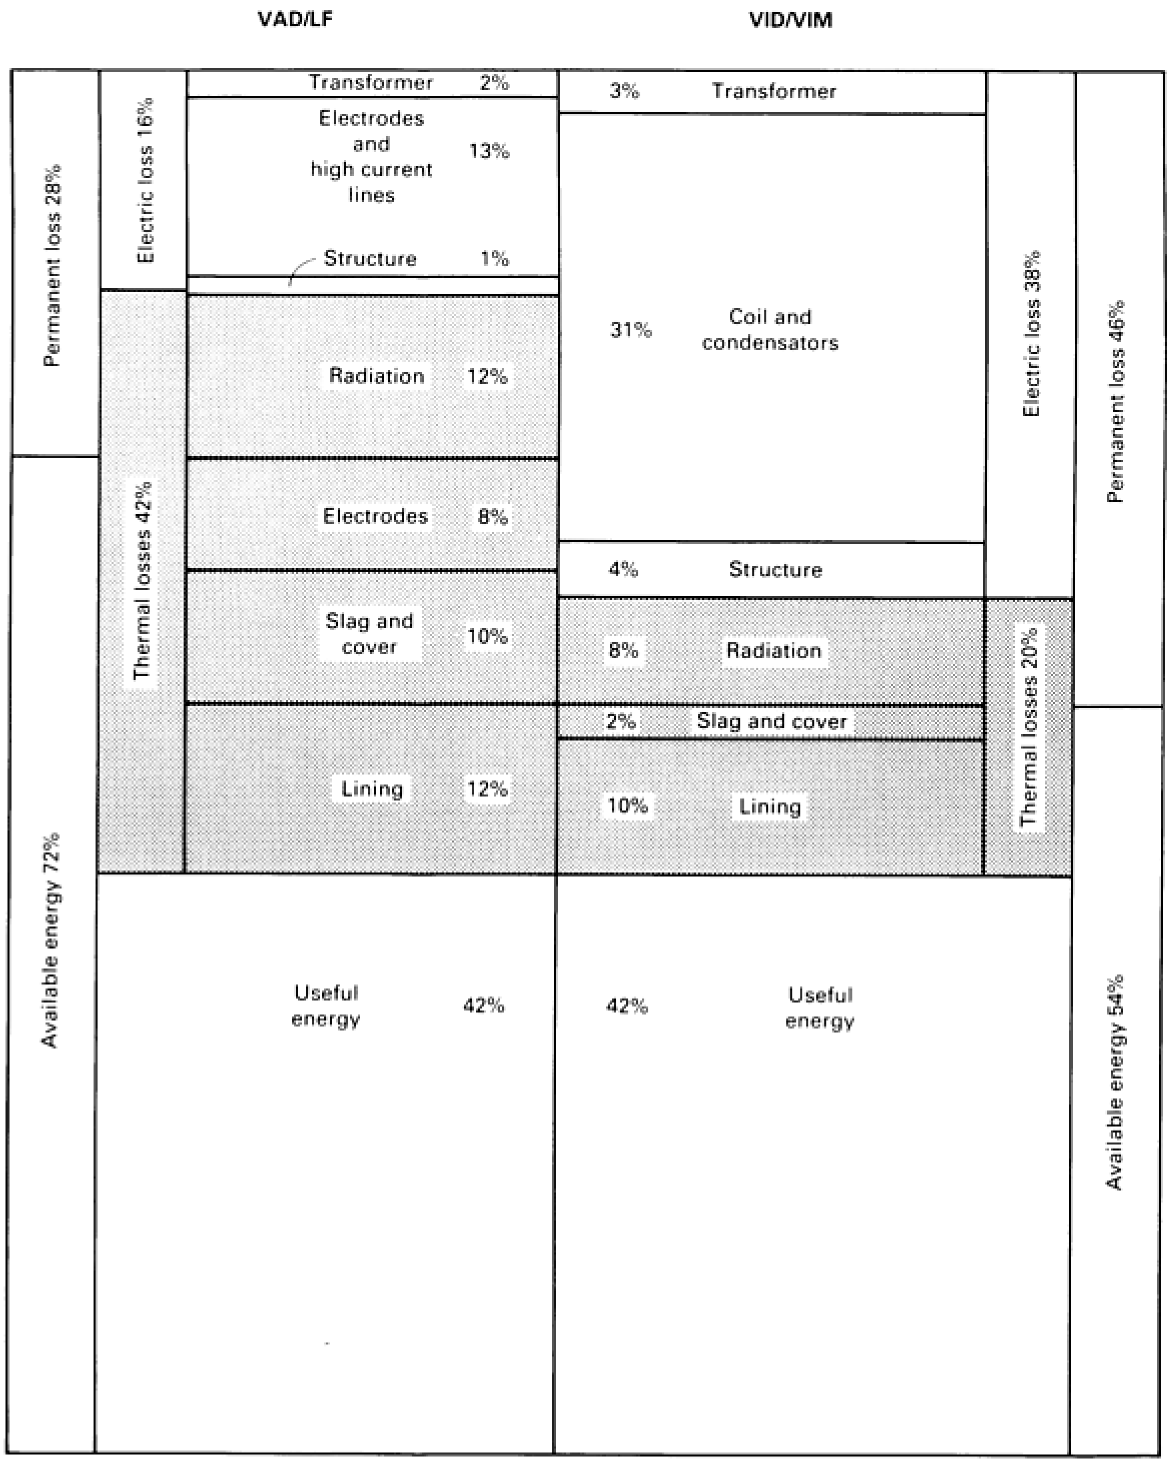

Fig. 9 Thermal energy balances for arc-heated and induction-heated processes

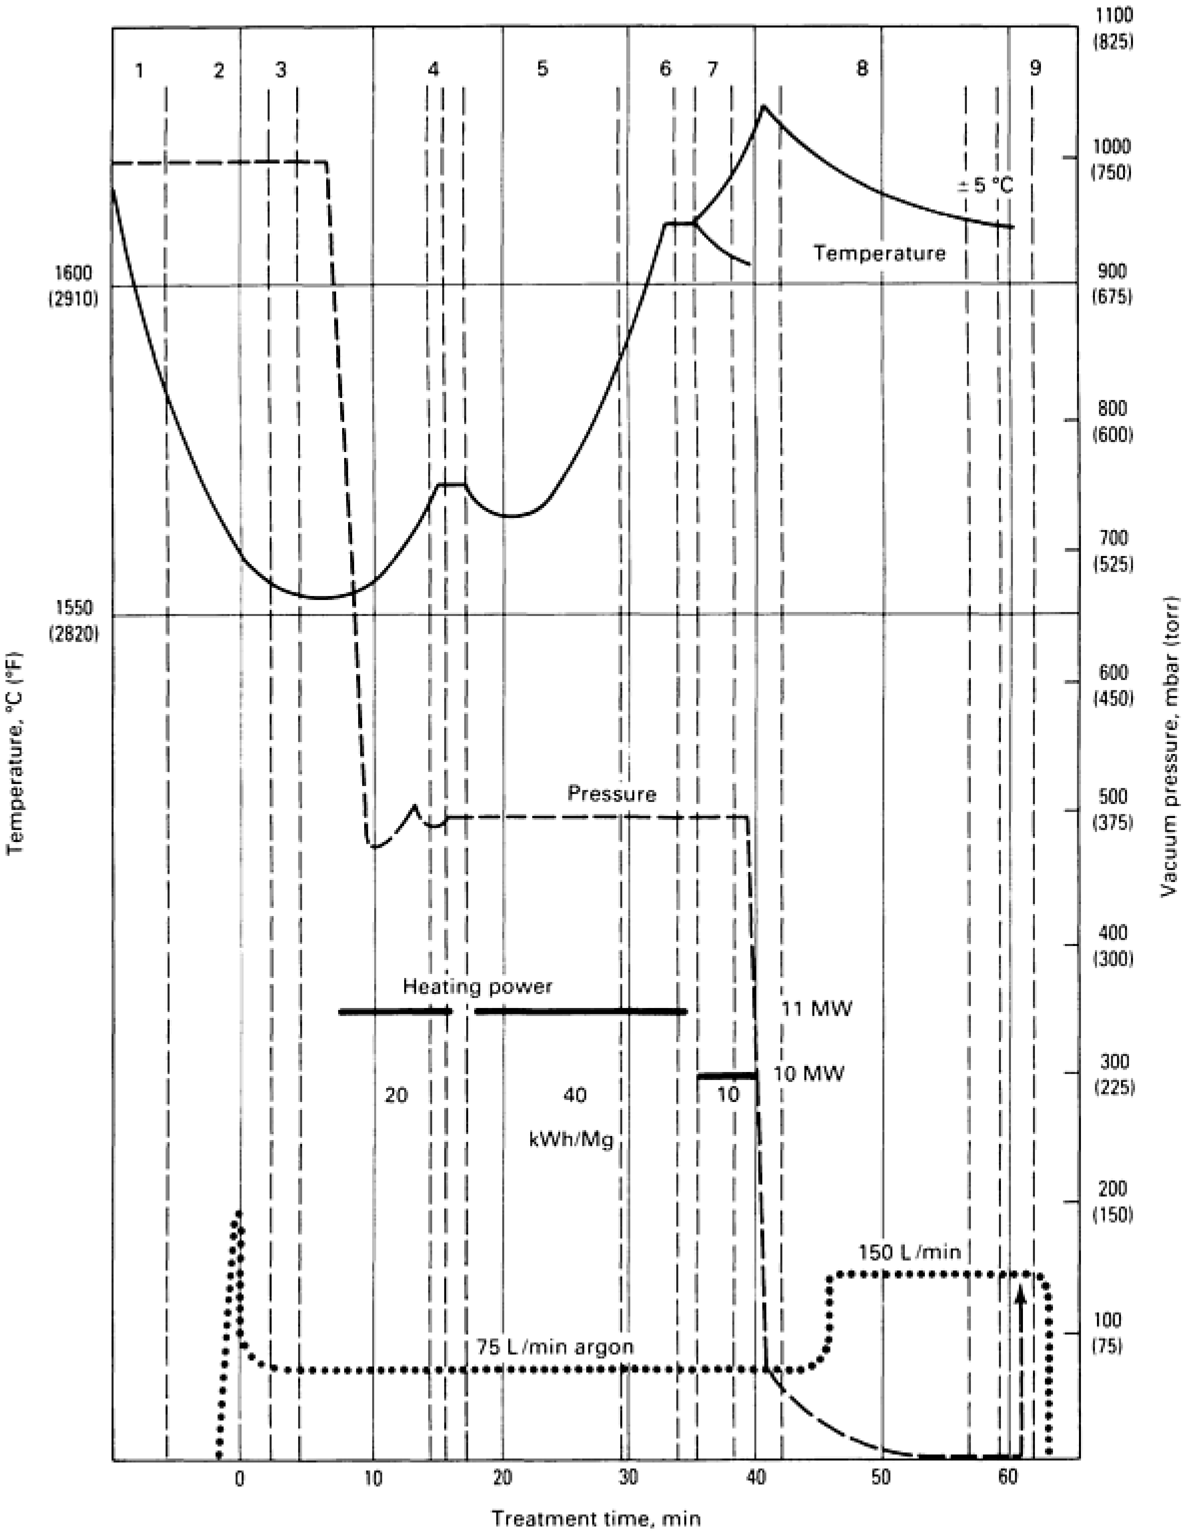

Fig. 10 Treatment cycle of a 75 Mg (80 ton) VAD-heated melt. 1, tapping; 2, additions of C + Al + 0.5% CaO; 3, temperature check; 4, sampling and temperature check; 5, addition of 1.5% alloys + 0.5% CaO; 6, temperature check; 7, additions + 0.5% CaO; 8, degassing; 9, venting

Independent of thermal yield, the physical boundary for heat transfer by arc, plasma, electron beams, and oxygen gas streams is that the melt evaporates at the heat transfer spots. Table 3 compares the various types of heating processes described in this section, in addition to vacuum induction degassing, plasma heating, and vacuum oxygen heating (VOH), which are described elsewhere in this article.

Vacuum Induction Degassing (VID)

H. Kemmer and U. Betz, Leybold AG, West Germany

Thermal balance is extremely critical for the secondary metallurgical treatment of small heats. In most cases, excessive chemical heating through aluminum additions is the only method of compensating for temperature losses during the secondary metallurgical treatment of melts below 15 Mg (16.5 tons). This technique, however, has various disadvantages, such as increased aluminum oxide (Al_2O_3) inclusion content in the final product and the high equipment costs associated with aluminum heating and oxygen (O_2) blowing. In such cases, vacuum induction degassing, a new secondary steelmaking technology, also permits economical vacuum treatment for small heat sizes ranging from 1 to 15 Mg (1.1 to 16.5 tons). Table 4 compares the metallurgical applications of vacuum induction degassing with other heating and melting operations.

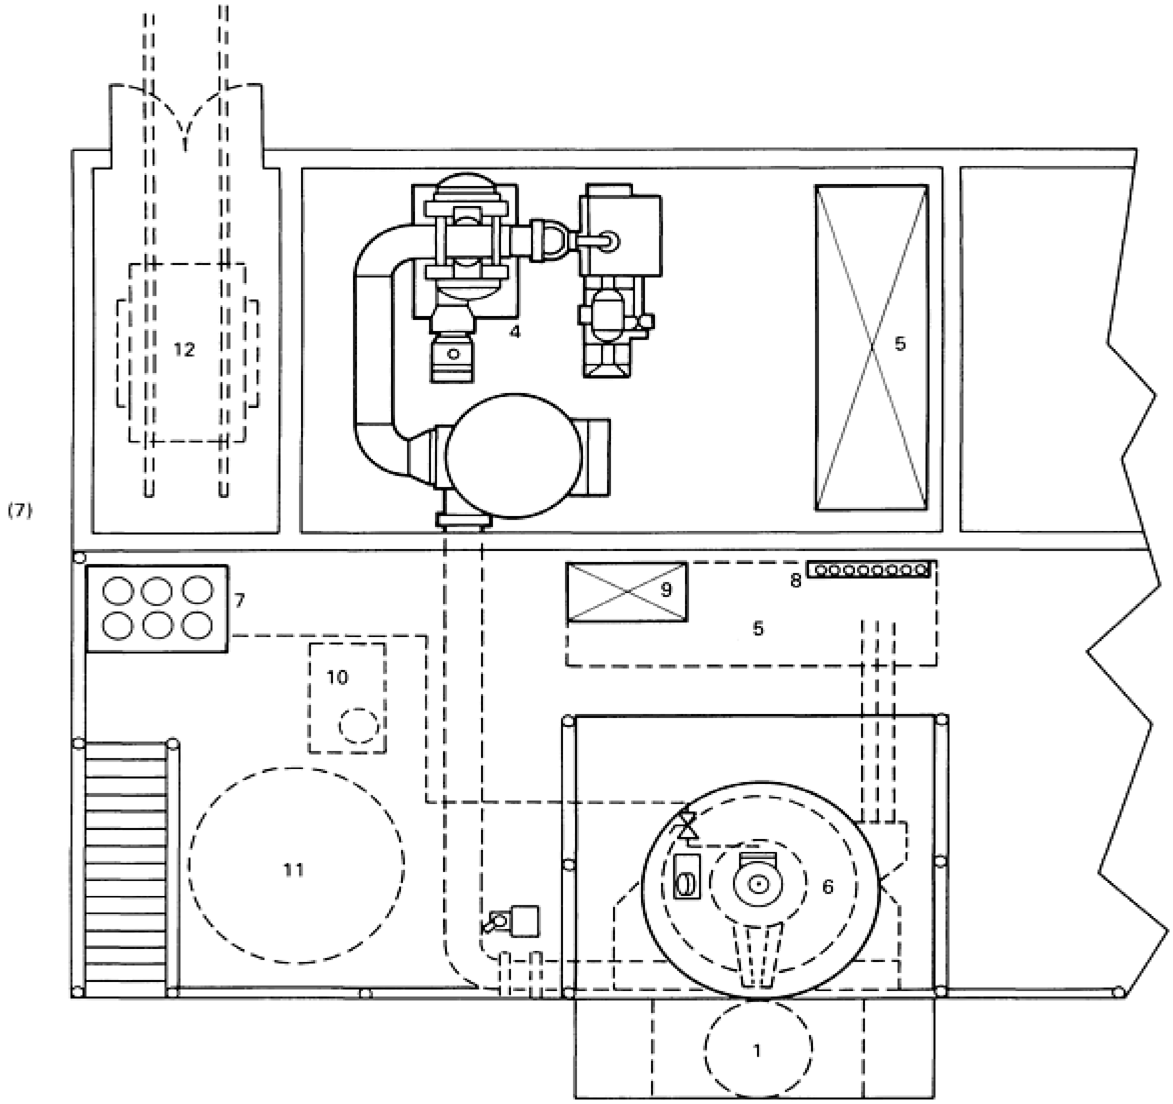
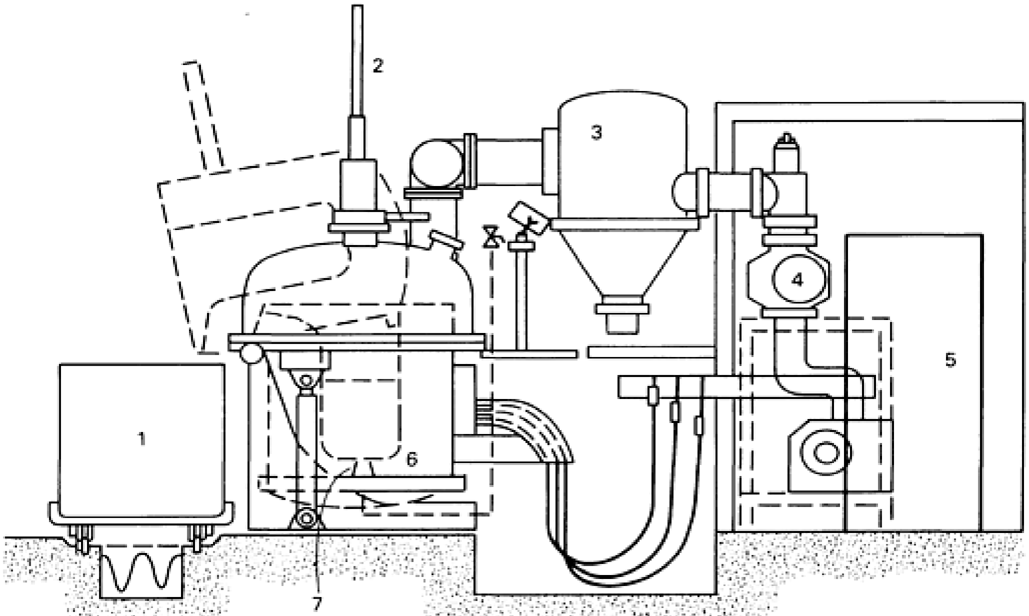
Equipment and Processing

Vacuum induction degassing units consist of a simple induction furnace, designed for vacuum operation, that is equipped with a bell-type vacuum cover (Fig. 11). The furnace crucible is either rammed or lined with brick and has a porous plug in the bottom. A frequency converter power supply provides the energy for the induction coil to control the temperature of the melt.



(a)



(b)

Fig. 11 Schematic of a VID unit. (a) Top view. (b) Side view. 1, mold, die, or ladle; 2, charging device; 3, filter; 4, vacuum pumping system; 5, melt current supply; 6, vessel with vacuum bell; 7, gas-purging set; 8, cooling water manifold; 9, control cabinet; 10, hydraulic unit; 11, lid station; 12, transformer

With the vacuum cover removed, the furnace is charged with either liquid or solid. For vacuum treatment, the vacuum cover is placed on the furnace body by crane. A mechanical pumping system is used to achieve an operating pressure of around 0.01 to 0.1 kPa (0.1 to 1 mbar, or 0.075 to 0.75 torr).

The process is primarily applied to tool and die steels, bearing steels, chromium steels, nickel-chromium steels, and nickel-base alloys to remove dissolved gases such as hydrogen and nitrogen and to remove oxide inclusions from the melt. Figure 12 shows the results of VID treatment on the hydrogen, nitrogen, and oxygen contents of a die steel. In Fig. 12(a), the use of vacuum induction degassing lowered the hydrogen content from more than 2.2 ppm to 0.60 ppm (hydrogen removal of 50%). With proper metallurgical treatment, the nitrogen content can also be decreased. Figure 12(b) shows that the nitrogen content was lowered from more than 370 ppm to approximately 50 ppm (nitrogen removal of 50%).

With vacuum induction degassing, oxide inclusions can be removed by applying metallurgically active slags as an absorbing buffer. In addition, VID units are equipped with argon bubbling systems, which accelerate and improve the removal of nonmetallic inclusions. Changes in oxygen content as a result of vacuum induction degassing, with and without argon bubbling, are shown in Fig. 12(c). The final total oxygen content when using VID with argon bubbling is 30% lower than VID without argon bubbling, which demonstrates the benefits of soft argon rinsing.

Plasma Heating and Degassing

H. Pannen and G. Sick, Leybold AG, West Germany

Plasma heating is a process that employs plasma arc torches to supply electric heat to a ladle of molten metal either to maintain the temperature or to raise the temperature of the melt. Until recently, heat losses during ladle metallurgy treatment were compensated for by means of graphite electrode arc heating or induction heating. However, for numerous steel grades, especially those with extremely low carbon contents, graphite electrodes cannot be used, because of the risk of carbon pickup. The demand for nonconsumable heat sources has increased interest in high-power plasma torches as heat sources, which can be used with minimum modification to the existing ladle design. Prior to their integration into ladle metallurgy stations, plasma torches had been used primarily for scrap melting and heat loss compensation before and during continuous casting.

In this section, ladle furnace concepts applicable to plasma technology will be outlined. Details on metallurgical reactions during the high-power plasma primary melting of various steel grades are available in Ref 11, 12, 13, and 14.

Nonferrous Molten Metal Processes

David V. Neff, Metaullics Systems

Introduction

IN THE MELTING of commercial nonferrous metals and alloys (aluminum, magnesium, copper, zinc, and lead), various auxiliary molten metal processing steps are necessary other than melting and alloying. For example, many nonferrous molten metal treatment technologies exist that improve metal quality through the control of impurities.

Generally, the historic practices of fluxing, metal refining, deoxidation, degassing, and grain refining have been used, and they apply to virtually all nonferrous metal systems. In addition, molten metal pumping and filtration are two somewhat newer but now commonly practiced technologies in nonferrous molten metal processing.

This article will describe the molten metal processing methodologies currently used in conventional nonferrous molten metal operations. These process methodologies pertain not only to foundry melting and casting but also to smelting, refining, and in certain cases mill product operations.

Fluxing

The term fluxing is used in this article to represent all additives to, and treatments of, molten metal in which chemical compounds or mixtures of such compounds are employed. These compounds are usually inorganic. In some cases, metallic salts are used in powder, granulated, or solid tablet form and may often melt to form a liquid when used. They can be added manually or can be automatically injected, and they can perform single or, in combination, various functions, including degassing, cleaning, alloying, oxidation, deoxidation, or refining. The term fluxing also includes the treatment of nonferrous melts by inert or reactive gases to remove solid or gaseous impurities. Fluxes are commonly used to some extent with virtually all nonferrous molten metal operations in both the foundry and in the production of mill products.

Fluxing of Aluminum Alloys

In aluminum melting, and especially in the remelting of foundry returns or other scrap, oxide formation and nonmetallic impurities are common. Impurities appear in the form of liquid and solid inclusions that persist through melt solidification into the casting. Inclusions can originate from dirty tools, sand and other molding debris, sludge (iron-chromium-nickel intermetallic compounds commonly found in die casting alloys), metalworking lubricant residues, and the oxidation of alloying elements and/or the base metal.

The term fluxing, in the broadest sense, applies to a treatment technique to the melt containing such impurities and inclusions as those mentioned above. Fluxing of the melt facilitates the agglomeration and separation of such undesirable constituents from the melt.

Fluxing is temperature dependent. The temperature must be high enough to achieve good physical separation or the desired chemical reaction. At sufficiently high temperatures, the fluidity of both the metal and the fluxing agent is likely to be very high, which provides for good contact between the two and better reactivity.

Flux Composition. The specific compounds or chemical reagents used in fluxes depend on the specific purpose of the flux. Most fluxing compounds consist of inorganic salt mixtures. The various constituents of these salts or other materials in the flux serve to:

- Form low-melting high-fluidity compounds at use temperature, as is the case with sodium chloride (NaCl)-potassium chloride (KCl) mixtures
- Decompose at use temperature to generate anions, such as nitrates, carbonates, and sulfates, capable of reacting with impurity constituents in the melt. This creates impurity metal oxides or other compounds with densities different from that of the base melt and facilitates physical separation
- Act as fillers to lower the cost per pound or to provide a matrix or carrier for active ingredients or adequately cover the melt
- Absorb or agglomerate reaction products from the fluxing action

Not all components are necessary or found in each flux. Table 1 lists the properties of numerous materials commonly used in commercial aluminum fluxes and fluxing reactions.

Table 1 Characteristics of some materials used as fluxes for aluminum alloys

Material	**Chemical formula**	**Density, g/m^3**		**Melting point**		Boiling point	
		Solid	**Liquid**	**°C**	**°F**	**°C**	°F

(a) Sublines at indicated temperature.

In general, the choice of which components to use in a flux depends on the temperature of use, whether the flux is to provide a molten cover or a solid cover, the desired reactivity, and the specific alloy chemistry. For example, sodium-

bearing fluxes should not be used with aluminum-magnesium alloys in order to avoid sodium salt flux decomposition and the attendant sodium contamination of the melt. Sodium fluxes should also not be used with hypereutectic aluminum-silicon alloys refined with phosphorus because an easily formable sodium phosphide compound will render the phosphorus ineffective as a refiner.

Types of Fluxes. Four principal types of fluxes are used for aluminum alloys. They are cover fluxes, cleaning fluxes, drossing fluxes, and refining fluxes. Wall-cleaning fluxes are also employed, but these are usually sprayed onto furnace walls rather than added to the melt.

Cover fluxes are designed to be used primarily with smaller (pot, crucible) furnaces to provide a physical barrier to oxidation of the melt or to serve as a cleanser for alloys, scrap foundry returns, or fresh ingot being charged. Such fluxes are dry, or they may be of such composition as to be molten on the melt surface, thereby wetting any materials being charged. This helps agglomerate loose debris, and it minimizes the oxidation of new surfaces. Such fluxes are often called wet fluxes. Figure 1 shows three binary phase diagrams for components commonly used in cover fluxes.

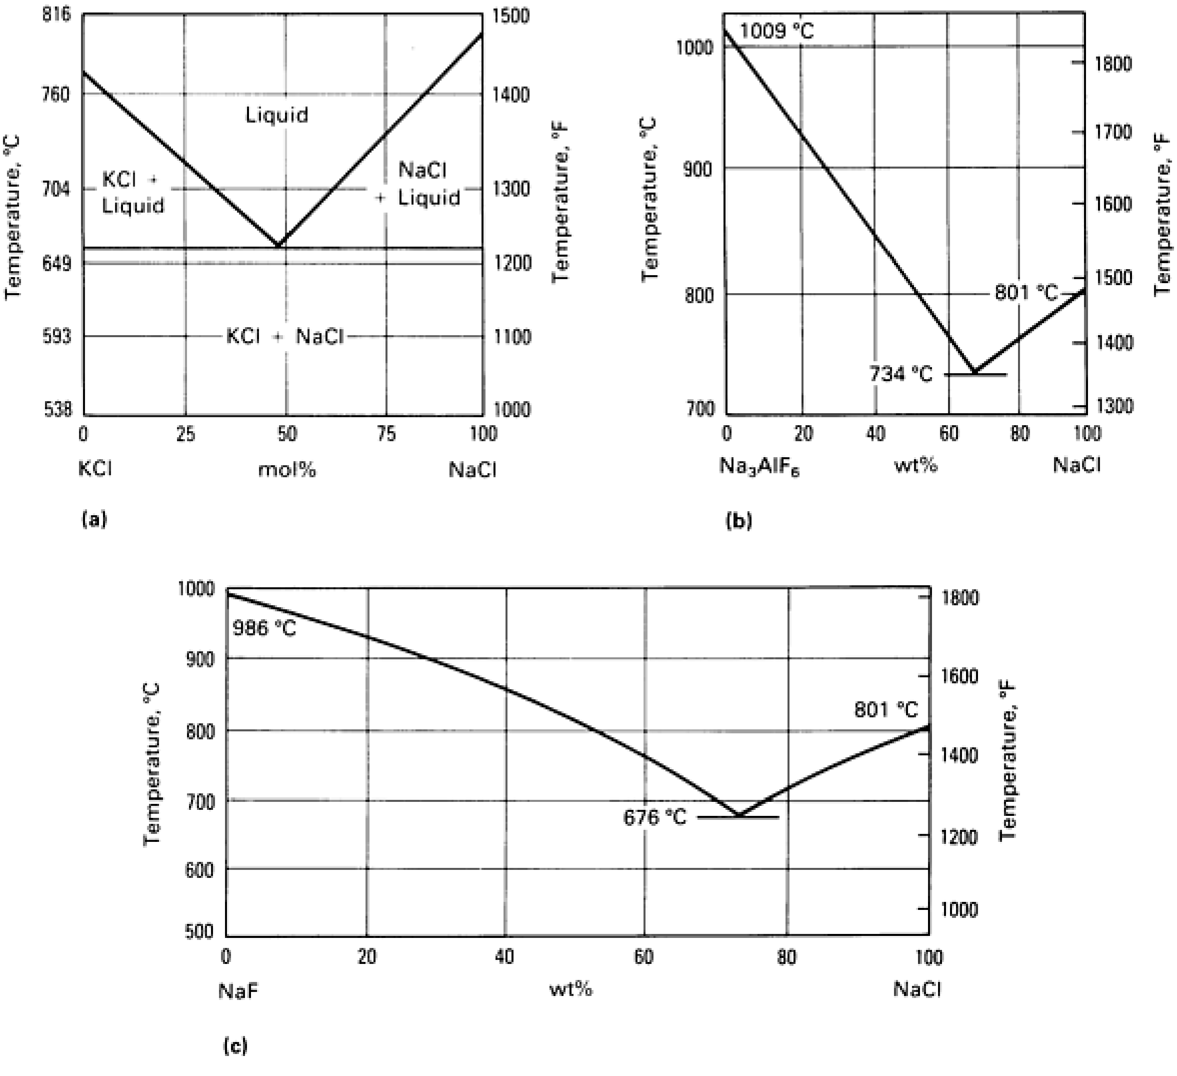

Fig. 1 Binary phase diagrams for three common aluminum fluxing compounds. Actual compositions are selected on the basis of melting point, cost, and performance. (a) KCl-NaCl. (b) Na_3AlF_6-NaCl. (c) NaF-NaCl. Source: Ref 2.

Cleaning fluxes are usually higher in chloride salt compound content and usually contain fluorides to facilitate wetting of the oxide inclusions for easier separation from the melt. Figure 2 illustrates a ternary phase diagram for the ingredients of a commonly used flux.

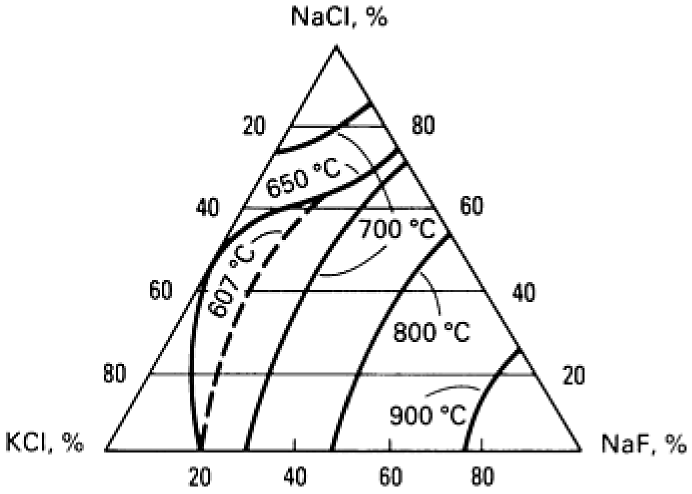

Fig. 2 Ternary phase diagram for a common commercial cleaning flux composition for aluminum alloys. Source: Ref 2.

Drossing fluxes are designed to promote separation of the aluminum oxide (Al_2O_3) dross layer that forms on the surface of the melt from the molten metal. Drosses and liquid or solid metal are usually intermingled in the dross layer. The drossing fluxes are designed to react with Al_2O_3 in the slag or dross layer and to recover metal. These fluxes usually contain compounds capable of reacting exothermically, such as double fluorides and salt compounds that melt (as a eutectic mixture) and increase wettability. The exothermic reaction raises the temperature, thus increasing the local fluidity. The fluorides wet and dissolve thin oxide films according to the general reaction $6Na_2SiF_6 + 2Al_2O_3 \rightarrow 4Na_3AlF_6 + 3SiO_2 + 3SiF_4$. With sufficient mechanical agitation through rabbling with a rake, these films will be broken long enough to release entrapped metal. These fluoride salts, however, cannot dissolve massive Al_2O_3 particles (only electrolysis would suffice, as is used for Al_2O_3 reduction in making primary aluminum).

Drossing fluxes are used to great advantage in the aluminum industry to reduce the rich metallic content of the dross (Ref 3). Untreated dross may contain 60 to 85% free metal, which, if allowed to burn or thermite, will convert to unrecoverable Al_2O_3. Untreated dross is often transferred to separate dross coolers to reduce this reaction. While on the melt surface, however, the dross can be reacted with an exothermic drossing flux and substantial metal recovered, reducing the overall metal content of the dross to about 30%. Considerable cost savings results because proper fluxing action will deliver perhaps 50% metal directly back into the melt. Figure 3 compares rich dross high in metal content with the dry, powdery residue low in metallics after proper fluxing.

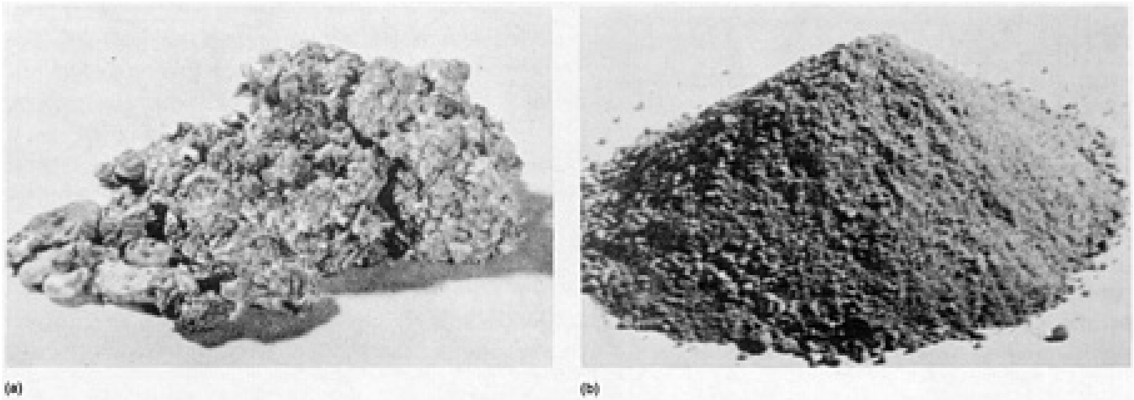

Fig. 3 Comparison of metal-rich (a) and powdery, low-metallic dross (b) from aluminum or zinc alloys. (b) is obtained by proper fluxing.

Refining fluxes contain compounds that break down at use temperature and are thermodynamically favorable to reaction with certain metallic elements in the base melt. For example, certain chlorine-containing compounds will react in molten aluminum containing magnesium, calcium, lithium, sodium, and potassium to form insoluble chlorides of these metals, which will then partition through density differential to the dross phase, where they can be removed by skimming. Sophisticated technologies for impurity refining are addressed in detail in the section "Melt Refining of Aluminum" in this article.

Wall-cleaning fluxes contain compounds that help soften the oxide buildup that occurs on furnace walls. These fluxes can often be applied with a typical refractory gunning device.

Proper Use of Fluxes. Fluxing compounds must be used at temperatures specified by the flux manufacturer to ensure proper reactivity capability. Fluxing compounds are usually hygroscopic to a certain extent and therefore must be stored in a safe, dry place. They should never be used if they are wet, because of the possibility of an explosive reaction. In addition, moisture-wet fluxing material will introduce hydrogen into the aluminum melt, which has great solubility for hydrogen in the liquid state. Tools (shovels, scrapers, rakes, perforated spoons) used to handle fluxes should be kept clean and dry and should always be preheated above 95 °C (200 °F) before use to avoid spitting and popping when they come into contact with the melt.

Flux should be applied in accordance with the manufacturer's recommendations, which have evolved over many years of experience. Cover fluxes can be spread over the melt by hand or with a shovel. Drossing fluxes usually need to be worked into the dross layer. The flux should be thoroughly mixed with this dross layer by rabbling with a rake. Care must be taken not to bring up too much new molten metal into this dross layer when rabbling.

When any flux is used, it should be carefully separated from the melt before pouring or casting. Thorough skimming is required to prevent flux inclusions from becoming entrapped within the cast metal.

In any situation where flux is used, a quiescent time for the bath is recommended to allow adequate settling of heavy inclusions or floating out of lighter-density fluxing salts and flux-wetted oxide inclusions. Optimal settling time may vary from 5 to 10 min for a small crucible melt to 1 to 2 h for a large (45 Mg, or 50 ton) furnace. More information on the fluxing of aluminum alloys is available in Ref 4, 5, and 6 (see also the article "Aluminum and Aluminum Alloys" in this Volume).

Fluxing of Magnesium Alloys

Magnesium and its alloys are exceptionally susceptible to oxidation, melt loss, and fires because of the extreme reactivity between magnesium and oxygen. Protection is therefore always required when melting this alloy family. Historically, this has involved the so-called flux process, which uses salt fluxes as a cover, or more recently the fluxless process, which uses inert gas. Although the latter is now preferred for quality, environmental, and cost reasons, there is still considerable use of the flux process in many magnesium alloy melting operations (see the article "Magnesium and Magnesium Alloys" in this Volume).

Molten magnesium oxidizes readily to form a magnesium oxide (MgO) film. This film is easily disturbed, and discontinuous MgO liquid film inclusions readily wet and coat solid charge materials and can also entrain liquid metal. Fluxes are therefore used to protect the melt from oxidation, to agglomerate nonmetallic inclusions originating with the charge, and to break up and collect the oxide inclusions and skins that may form during melting. These fluxes are usually low-melting mixtures of halide salts capable of wetting both solid and liquid metal surfaces. In addition, they specifically wet MgO skins to aid in their removal. Because the density of molten magnesium alloy is so low (about 1.55 g/cm^3, or 0.056 $lb/in.^3$), it is most desirable and practical for magnesium fluxes to have a higher density than the liquid metal, facilitating better mixing of flux and metal within the melt for maximum efficiency. These fluxes then collect at the bottom of the melting vessel as a sludge that must be drawn off or removed periodically.

Types of Fluxes. A typical flux composition includes approximately 49% $MgCl_2$, 27% KCl, 20% barium chloride ($BaCl_2$), and 4% CaF_2 (Ref 7). The magnesium and potassium chloride salts provide the low-melting eutectic; the fluoride, the surface wettability and chemical reactivity with magnesium oxide; and the heavy barium chloride salt constituent, the density component to effect mixing and sludging capability for separation. Magnesium chloride in the flux also appears to minimize or extinguish burning by providing a thin-film layer on the metal surface, thus retarding magnesium/oxygen reactivity. Other useful cover fluxes include a simple mixture of sulfurous compounds with fluoborate salts or boric acid. However, these merely prevent surface burning and do not clean the melt.

Certain magnesium alloys contain rare-earth elements (mischmetal) as an alloy requirement. Fluxes containing substantial quantities of $MgCl_2$ tend to react with these rare-earth elements. For this reason, most, if not all, of the $MgCl_2$ in the flux can be replaced by more stable $CaCl_2$. However, it is desirable to retain a small amount of $MgCl_2$ to avoid burning on the surface. Therefore, suitable fluxes for rare-earth alloys contain $MgCl_2$ in slight excess only of the CaF_2 content. One flux composition for rare-earth alloys is 28% $BaCl_2$, 26% $CaCl_2$, 10% KCl, 16% NaCl, and 20% MgF_2 (Ref 7).

Use of Fluxes. All flux materials should be kept clean and dry and should be stored in their original containers. All tools used with fluxes should be clean, dry, and preheated to drive off any surface moisture and to minimize thermal shock when placed into the melt.

When melting only ingot or very clean scrap, only a dry flux powder cover to prevent burning or a liquid flux sufficient to melt and form a continuous flux blanket over the molten metal surface need be used. This can be as little as 1% by weight of the melt. However, more flux may be required when melting dirty charge materials, such as gates and runners with oxide and sand debris, scrap castings, or die casting scrap containing lubricants and other contaminants. Indeed, a fluid cover flux is desirable to agglomerate impurities as the dirty charge melts.

The chloride-containing salts used as cover fluxes are hygroscopic and will react in time with moisture in the air to form HCl and oxychloride. This is especially true with $MgCl_2$. Therefore, a flux cover will lose fluidity and begin to crust over, and it is also possible for fine oxide particles to become airborne. When holding molten magnesium alloy for any period of time, it is necessary to replenish the flux cover with fresh flux.

It is often desirable when melting ingot and scrap materials to charge directly into an already molten pool of flux. In this way, the flux precoats the solid metal as it melts to prevent the burning of clean metal, to clean obvious debris, and to prevent further oxidation (Ref 8).

Flux refining is widely used. In this technique, additional flux is mixed into the melt to come into greater contact with the oxide skins and other nonmetallic inclusions (silica sand, and so on) to render them more easily removable. Stirring is usually accomplished with graphite, cast iron, low-carbon steel, or 400-series stainless steel tools. Overmixing, agitation, or violent stirring must be avoided, because the flux globules will break up into a too-fine dispersion that will retard the desired settling of dross or sludge. It is important to allow sufficient settling time when using the flux process for melt refining so that the salt-wetted inclusions can settle into the sludge properly. Settling time is usually at least 10 to 20 min, but it varies with the size of the melt, the nature of the charge, and the amount of flux added.

In addition, the temperature at which flux refining is carried out must be carefully controlled. A normal temperature of about 705 °C (1300 °F) is preferred; this provides the optimum surface energy characteristics between liquid flux and molten metal to achieve good inclusion agglomeration without excessive flux dispersion into fine globules. Lowering the temperature of the melt from 705 °C (1300 °F) to closer to the casting temperature after stirring also helps achieve better flux/metal separation.

Flux/metal separation may be difficult in some magnesium alloys containing zirconium along with iron, zinc, and magnesium. Insoluble metallic compounds of these elements may be present in concentrations exceeding the solubility limit. These insoluble compounds generally collect at the flux/metal interface and favor continued dispersion of the flux globules rather than recoalescence and settling to the sludge (Ref 9).

As with the use of fluxes in other alloy systems, good housekeeping, sludge removal, skimming, and proper handling and pouring practices of the molten alloy must be observed to minimize contamination by flux inclusions. More detailed information on the basis of fluxing processes used for magnesium alloys is available in Ref 7.

Fluxless Melting. The problems associated with the flux melting and refining of magnesium alloys--for example, melt loss, inclusions, and flux disposal problems--have led to the development of the fluxless process. The first protective atmosphere used sulfur dioxide (SO_2). This gas, however, is toxic and malodorous (and thus requires containment and ventilation), and it was necessary to direct the gas atmosphere into direct contact with the molten metal surface to provide satisfactory protection. In addition, SO_2 presents the possibility of an explosion hazard in order to provide satisfactory protection. Therefore, an improved system was still needed.

Sulfur hexafluoride (SF_6) is now commonly used in the fluxless melting process. This gas satisfies the objective of an alternative to salt fluxes, thus eliminating the possibility of salt flux inclusions and high melt loss. In addition, the

corrosive nature of salt flux fumes is avoided. The SF_6 gas is also nontoxic, odorless, and safe (the explosion hazard associated with SO_2 is not present with SF_6).

It is generally believed that SF_6 reacts with molten magnesium to form a continuous layer of MgF_2 on the surface of the melt, serving as a barrier to prevent oxygen from reaching the melt surface and to prevent burning (Ref 10). Because the density of SF_6 is greater than that of air, it readily covers the melt surface and displaces air and oxygen from just above the melt. Very low concentrations of SF_6 are required to achieve the desired result, and it is usually mixed with a less expensive inert carrier gas such as carbon dioxide (CO_2) or nitrogen. Only 0.5 to 1.0% SF_6 is needed. Above 0.8%, SF_6 may cause unwanted corrosion problems with iron and steel equipment used in the melting process and in the environment (Ref 11). It is also necessary to provide proper hooding or sealing of the furnace for optimum economy and to prevent oxygen and air ingestion from drafts.

Fluxing of Copper Alloys

Fluxing practice in copper alloy melting and casting encompasses a variety of different fluxing materials and functions. Fluxes are specifically used to remove gas or prevent its absorption into the melt, to reduce metal loss, to remove specific impurities and nonmetallic inclusions, to refine metallic constituents, or to lubricate and control surface structure in the semicontinuous casting of mill alloys. The last item is included because even these fluxes fall under the definition of inorganic chemical compounds used to treat molten metal.

Types of Fluxes. Fluxes for copper alloys fall into five basic categories: oxidizing fluxes, neutral cover fluxes, reducing fluxes (usually graphite or charcoal), refining fluxes, and semicontinuous casting mold fluxes.

Oxidizing fluxes are used in the oxidation-deoxidation process; the principal function here is control of hydrogen gas content. This technique is still practiced in melting copper alloys in fuel-fired crucible furnaces, where the products of combustion are usually incompletely reacted and thus lead to hydrogen absorption and potential steam reaction (see the section "Degassing of Copper Alloys" in this article). The oxidizing fluxes usually include cupric oxide or manganese dioxide (MnO_2), which decompose at copper alloy melting temperatures to generate the oxygen required. Figure 4 illustrates the effectiveness of oxidizing fluxes in reducing porosity due to hydrogen and in improving mechanical properties for a tin bronze alloy.

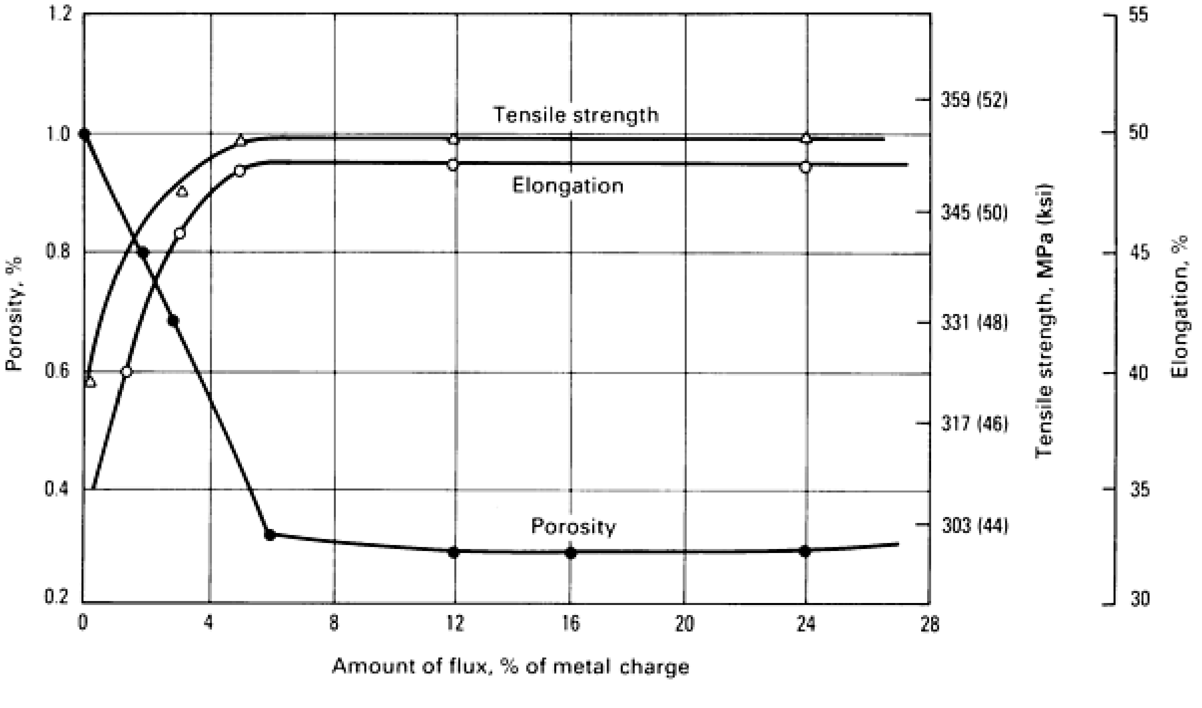

Fig. 4 Effect of amount of flux used on the porosity and mechanical properties of cast tin bronze alloy. Source: Ref 12.

Neutral cover fluxes are used to reduce metal loss by providing a fluid cover. Fluxes of this type are usually based on borax, boric acid, or glass, which melts at copper alloy melting temperatures to provide a fluid slag cover. Borax melts at approximately 740 °C (1365 °F). Such glassy fluxes are especially effective when used with zinc-containing alloys, preventing zinc flaring and reducing subsequent zinc loss by 3 to 10%. The glassy fluid cover fluxes also agglomerate and absorb nonmetallic impurities from the charge (oxides, molding sand, machining lubricants, and so on). As with aluminum alloys, fluxes containing reactive fluoride salts (CaF_2 and NaF) can strip oxide films in copper-base alloys, thus permitting entrained metallic droplets to return to the melt phase. Table 2 indicates the effectiveness of this type of flux in reducing melt loss in yellow and high-tensile brass. For red brasses, however, it may not be proper to use a glassy flux cover, because such a cover will prevent or limit beneficial oxidation of the melt (see the section "Degassing of Copper Alloys" in this article). Use of a glassy cover flux can sometimes result in reduced alloy properties (Ref 12).

Table 2 Effect of various slags and covers on losses in the melting of high-tensile and yellow brass

Alloy	**Melting conditions**	**Metal temperature**		**Melting time, min**	**Gross loss, %**	Net loss, %
		°C	**°F**			
Yellow brass	No lid or cover	1085	1985	50	2.8	**1.8**
Yellow brass	Charcoal	1087	1989	49	1.1	**0.6**
Yellow brass	Glassy cover flux	1100	2012	62	0.9	**0.4**
High-tensile brass	No lid or cover	1090	1994	65	2.5	**1.2**
High-tensile brass	Charcoal	1095	2003	60	1.9	**0.7**
High-tensile brass	**Cleaning cover flux**	**1090**	**1994**	**54**	**0.6**	**0.3**

Oxide films in aluminum and silicon bronzes also reduce fluidity and mechanical properties. Fluxes containing fluorides, chlorides, silica, and borax provide both covering and cleaning, along with the ability to dissolve and collect these objectionable oxide skins. Chromium and beryllium-copper alloys oxidize readily when molten; therefore, glassy cover fluxes and fluoride salt components are useful here in controlling melt loss and achieving good separation of oxides from the melt.

Reducing fluxes containing carbonaceous materials such as charcoal or graphite are used on higher-copper lower-zinc alloys. Their principal advantage lies in reducing oxygen absorption of the copper and reducing melt loss. Low-sulfur, dry, carbonaceous flux materials should always be used with copper alloys to avoid gaseous reactions with sulfur or with hydrogen from contained moisture. However, carbonaceous materials will not agglomerate nonmetallic residues or provide any cleaning action when melting fine or dirty scrap. For this reason, a glassy cover must also be used in the latter case. Table 2 indicates the beneficial effects of a glassy cover when melting brass turnings.

Use of Fluxes. As with all fluxes, the flux materials for copper alloys should be stored in a clean dry place and should be kept covered to prevent contamination from unwanted materials. Manufacturer's recommendations should always be followed. The tools used must be kept clean and dry. Because many flux materials are hygroscopic, tools with flux residue from previous use will pick up moisture. Any residual flux should be cleaned from the tool, and the tool should be preheated above 105 °C (225 °F) before its reuse. Proper rabbling must be done when required for optimum flux reactivity, and fluxes should be thoroughly skimmed from the melt surface before or during pouring to prevent flux

entrapment during the casting process. Unlike aluminum or magnesium, most copper fluxes have significantly lower density than the base metal; this permits easy gravity separation before skimming and facilitates skimming.

Melt Refining of Copper Alloys. It is possible to remove many metallic impurity constituents from copper alloys through the judicious use of fire refining (oxidation). According to standard free energy of reaction (Fig. 5), elements such as iron, tin, aluminum, silicon, zinc, and lead are preferentially oxidized before copper during fire refining (Ref 13), and there is an order of preference for their removal (Fig. 6). These metallic impurities are thus rendered removable if the oxide product formed can be adequately separated from the melt phase itself. A wet cover flux such as borax is useful with fire refining because it will agglomerate the impurity metal oxides formed and minimize the metal content of the dross.

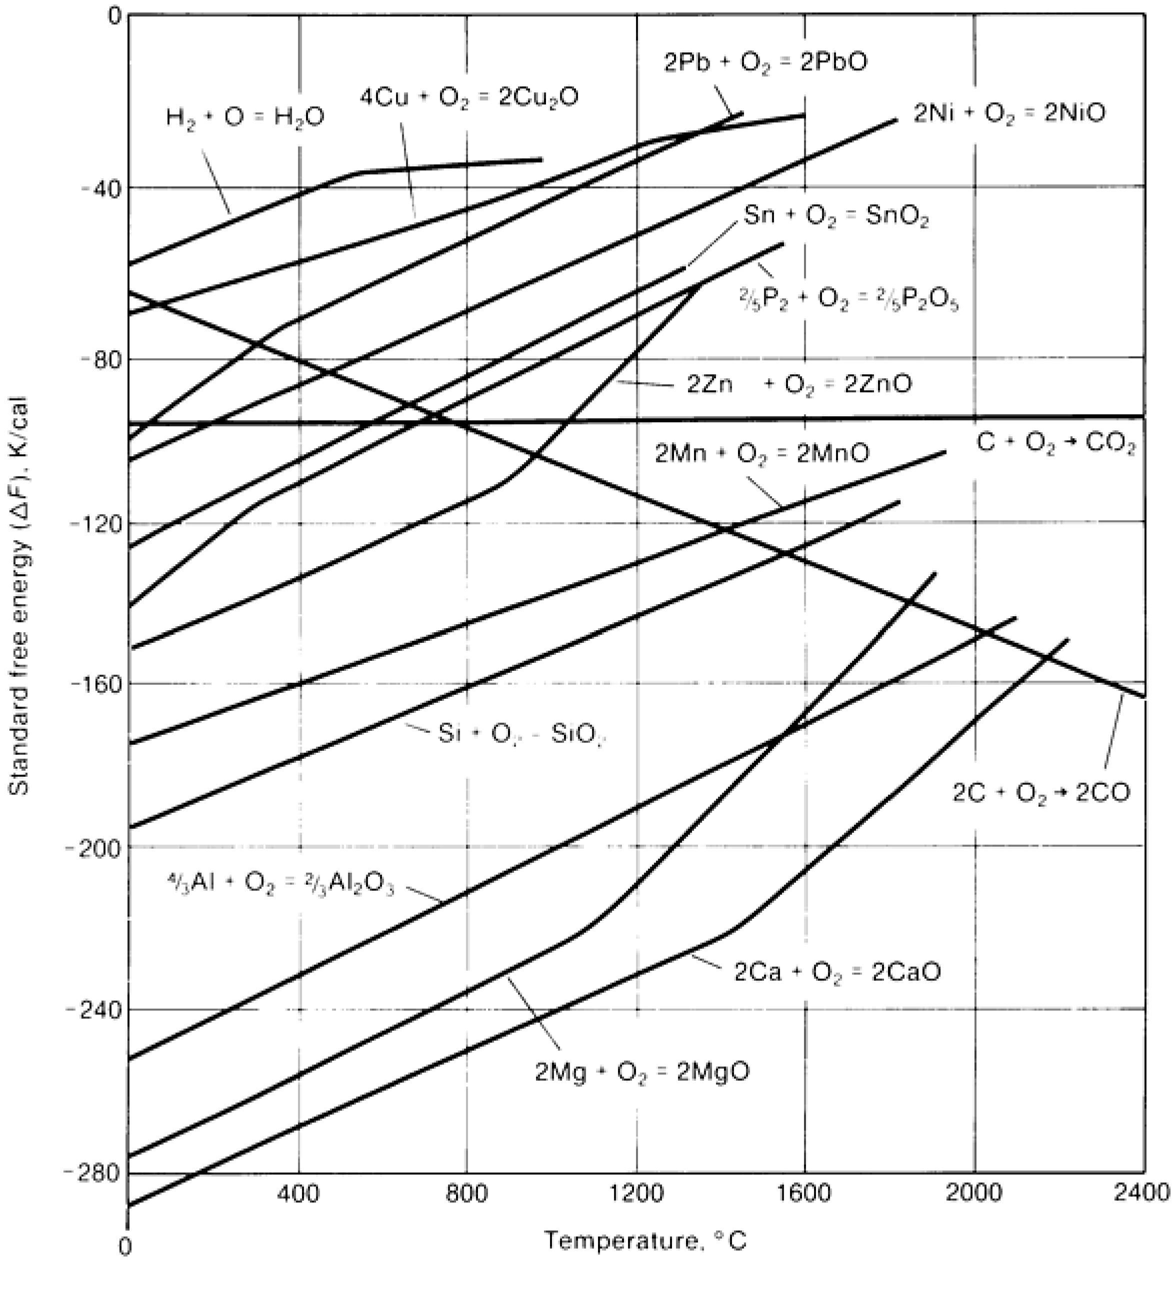

Fig. 5 Free energy changes for various metal oxidation reactions. Source: Ref 12.

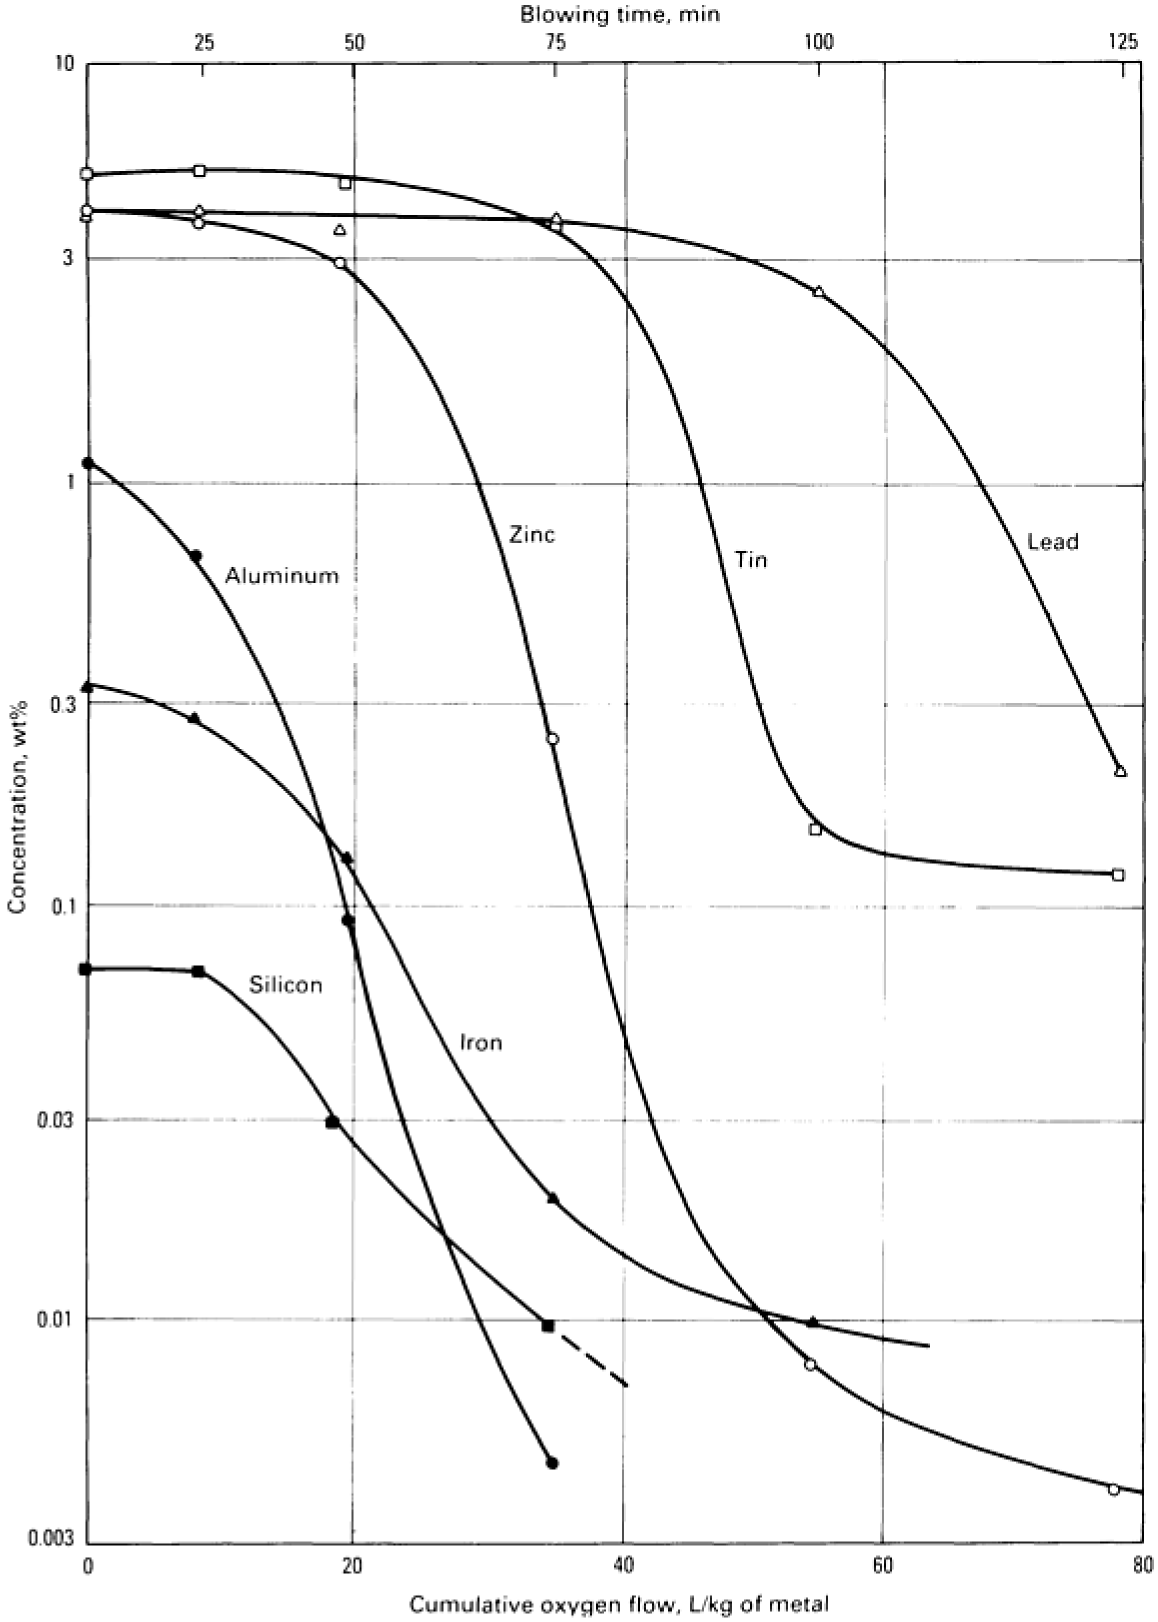

Fig. 6 Effect of fire refining (oxygen blowing) on the impurity content of molten copper. Source: Ref 14.

The need to refine specific metallic impurities is highly dependent on and variable with the specific alloy system being refined. An alloying element in one family of copper alloys may be an impurity in another, and vice versa. In red brass (Cu-5Zn-5Pb-5Sn; UNS/CDA C83600), the elements lead, tin, and zinc are used for alloying, while aluminum, iron, and

silicon are impurities. In aluminum bronzes, on the other hand, lead, tin, and zinc become contaminants, while aluminum and iron are alloying elements.

Foundries typically do little melt refining, leaving this assignment to the secondary smelter supplier of their foundry ingot. However, there may be certain instances when additional refining capability is necessary within the foundry or mill. Table 3 gives the results of fire refining a melt of C83600 with aluminum, silicon, and iron contaminants under a variety of flux covers.

Table 3 Effect of fire refining under various fluxes on impurity levels in leaded red brass

50 kg (110 lb) heats were melted under 1 kg (2.2 lb) of flux at 1150 °C (2100 °F).

Melt No.	**Flux**	**Refining time, min**	**Oxygen used, liters per kilogram of metal**	**Amount of zinc in refined metal, %**	Impurities in refined metal, %

Fire refining (oxidation) can be used to remove impurities from copper-base melts roughly in the following order: aluminum, manganese, silicon, phosphorus, iron, zinc, tin, and lead. Nickel, a deliberate alloying element in certain alloys but an impurity in others, is not readily removed by fire refining, but nickel oxide can be reduced at such operating temperatures. Mechanical mixing or agitation during fire refining improves the removal capability by increasing the reaction kinetics. Removal is limited, however, and in dilute amounts (<0.05 to 0.10%) many impurities cannot be removed economically.

Oxygen-bearing fluxes can be effective in removing certain impurities, although they are less efficient than direct air or oxygen injection. Figure 7 demonstrates the effect of increasing the copper oxide content of a flux in removing iron and zinc from phosphor bronze.

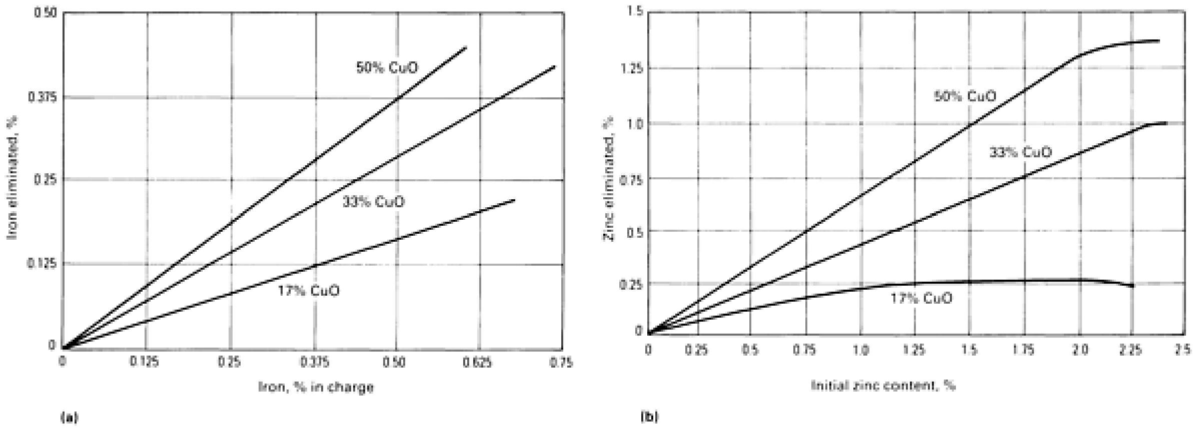

Fig. 7 Influence of oxygen content of flux in reducing iron (a) and zinc (b) impurities in phosphor bronze. Source: Ref 12.

Lead has been removed from copper alloy melts by the application of silicate fluxes or slags. The addition of phosphor copper or the use of a phosphate or borate slag flux cover and thorough stirring improves the rate of lead removal, as shown in Fig. 8 (Ref 15).

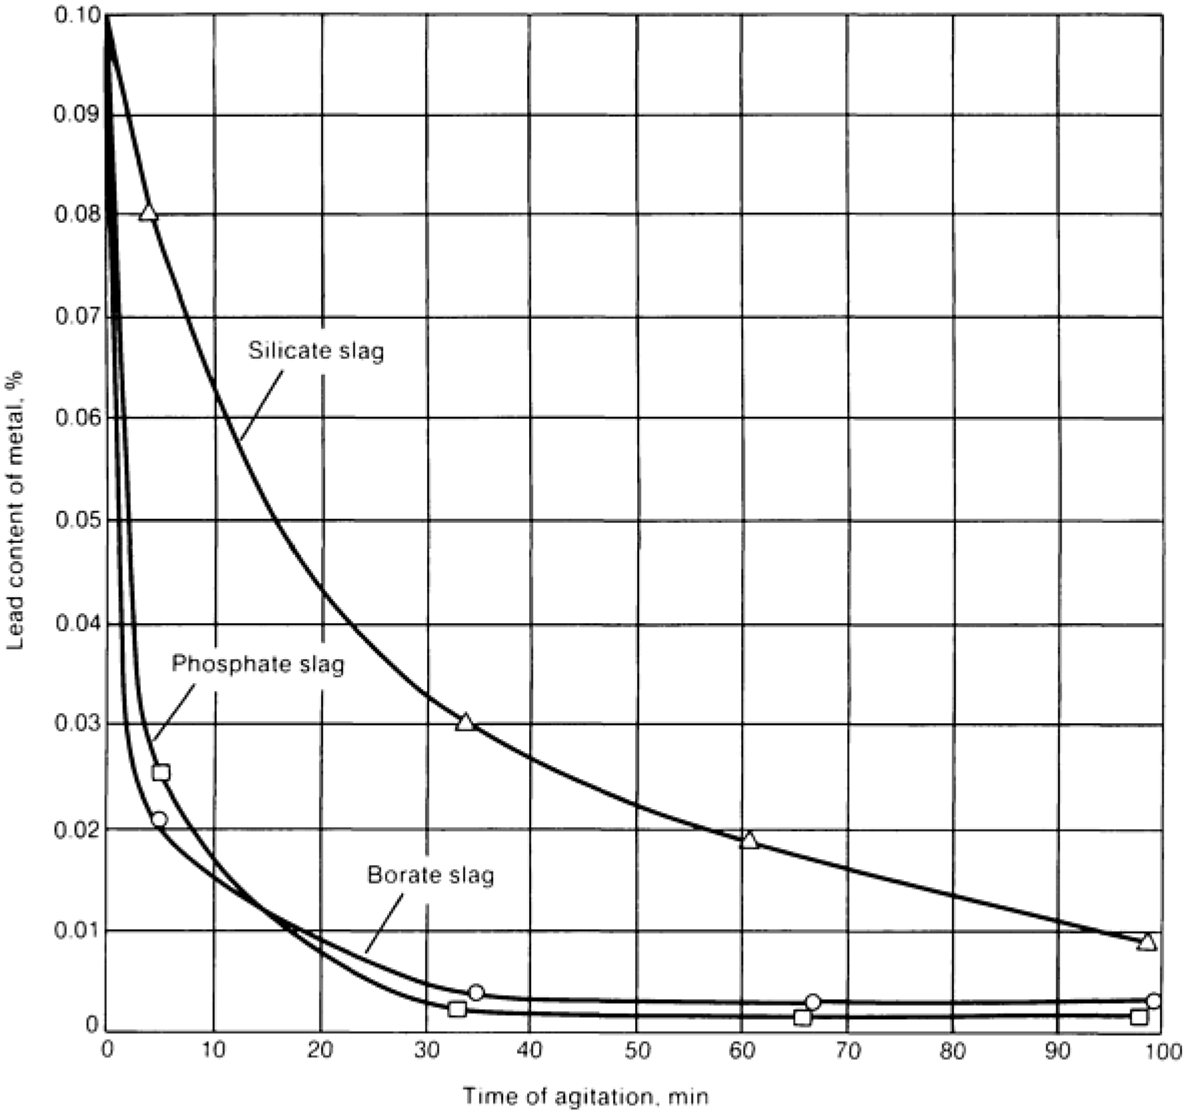

Fig. 8 Removal of lead from oxidized Cu-0.1 Pb melts at 1150 °C (2100 °F by different slags (fluxes) 2% of charge weight. Melt stirred with nitrogen at 2 L/min. Source: Ref 15.

Sulfur, arsenic, selenium, antimony, bismuth, and tellurium can occur as impurities in copper alloy scrap, foundry ingot, and prime metal through incomplete refining of metal from the ore, electronic scrap, other scrap materials, or cutting lubricant. These impurities can largely be controlled by application and thorough contacting with fluxes containing sodium carbonate (Na_2CO_3) or other basic flux additives such as potassium carbonate (K_2CO_3). Figure 9 demonstrates the ability of Na_2CO_3 fluxes plus fire refining in eliminating arsenic, bismuth, and antimony from copper.

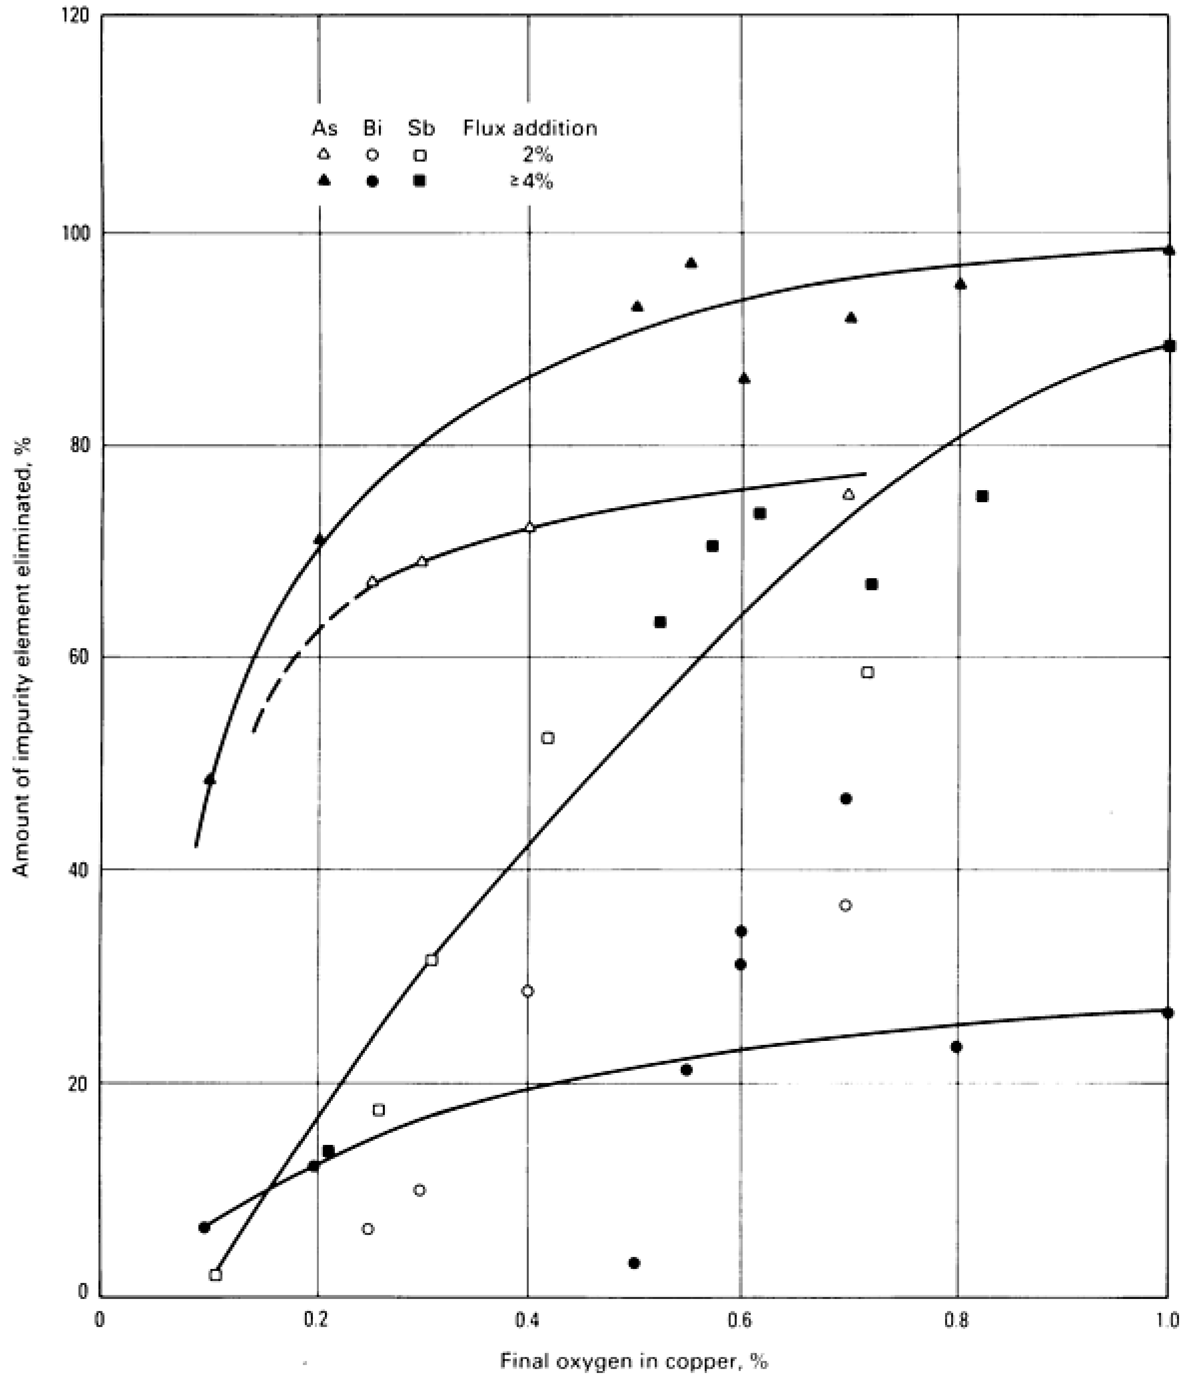

Fig. 9 Effect of fire refining and use of Na_2CO_3 flux on removal of arsenic, bismuth, and antimony impurities from copper. Source: Ref 16.

Sulfur is a harmful impurity in copper-nickel or nickel silver alloys. It can be removed from these materials by an addition of manganese metal or magnesium.

Aluminum is often a contaminant in copper alloy systems, particularly the leaded tin bronzes and red brasses. Porosity and lack of pressure tightness result when the aluminum content is as little as 0.01%. Aluminum can be removed by a flux containing oxidizing agents to oxidize the aluminum, and fluoride salts to divert the Al_2O_3 from the melt and render it removable. Silicon can also be removed, but only after the aluminum has reacted. As much as 0.3% contaminant can be reduced to less than 0.01%, ensuring pressure tightness, by using a flux consisting of 30% NaF, 20% CaF_2, 20% Na_3AlF_6, 20% Na_2SO_4, and 10% Na_2CO_3 at an addition rate of 1 to 1.5% for 10 min at about 1100 °C (2010 °F) (Ref 17). As usual,

the flux must be intimately mixed with the melt to ensure good reactivity. The melt should then be allowed to settle, and the flux residue or slag layer should be thoroughly skimmed.

Borax is useful as a flux constituent for refining to provide adequate fluidity and to agglomerate flux-reacted impurity oxides without excessive entrapment and loss of alloying elements. The borax mineral fluxes razorite and colemanite are commonly used in secondary smelting practice in converting copper alloy brass and bronze scrap to specified-composition foundry ingot.

Chlorine fluxing also has potential for refining impurities from copper-base melts, particularly magnesium, aluminum, manganese, zinc, iron, lead, and silicon. However, very little chlorine refining is practiced commercially; the process may be cost effective only when removing aluminum.

Mold Fluxes. Certain mold-lubricating fluxes have been used in the direct chill semicontinuous casting of brass and copper alloys into semifinished wrought shapes. These fluxes serve to protect the metal from oxidation during casting. They also act as lubricants so that the solidifying skin separates easily from the mold wall as the solidifying billet or slab moves downward from the mold during casting. Especially in brass alloys, zinc flaring and zinc oxide (ZnO) formation on the melt surface reduce lubricity, causing tearing and other undesirable skin defects during solidification that are detrimental to subsequent forming operations. Fluxing compounds are used on the melt surface feeding the mold to alleviate these problems. Fluxes used to alleviate this problem usually contain borax, fluoride salts, soda ash, and eutectic salt mixtures to ensure that the flux is molten as the cast continues. In the direct chill casting of higher-copper alloys, graphite may also be present in such fluxes. Because solid flux particles can cause inclusions in the solidifying skin, the flux must be free of coarse particles and must melt quickly.

Fluxing of Zinc Alloys

In the melting of clean, pure zinc and zinc alloys, there is little need for cover fluxes to protect the melt because zinc does not oxidize appreciably or absorb hydrogen at normal melting temperatures. However, chloride-containing fluxes that form fluid slag covers can be used to minimize melt loss if they are carefully skimmed from the melt before pouring. When melting dirty metal, scrap returns, and the like, both a cover flux and a reactive flux are advantageously used to separate entrapped metal from oxides.

The principal alloying elements present in zinc die casting alloys include aluminum, magnesium, and copper. Manganese and silicon may be present as impurities in the remelt; chromium and nickel are often seen when plated scrap is remelted. In most cases, zinc die casting alloys can tolerate these impurity amounts up to the limit of their solubility during solidification (generally $<0.02\%$). The quantities of these elements present in excess of solubility limits will form oxides and/or complex intermetallic compounds, especially when iron is present (from melting or casting vessels). It is possible to collect some of these impurity constituents, particularly oxides, in the dross phase; therefore, a fluid slag or flux cover is beneficial. At typical zinc melt operating temperatures, various mixtures of zinc chloride ($ZnCl_2$), KCl, and NaCl form the basis of such fluxes. These fluxes will also agglomerate nonmetallic residues and contaminants from dirty scrap and will help cleanse charge materials during remelting (Ref 18).

The zinc alloy drosses that form during melting, holding, turbulent transfer, and remelt operations can contain as much as 90% entrapped finely divided free metallic zinc, in addition to oxides, intermetallic compounds, and other debris. An exothermic drossing flux, usually containing nitrate salts and silicofluoride double salts, can be used to recover much of this entrapped zinc. The exothermic reaction, assisted by rabbling or raking the flux into intimate contact with the dross phase, serves to raise the local temperature, increase fluidity, decrease the surface tension of the oxide skin, and chemically reduce ZnO.

Proper fluxing procedures will permit more than half of the entrapped zinc to be recovered, yielding only about 35 to 40% unrecoverable and oxidized fines. The amount of flux to be added is often determined empirically and is usually 1 to 4.5 kg (2 to 10 lb) per ton of metal being treated, but this may vary considerably. Suitable melt temperatures are usually above 480 °C (900 °F). As the flux is worked into the dross, the rich metallic appearance will give way to a drier, duller, and more powdery residue ready for final skimming (Fig. 3).

The dross reclamation process is often carried out directly on zinc remelt pot furnaces. Alternatively, a separate dross mixer consisting of a vessel and a rotating paddle is used in which hot drosses and flux are added, mixing begins, and the fluid metal being recovered runs out the bottom and is collected in an ingot mold beneath the dross mixer.

Galvanizing Fluxes

Galvanizing is the practice of applying a protective zinc or zinc alloy coating on iron or steel surfaces. The zinc oxidizes or is attacked preferentially and thus protects the underlying metal from corrosion.

In hot dip galvanizing, the articles to be coated are immersed in molten zinc in a galvanizing tank or kettle at a temperature ranging from 450 to 460 °C (840 to 860 °F). A molten salt flux is usually maintained on the surface of the kettle, serving a number of important functions. The flux serves as a preheating and drying medium to reduce sputtering and explosions, and it keeps the galvanizing zinc metal itself free from oxides. The flux also precleans the article being galvanized.

The principal ingredients of galvanizing fluxes include ZnCl, ammonium chloride (NH_4Cl), zinc ammonium chloride ($ZnCl_2 \cdot NH_3$), and occasionally other chloride salts used as extenders. Typical reactions that take place in the flux during the galvanizing process include:

$$2NH_4Cl + Zn \rightarrow H_2 + NH_3 + ZnCl_2 \cdot NH_3 \quad \textbf{(Eq 1)}$$

$$2NH_4Cl + FeO \rightarrow H_2O + 2NH_3 + FeCl_2 \quad \textbf{(Eq 2)}$$

$$FeCl_2 + Zn \rightarrow Fe + ZnCl_2 \quad \textbf{(Eq 3)}$$

$$2NH_4Cl + ZnO \rightarrow H_2O + NH_3 + ZnCl_2 \cdot NH_3 \quad \textbf{(Eq 4)}$$

Equation 1 explains the occurrence of zinc consumption, hydrogen fires in the flux, and ammonia odors. Equations 2 and 3 show how the flux dissolves iron oxide and how elemental iron is freed both to alloy with zinc (desirable) and to form dross (undesirable). When fresh flux containing the active ingredient NH_4Cl is added to partially spent flux, the high-melting viscous basic zinc chlorides (shown as ZnO) are converted to the lower-melting zinc ammonium chlorides. Figure 10 shows the phase diagram of the $ZnCl_2/NH_4Cl$ system. At a normal operating temperature of 455 °C (850 °F), NH_4Cl would vaporize. However, the liquidus boundary indicates that as the mixture becomes richer in $ZnCl_2$, the mixture of chloride can contain 3 to 4% NH_4Cl and remain a liquid rather than become a gas. Foaming agents (glycerin) are often added to slow the loss of NH_4Cl due to vaporization.

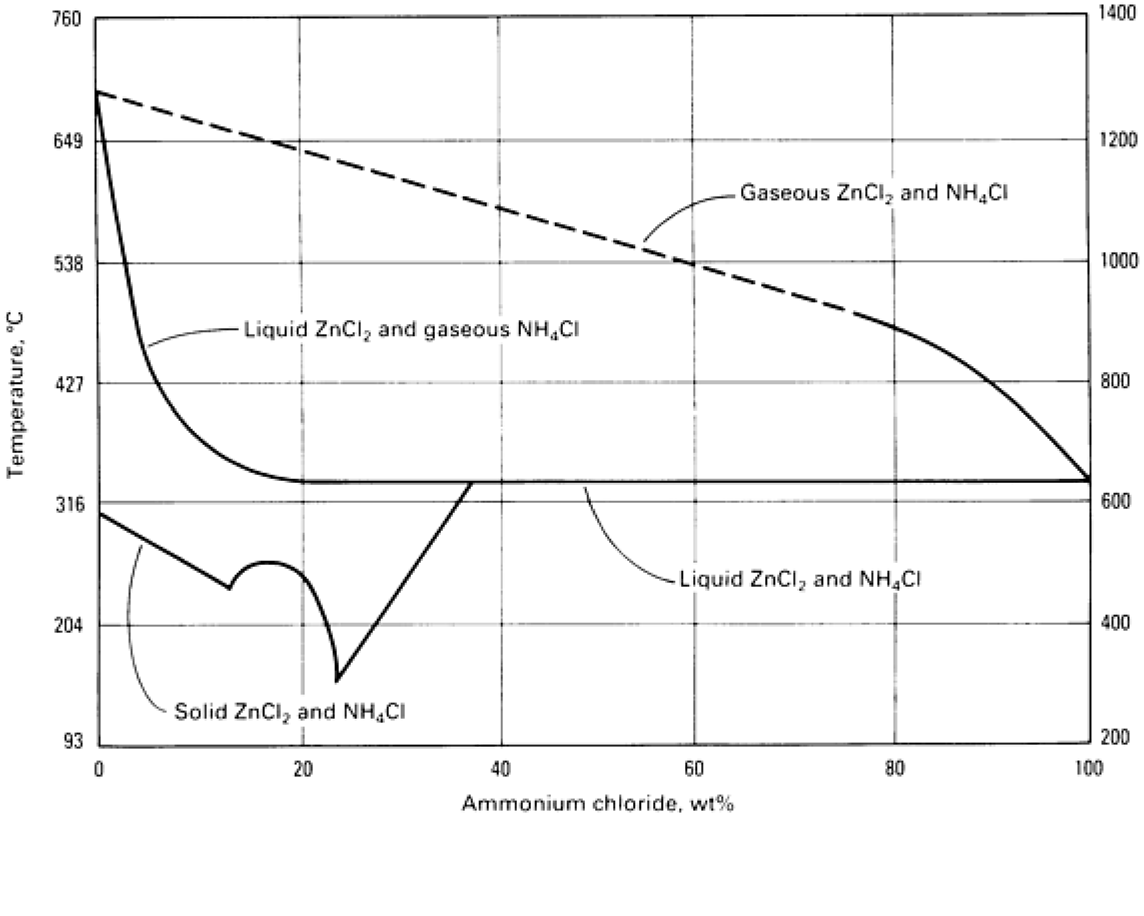

Fig. 10 Binary phase diagram for the system $ZnCl_2/NH_4Cl$. Source: Ref 19.

The working galvanizing flux is therefore metastable. Because NH_4Cl is lost through vaporization and is used up in reactions, fresh flux containing NH_4Cl must be added continuously to keep the flux active. The viscosity of the flux will also increase because of the loading or buildup of high-melting zinc and iron oxides and debris carried in with the steel articles. The addition of fresh flux reduces viscosity by converting these compounds to ammoniated zinc chloride.

Aluminum is often added (usually <0.1%) to galvanizing baths to serve as a brightener for the zinc coating on the workpiece. Aluminum oxidizes readily and will also form $AlCl_3$. The viscosity of the flux is increased with the presence of Al_2O_3, and $AlCl_3$ formation depletes the flux of active NH_4Cl.

Flux Injection

Flux injection is a relatively new process in which fluxing compounds are introduced into the molten metal by a mechanical device using an inert gas carrier. Typical components of the flux injection process, shown schematically in Fig. 11, consist of a flux feeder supply, a mixing chamber for the inert gas carrier and the flux, and a lance for injecting the flux. Appropriate nozzle mixing technology and the use of special lance materials and insulated construction have been developed by the manufacturers of flux injection equipment to overcome clogging and premature melting or reaction of flux materials within the lance.

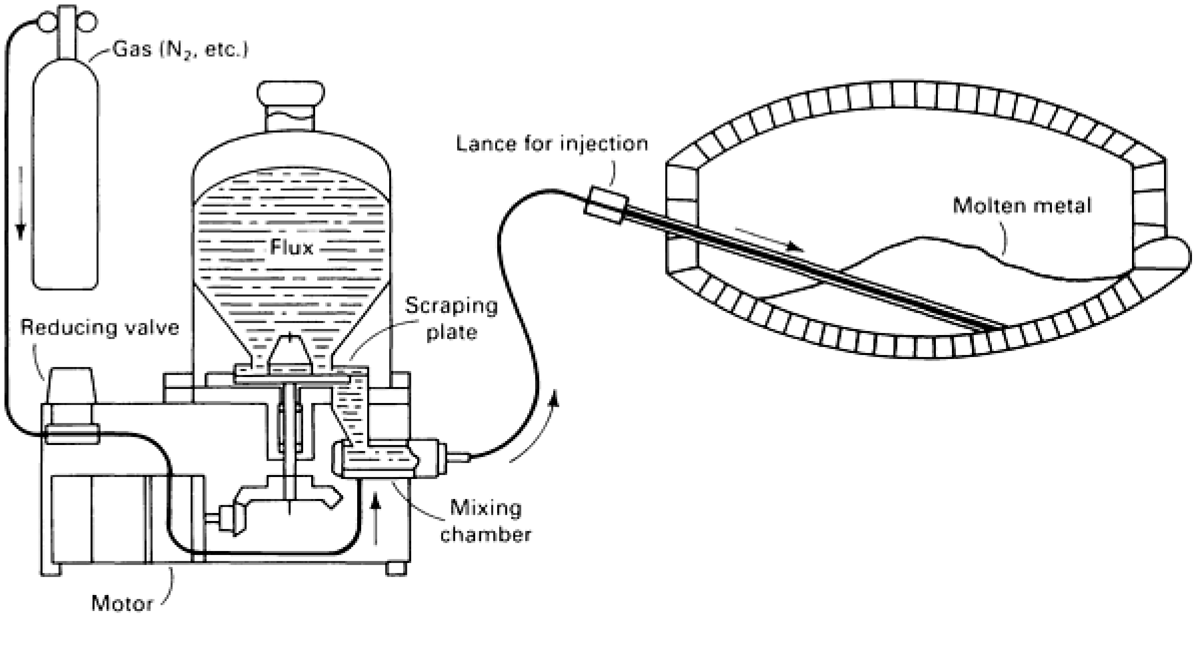

Fig. 11 Schematic of the flux injection process. Source: Ref 20.

Current manual application of fluxing compounds usually involves surface application and subsequent manual raking or rabbling of the flux to achieve good mixing and reactivity. Essentially, the manual process is labor intensive and is often merely a surface or near-surface treatment limited to the dross and the molten metal immediately adjacent to the dross layer. Flux injection permits better reactivity and mixing through the bubbling action of the inert gas carrier, and it also permits refining of the full molten metal bath because it submerges the fluxing materials to substantial depths within the melt. The fluxing materials can thus be used to full efficiency. The injection process can be automated for specific injection amounts and treatment times, thus minimizing waste. Additional benefits of the flux injection process include reduced treatment times over manual methods, less metal loss in the dross, and fewer emissions.

It has been reported that all aspects of molten metal treatment are possible with flux injection. Most of these techniques are being practiced in the aluminum industry, though not extensively. There has been little activity thus far with other nonferrous metals. Capabilities of flux injection are summarized below.

Degassing can be accomplished with the carrier gas itself or with an inert gas plus compounds such as hexachloroethane. The hexachloroethane decomposes to form chlorine, which then forms an $AlCl_3$ gas bubble that collects hydrogen gas as it ascends to the melt surface. At an addition rate of 0.2%, a 10-min flux injection treatment is reported to be capable of reducing hydrogen content from 0.35 mL/100 g to as little as 0.05 mL/100 g (Fig. 12a). This level of hydrogen is more than acceptable for all aluminum foundry alloy applications.

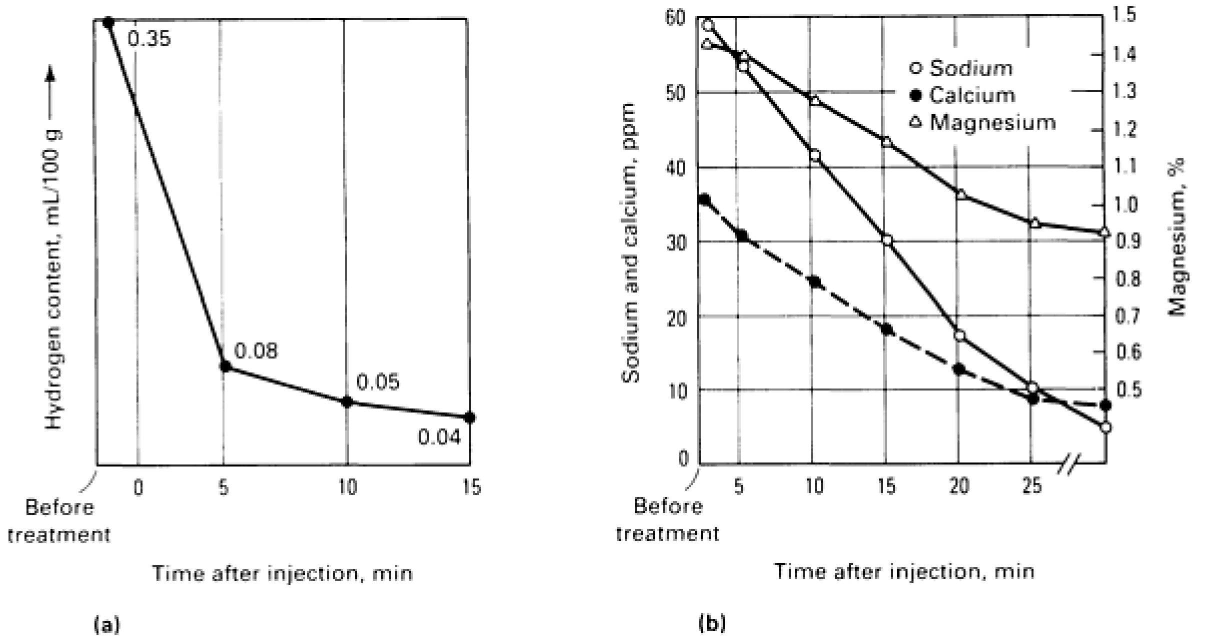

Fig. 12 Effectiveness of flux injection in removing hydrogen (a) and alkali metals (b) from an aluminum alloy melt. Source: Ref 20.

Nonmetallic inclusions can be removed by injecting salt fluxes that dewet these particles from the molten aluminum. Varying amounts of flux can be added in the range of 0.2 to 0.5% by weight of the entire melt. A settling time or standing time of the melt (usually 5 min for small foundry melts) is required to allow flux particles and nonmetallic inclusions to agglomerate and float to the surface for removal.

Hypoeutectic Alloy Modification. In aluminum alloys with less than 12% Si, the as-cast structure is very coarse, with an acicular silicon eutectic phase. Modifiers are therefore added to cause this structure to be a more rounded, dispersed phase with better mechanical properties. Modification is usually achieved by using sodium, strontium, calcium, or antimony in the form of pure metals, master alloys, or salt fluxes that contain these modifiers. Currently, injection fluxes containing sodium salts are available and are used at an addition rate of 0.2 to 0.4% to achieve modification.

The modification process, however, is sensitive to several variables, and reversion of the structure back to the unmodified state is well recognized. Higher silicon contents, temperatures, turbulence, standing times, and melt surface areas favor reversion.

Grain Refinement. The flux injection process can be used to grain refine aluminum melts. Conventional applications would use master alloys or salts containing titanium and boron, which decompose and recombine to form a fine titanium diboride particle that serves as a nucleating agent during the solidification of the cast structure. Titanium carbides have also been used. It has been reported that a titanium addition in the range of 0.45 to 0.90% and a carbon level of 0.003 to 0.005% are sufficient to form the titanium carbide sites required for grain nucleation (Ref 21). The dispersion capabilities of the fluxing injection process enhance the effective use of whichever titanium compound and grain-refining mechanism is employed.

Alkali Metal Removal. Calcium, sodium, lithium, and magnesium impurities can be removed from aluminum alloy melts to a large extent by employing salt fluxes and/or reactive gas mixtures that contain chlorine and fluorine. Such halogen compounds react preferentially with the impurities to form chlorides and/or fluorides with different densities,

which will then separate from the base melt. Figure 12(b) shows the results of alkali impurity removal with a 0.36% by weight flux injection.

Hypereutectic Silicon Refinement. Hypereutectic aluminum alloys (>12% Si) form a primary silicon phase upon solidifying. Although these alloys depend on the properties provided by silicon (strength, wear resistance), it is important to avoid coarse primary silicon structures, which cause reduced mechanical properties and poor machinability. Refinement of this structure is therefore usually accomplished through an addition of 0.007 to 0.01% P, depending on silicon content. Pure phosphorus is an explosion and fire hazard, and the commercially available phoscopper shot often employed adds copper to the melt. A nickel-phosphorus compound (Ni_3P) is reported to provide favorable phosphorus recovery and reaction.

It is expected that advances in flux injection technology will give rise to additional possibilities, including perhaps multipurpose fluxes that will perform several molten metal treatment functions in a single injection. Although currently limited to smaller foundry applications, flux injection is being explored on a larger scale to produce aluminum alloys by the metal powder or flux injection of such alloying elements as magnesium, silicon, manganese, copper, and iron (Ref 22, 23, 24).

Circulation of Aluminum Melts (Forced Convection)

In the melting of aluminum and its alloys, forced convectional heat transfer within the melt often plays an important role. There is a considerable latent heat of fusion (95 cal/g) associated with taking aluminum at its melting point from a solid to a liquid. Forced convection assists this transition, particularly for larger volumes of metal, by better mixing of the solid metal with already molten metal, thus reducing time and energy input into the melting process. Other nonferrous alloys, such as zinc, magnesium, and copper, could also benefit from molten metal circulation, but pumping systems for circulation are not usually employed. Mechanical stirrers are effective, particularly for zinc, owing in part to the lower heat of fusion of zinc and the smaller melt sizes usually used.

Heat Transfer in an Aluminum Furnace. In a gas- or oil-fired aluminum reverberatory furnace, heat is transferred to the bath from the burners by radiation (see the discussion of reverberatory furnaces in the article "Melting Furnaces: Reverberatory Furnaces and Crucible Furnaces" in this Volume). The furnace roof and walls are heated and radiate this heat energy onto the bath surface. High wall and roof temperatures create a significant thermal head to the melting furnace. Radiant heat is absorbed by the molten metal or charge to the extent of its heat capacity. Other types of heat transfer (conduction and convection) must take place to transmit thermal energy further, either in the solid charge or the molten metal. Conduction is a fundamental property of the material in question (aluminum or an aluminum alloy). Convection--heat transfer in a gas or liquid by moving masses of matter--is influenced by momentum and velocity within the molten metal. Natural convection takes place because of the density and thermal gradients within a molten metal bath, but it is extremely small in magnitude compared to forced convection.

Forced convection enables the radiant heat energy absorbed by the bath surface to move, that is, to be transmitted throughout the bath depth, so that a steady heat flux is developed and continuing heat transfer to the surface occurs by radiation. Without such forced convection, the surface layer of the molten metal becomes heat saturated, and the surface temperature rises. Ultimately, excessive surface temperature will result in oxidation and dross buildup, which reduces energy efficiency. Forced convection is produced by the circulation of the molten metal bath, either by stirring (in small pot furnaces, crucibles, and so on) or by using a molten metal circulation pump (in larger furnaces of 2000 to 110,000 kg or 5000 to 250,000 lb, capacity). Forced convection improves the heat transfer rate and energy efficiency.

The Molten Metal Pump (Ref 25, 26). Forced circulation is usually best achieved in large furnaces by using a submerged discharge molten metal pump. Although several types of pumps have appeared over the years (electromagnetic, pressure), the centrifugal pump is the most common type currently used. These pumps are usually installed in the pump wells of the open-well reverberatory furnaces used for remelting in large aluminum foundries, die casting operations, secondary smelters producing foundry ingot, and in mill products casthouses. Figure 13 shows a typical installation.

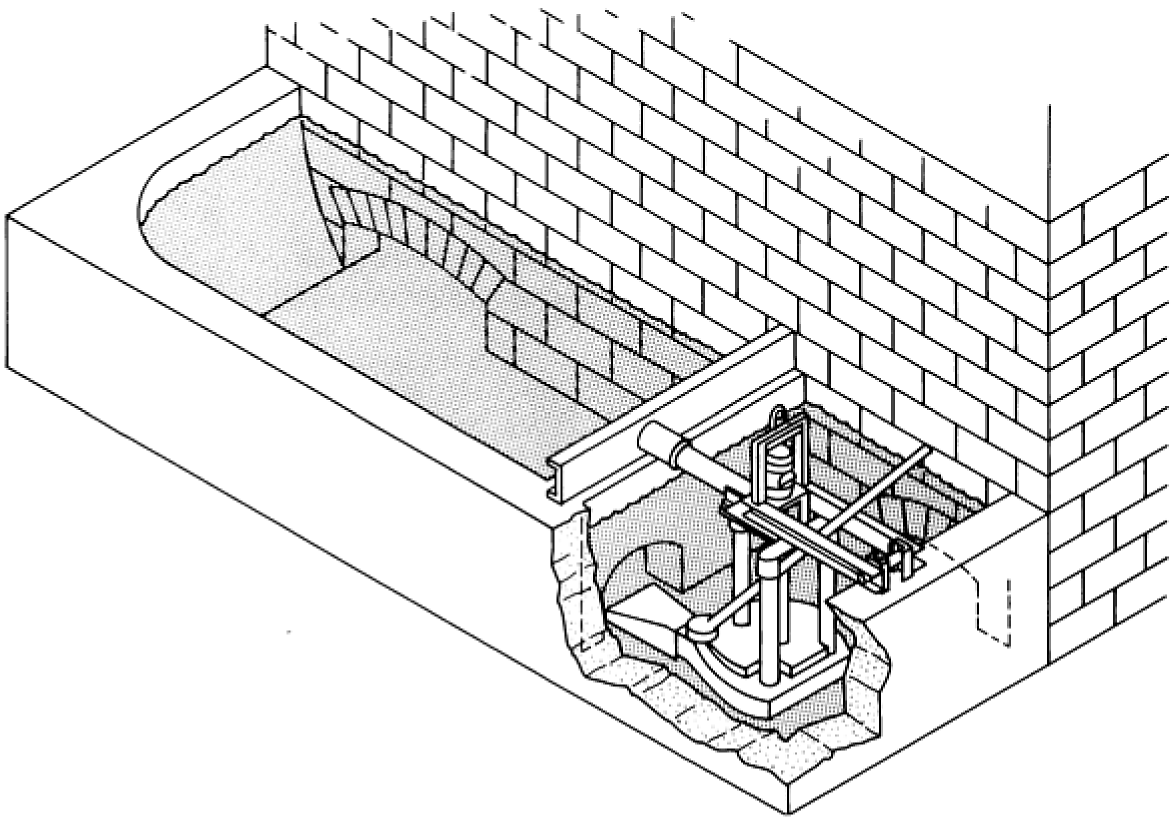

Fig. 13 Typical placement of a molten metal gas injection/circulation pump in an open-well reverberatory aluminum-melting furnace.

Forced circulation, which provides the highest convectional heat transfer, is related to the kinetic energy imparted to, and thus the velocity of, the moving molten metal. A centrifugal pump creates a steady flow and a discharge velocity in direct proportion to the speed of impeller rotation. Pumps operating on other principles are generally not capable of producing steady fluid flows or discharge velocities as high as those associated with centrifugal pumps. Accordingly, these systems are not as efficient or as capable of producing maximum forced circulation as a centrifugal pump. For example, one electrically driven centrifugal pump can create a discharge velocity measured in excess of 5.6 m/s (1100 ft/min), while certain electromagnetic pumps can create an equivalent velocity component of about 0.76 m/s (150 ft/min) (Ref 27).

Advantages of Forced Circulation. Centrifugal circulation pumps increase energy efficiency, productivity, and quality. Improved melting rates, reduced energy consumption, elimination of stratification in the bath, and longer furnace refractory life are among the potential benefits (Ref 25, 26).

For example, 50 to 100% improvements in melt rates in remelt operations are not uncommon. In one installation, a 4.5 Mg (5 ton) charge was increased to 10 Mg (11 tons) in the same melting time. In many cases, melt cycles in large furnaces have been cut in half. Lesser improvements, although still quite cost effective, have also been realized in many installations.

Energy consumption (as measured by energy used per unit weight of aluminum produced) has also been significantly reduced. Use of a circulation pump has commonly resulted in energy savings ranging from 1160 to 4600 kJ/kg (500 to 2000 Btu/lb). Overall energy consumption in open-well scrap melting can be reduced to well below 4600 kJ/kg (2000 Btu/lb) with a pump and prudent furnace management. Smaller furnaces (<18 Mg, or 20 ton, capacity) in foundry operations can show energy usage as low as 2300 kJ/kg (1000 Btu/lb) using molten metal pumping, combined with other technologies such as heat recuperation and regenerative burner systems. Preheating the charge can also substantially reduce the energy input required for melting.

A circulation pump provides better mixing of the melt and charge, and it overcomes stratification in bath temperature and alloying inhomogeneity. In an uncirculated, large melting furnace, it is common to experience a temperature differential

of 28 °C (50 °F) per foot of bath depth from bottom to top. Circulation pumps have reduced temperature variation between the top and bottom of the melt to less than 10 °C (18 °F). Figure 14 shows the temperature homogenization that has been achieved by using a centrifugal circulation pump even in a very large (86 Mg, or 95 ton) furnace. In smaller furnaces, homogenization can be achieved more quickly. Holding furnaces also benefit from the alloy concentration and temperature homogenization provided by a circulation pump.

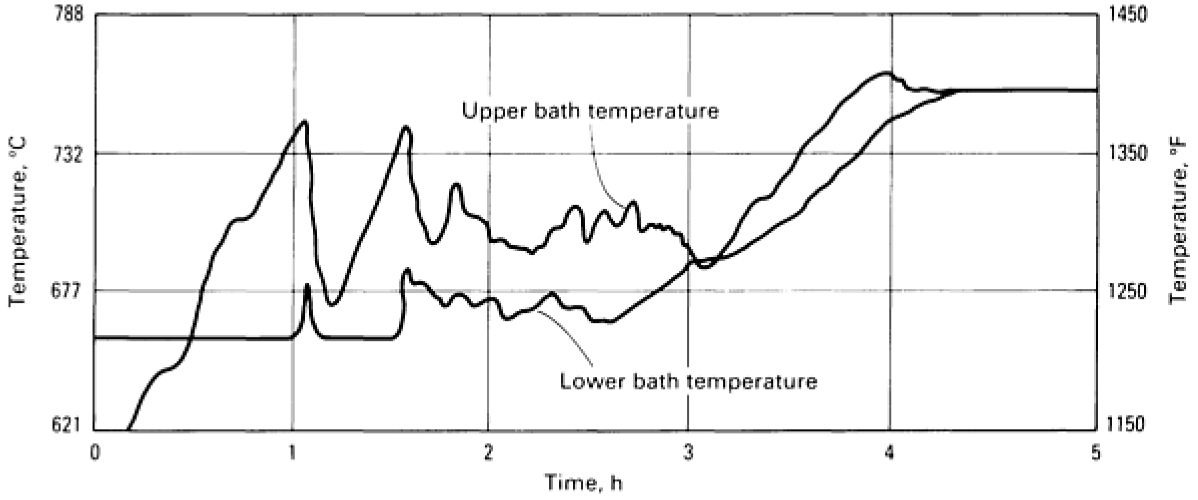

Fig. 14 Temperature homogeneity obtained in a large (86 Mg, or 95 ton) aluminum-melting furnace using a circulation pump. Source: Ref 25.

The improved heat transfer produced by forced convection also results in lower thermal heads. Reduced roof, sidewall, and bath surface temperatures mean reduced energy costs, less dross, and longer furnace life.

Most centrifugal pumps have traditionally been powered by air motors. However, air motors require substantial lubrication and maintenance, and variable incoming air line pressure is also a potential problem. Consequently, electric drive systems (Fig. 15) are currently replacing air-powered systems in many applications. Operating costs are lower than those for air motors, and more controllable, variable-speed operation permits smoother running of the pump and less maintenance.

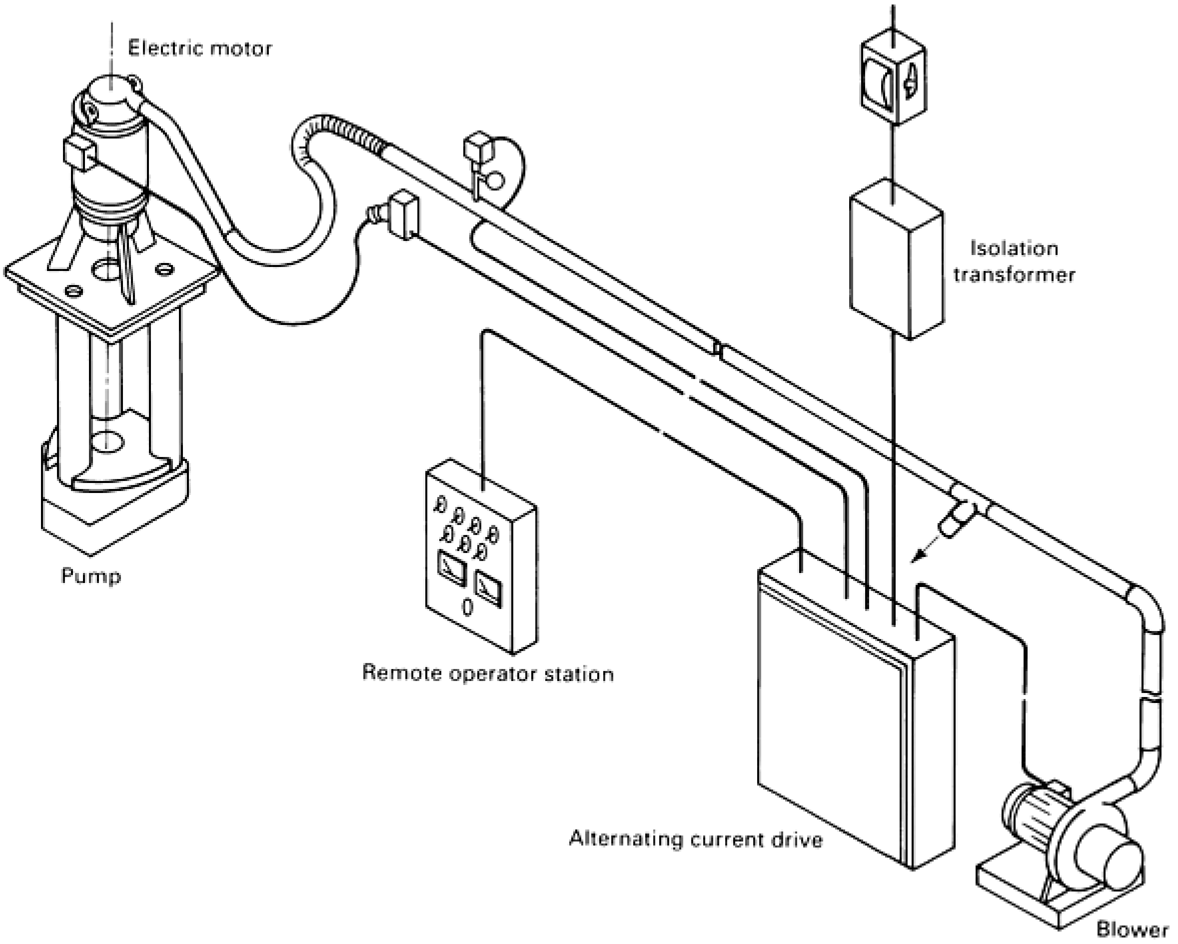

Fig. 15 Schematic of an electrically driven centrifugal circulation pump.

The principal advantage of an electric drive system, however, is in the higher output energy created. Typically, an air motor will produce 650 to 700 rpm in the pump, while an electric drive system can achieve 1100 to 1200 rpm. This results in substantially higher discharge velocities and therefore more forced convection.

Applications. Circulation pumps can be used to advantage in the remelting of scrap materials such as gates and risers, scrap castings, turnings and borings, used beverage containers, mill scrap, siding, and old extrusions. In addition, any large solid material (ingot, pig) for remelt can be more easily melted using forced convectional circulation. Circulation pumps are also commonly used in secondary smelting, in the production of cast extrusion billets, and in large foundries. Circulation pumps can also be used even with much smaller furnaces to facilitate the remelting of gates, runners, and scrap castings, along with foundry ingot.

Recently, pumps have been applied to direct-charged closed hearth furnaces (Ref 28, 29). In this case, a separate pump well is added to the furnace. The charge, often large pigs or ingot plus scrap, is placed directly into the hearth area of the furnace.

The advantages of using circulation pumping in this type of furnace include increased melt rate and energy efficiency improvements near 15%. Moreover, with gas injection/circulation pumps (described later in this article), it is possible to degas the melt *in situ.* This avoids an additional degassing step using flux wands, which usually requires opening of the furnace door with the attendant temperature loss. Quality improvement has been realized, along with productivity gains, in such applications.

Factors Affecting Pump Performance. Because of the hostile nature of the molten aluminum environment (heat, oxidation, corrosion), the principal materials used in the construction of molten metal pumping systems are usually graphite and ceramics. These materials provide the thermal shock resistance, corrosion resistance, and stability needed to

survive the hostile conditions. However, care must be exercised during handling. Preheating and/or slow immersion into the molten metal are required. Impellers can become plugged with dross, sludge, rocks, and steel contaminants. Not only is pump performance reduced but shaft breakage can also occur.

Fluxing salts will generally attack graphite, silicon carbide, and oxide ceramics (alumina, silica), causing a buildup of corrosion products. At the melt surface, residual fluxes and moisture present in the air will combine with oxides to form a tenacious corrosion product that could alter pump performance and limit pump life. Consequently, a preventive maintenance schedule of periodic hot cleaning of the molten metal pump is usually prescribed by the manufacturer to remove buildups from the intake, discharge, and melt line on the pump.

Degassing of Aluminum Alloys

Aluminum and its alloys are very susceptible to hydrogen absorption in the molten state. Solubility is much lower in the solid state (Fig. 16). Hydrogen is the only gas that is appreciably soluble in molten aluminum. Because of the affinity of the metal for oxygen, the principal source of hydrogen absorption will be the reduction of water vapor from the atmosphere in contact with the melt:

$$3H_2O + 2Al \rightarrow 6H + Al_2O_3$$

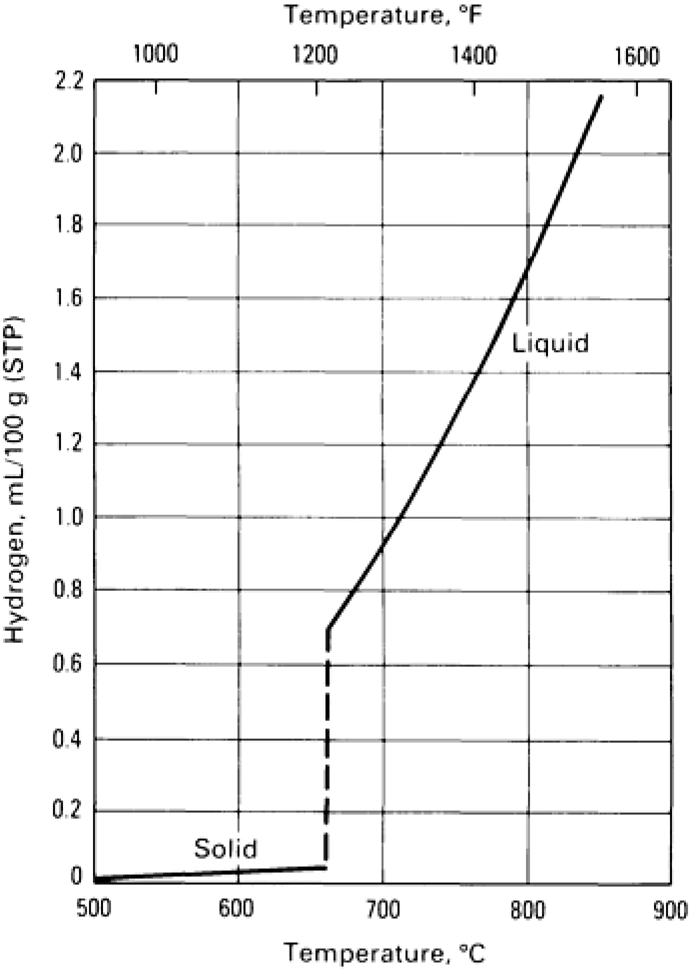

Fig. 16 Solubility of hydrogen in aluminum. Source: Ref 30.

The solubility of hydrogen gas increases exponentially as the temperature is raised. Therefore, it is imperative that excessive temperatures be avoided during melting to minimize gas absorption, especially if a standard degassing treatment is used based on a given initial expected gas content (Ref 6).

Alloy Sensitivity to Hydrogen Absorption

Various aluminum alloys have different sensitivities to hydrogen absorption and ensuing gas porosity if removal is not accomplished. The major alloying elements in aluminum foundry alloys are silicon, copper, and magnesium. Increasing silicon and copper contents decrease hydrogen solubility, although the effect is greater for copper (Ref 31). Magnesium, on the other hand, increases hydrogen solubility, and recent studies have shown that lithium behaves similarly (Ref 32).

Theory of Hydrogen Removal

Various thermodynamic and kinetic factors govern the removal of hydrogen from molten aluminum, and these factors have been extensively studied. Gas removal is easier or quicker at lower temperatures and higher concentrations, following the thermodynamic solubility changes with temperature. Kinetic factors, however, determine whether the hydrogen concentration will follow thermodynamic solubility and how close the concentration will come to equilibrium.

Hydrogen is removed by (Ref 33):

- Hydrogen transport in the melt to the vicinity of an inert gas bubble by a combination of convection and diffusion
- Diffusive transport through a thin, stagnant layer of fluid, called a boundary layer, surrounding the bubble
- The chemical adsorption onto and subsequent desorption from the bubble surface

- Diffusion of hydrogen as a gas inside the bubble of purge gas
- Escape of hydrogen from the melt surface or at refractory vessel walls

Consequently, hydrogen removal is dependent on mass transfer coefficients. Two fundamental results of theoretical investigations that have been borne out by actual practice are that:

- Smaller purge gas bubbles produce more efficient degassing results
- Chlorine usually improves degassing efficiency when medium or large purge gas bubbles (>6 mm, or 0.25 in.) are present because the mass transfer coefficient is increased

A full discussion of the scientific aspects is beyond the scope of this article, but additional information on hydrogen removal is available in Ref 33, 34, 35, and 36.

Sources of Hydrogen in Aluminum

There are many potential sources of hydrogen in aluminum, including the furnace atmosphere, charge materials, fluxes, external components, and reactions between the molten metal and the mold.

Furnace Atmosphere. The fuel-fired furnaces sometimes used in melting can generate free hydrogen because of the incomplete combustion of fuel oil or natural gas.

Charge Materials. Ingot, scrap, and foundry returns may contain oxides, corrosion products, sand or other molding debris, and metalworking lubricants. All these contaminants are potential sources of hydrogen through the reduction of organic compounds or through the decomposition of water vapor from contained moisture.

Fluxes. Most salt fluxes used in aluminum melt treatment are hygroscopic. Damp fluxes can therefore result in hydrogen pickup in the melt from the decomposition of water.

External Components. Furnace tools such as rakes, puddlers, skimmers, and shovels can deliver hydrogen to the melt if they are not kept clean. Oxides and flux residues on such tools are particularly insidious sources of contamination because they will absorb moisture directly from the atmosphere. Furnace refractories, troughs and launders, mortars and cements, sampling ladles, hand ladles, and pouring ladles also are potential sources of hydrogen, especially if refractories are not fully cured.

Metal/Mold Reactions. If metal flow is excessively turbulent during the pouring process, air can be aspirated into the mold. If the air cannot be expelled before the start of solidification, hydrogen pickup can result. Improper gating can also cause turbulence and suctioning. Excessive moisture in green sand molds can provide a source of hydrogen as water turns to steam.

Effects of Hydrogen

When the dissolved hydrogen in molten aluminum cannot be thoroughly expelled from the casting product as it solidifies, porosity defects will result. Porosity can be very fine, widely dispersed, or localized in those areas of the casting that are the last to solidify if the entrapped gas concentration is relatively low. Hydrogen microporosity may not be particularly harmful except when pressure tightness is required. On the other hand, some gas porosity defects can be fairly large, and they appear as blowholes and cracks.

It is important to differentiate between true gas porosity and shrinkage porosity. The former is due to the presence of trapped gas, and such defects are usually rounder and shinier upon metallographic examination. The latter is due simply to inadequate feed metal during final solidification. Shrinkage porosity is usually more irregular in shape than gas porosity (Ref 37).

Porosity defects result in a loss of mechanical properties in aluminum alloys. Figure 17 shows the effect of hydrogen porosity on the mechanical properties of alloy 356.

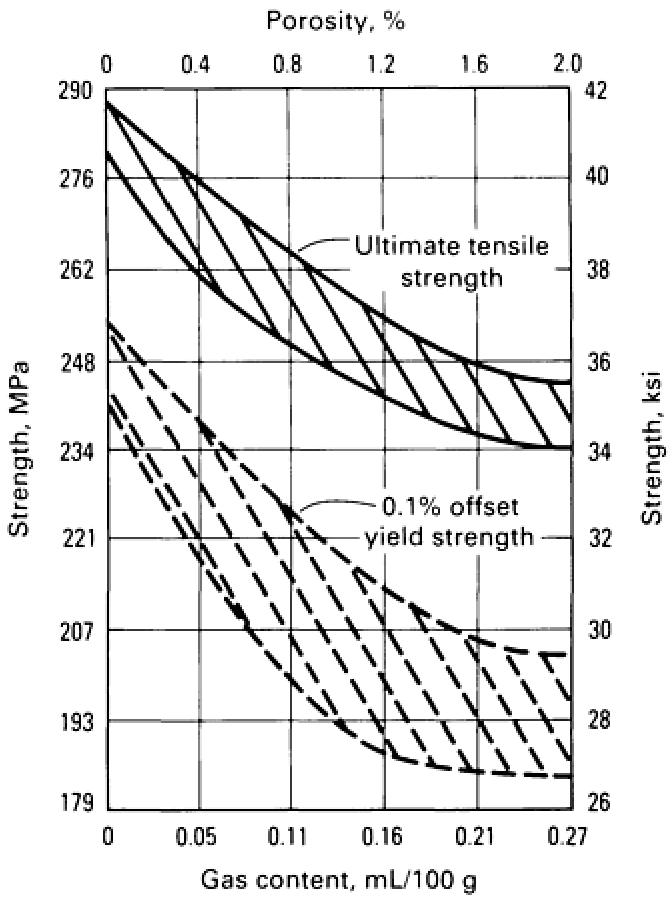

Fig. 17 Influence of gas content on the tensile and yield strengths of aluminum alloy 356. Source: Ref 38.

A certain amount of gas retained in aluminum during solidification can be beneficial. Permanent mold castings often contain some unremoved or unexpelled hydrogen or sometimes gas is even added. This retained gas offsets gross solidification and aids in complete mold filling and does not detract from surface characteristics or minimum mechanical properties required for most commercial castings. The more rapid chilling and solidification rate of permanent mold casting versus sand casting facilitates the acceptance of hydrogen; the faster solidification rate usually results in finer grain size and enhanced mechanical properties. The same is true for die casting, in which extremely rapid solidification under pressure greatly reduces the tendency toward hydrogen porosity.

Testing for Hydrogen

The Straube-Pfeiffer test (reduced-pressure test) for the measurement of hydrogen is a qualitative method that has been commonly used. A small sample of melt is placed in a crucible in a chamber, which is then evacuated to a specified pressure and held until the metal solidifies. Bubble evolution during solidification and the appearance of the sample surface are indicators of the amount of hydrogen present. A mushroom head indicates a gassy sample, while a recessed surface would indicate a relatively gas-free sample. The solidified sample is often sectioned and the evident porosity compared with a series of standards (Fig. 18). It is important to specify the reduced pressure used for repeated tests in order to make valid comparisons. Figure 19 shows the effect of different pressures on the observed response for samples containing the same amount of gas. These standards can be correlated with analytically determined specific hydrogen results or with individual foundry and casting acceptance criteria. If such standards are used, they must be evaluated in terms of each individual alloy, casting, and foundry experience and practice.

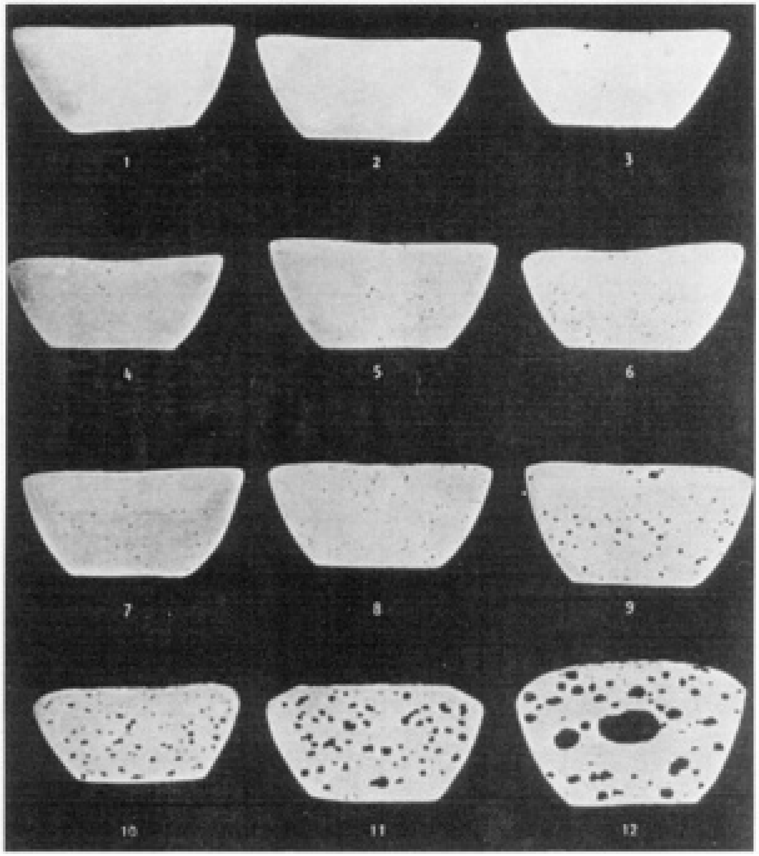

Fig. 18 Standards for comparison with reduced-pressure test specimen used to check the amount of hydrogen gas present in aluminum alloys. Such standards must be developed for a given alloy and set of test conditions. Courtesy of Wabash Alloys.

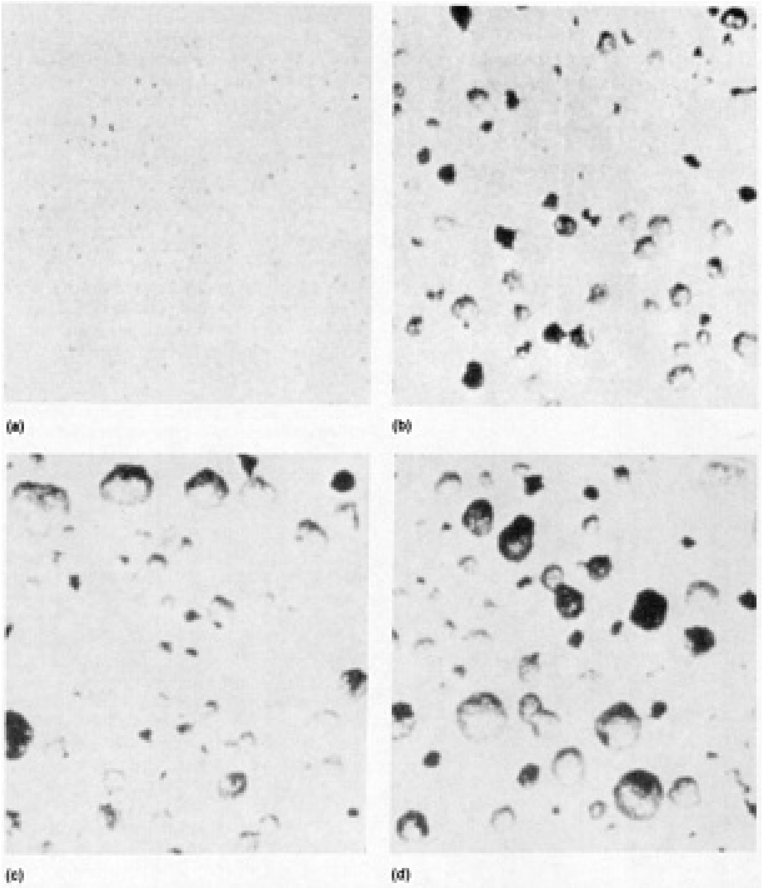

Fig. 19 Effect of pressure on the appearance of aluminum alloy reduced-pressure test samples obtained from the same melt. (a) Pressure: 100 kPa (760 torr). (b) 12 kPa (90 torr). (c) 6 kPa (45 torr). (d) 3 kPa (22.5 torr). Courtesy of Wabash Alloys.

In the Straube-Pfeiffer test the sample behavior is influenced by general melt cleanliness as well as by hydrogen. Inclusions will nucleate hydrogen gas bubble formation during solidification; therefore, the test does not provide an absolute measurement or effect of dissolved hydrogen alone.

The Straube-Pfeiffer test is also used to determine the sample density *D* under specific test conditions and to correlate the result with the known full density of the alloy (Ref 39). Hydrogen gas content can then be determined from the difference in densities plus a correction for standard temperature and pressure (STP) conditions, because the gas forms in the sample during testing at a reduced pressure and at the freezing temperature of the alloy. The calculation is:

$$D = \frac{Weight \text{ of metal + weight of gas}}{\text{Volume of netal + volume of gas}} \quad \textbf{(Eq 5)}$$

The weight of the gas can be neglected. Therefore:

$$\frac{1}{D} = \frac{\text{Volume of netal + volume of gas}}{Weight \text{ of metal}} \quad \textbf{(Eq 6)}$$

The first term on the right-hand side of Eq 5 is simply the known theoretical density D_0, of the alloy in question. The measured volume of gas V_m is therefore given by:

$$V_m = \frac{1}{D} - \frac{1}{D_0} \qquad \textbf{(Eq 7)}$$

where V_m is in milliliters per 100 g of metal.

The measured volume of gas V_m must then be corrected to the volume of gas at standard conditions V_{STP} using Boyle's and Charles's laws:

$$V_{STP} = \left(\frac{\textit{Test}\ \text{pressure}}{760} \right) \left(\frac{273}{273 + \text{ alloy freezing temperature}} \right) . V_m \qquad \textbf{(Eq 8)}$$

where test pressure is in millimeters of mercury (torr) and alloy freezing temperature is in degrees Celsius. Finally:

$$V_{STP} = k \left(\frac{1}{D} - \frac{1}{D_0} \right) \qquad \textbf{(Eq 9)}$$

where K is a constant and V_{STP} is in milliliters per 100 g of metal.

For each alloy and set of test conditions, a different K must be calculated. For a given alloy, however, it is possible to develop a relationship between density and actual hydrogen content. Densities of samples with varying gas contents can be measured by the Archimedes principle of weighing in air and water:

$$D = \frac{W_a}{W_a - W_w} \qquad \textbf{(Eq 10)}$$

where W_a and W_w are the weights in air and water, respectively.

Nomographs can then be developed from derived results such that the hydrogen content can be determined directly from weight determination of the reduced-pressure test specimens rather than by mathematical manipulation. Figure 20 shows a nomograph developed for aluminum alloy 1100 that relates observed first bubble pressure with hydrogen content.

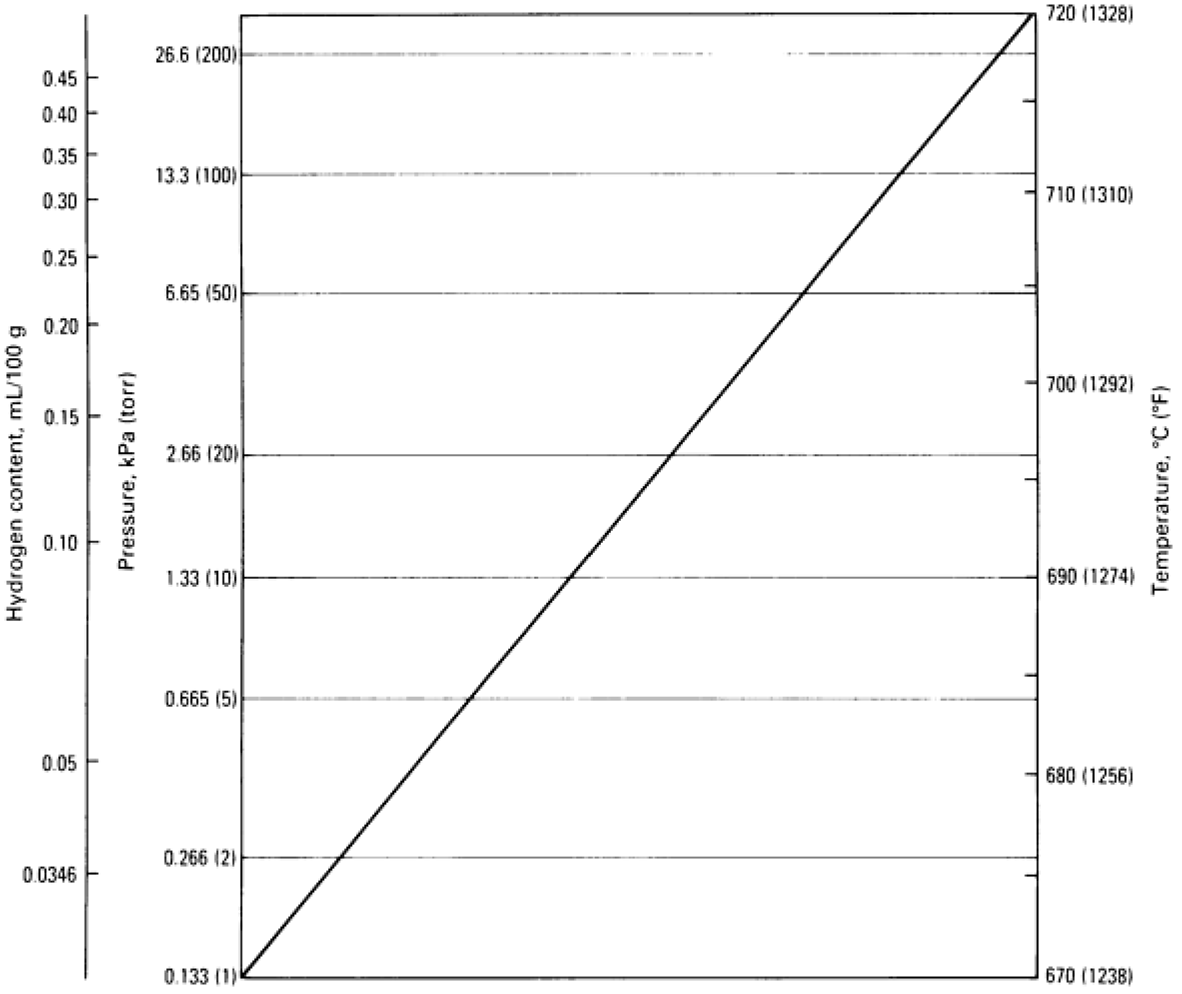

Fig. 20 Nomograph correlating reduced-pressure reading at appearance of first bubble with actual hydrogen content of aluminum alloy 1100. Melt temperature, 730 °C (1350 °F); gas flow rate, 6 L/min (0.2 scfm) Source: Ref 40.

Quantitative Reduced-Pressure Technique (Ref 41). The standard reduced-pressure test gives only a semiquantitative measure of hydrogen content, which is usually then visually interpreted and correlated with comparison samples exhibiting varying degrees of porosity. Inclusions nucleate porosity effects; therefore, the reduced-pressure test does result in the determination of true hydrogen content.

An instrument is available that measures hydrogen directly. A constant mass (100 g, or 0.22 lb, of metal) is placed in the chamber, and the pressure is rapidly reduced to a specific predetermined value. The sample is then allowed to solidify under vacuum in isolation from the pump.

As hydrogen gas is evolved during solidification, the gas partial pressure is measured by a calibrated Pirani gage whose output is converted continuously to a digital display of hydrogen content. The Pirani gage operates on the principle that at low pressure the thermal conductivity of any gas varies with pressure.

A test can be completed in about 5 min, and results with several foundry casting alloys have been shown to be accurate within 5%. However, high hydrogen readings have been obtained for wrought aluminum alloys, possibly because of the fundamental differences in oxide structure and hydrogen retention or occlusion capabilities of wrought alloy compositions.

The Telegas instrument (Ref 42) is a shop floor instrument for hydrogen determination that has been extensively used for many years (Fig. 21). Its primary application is in the wrought industry or for research purposes. The unit operates with a nitrogen carrier gas, which dissolves hydrogen from the melt. The nitrogen is bubbled through the melt for

a sufficiently long period of time such that equilibrium is achieved with respect to hydrogen dissolved in the melt versus hydrogen dissolved in the nitrogen. The hydrogen within the nitrogen carrier gas is then measured using a Wheatstone bridge circuit and a thermal conductivity cell known as a katharometer. The instrument is precalibrated, and the result is correlated with known standards of premixed gases containing a known level of hydrogen.

Fig. 21 The Telegas unit for hydrogen determination. Courtesy of Aluminum Company of America.

Instrument readings are converted into hydrogen content by using a family of curves relating to hydrogen concentration. Correlations are available that cover the normal melt temperature range of 675 to 750 °C (1245 to 1380 °F) and hydrogen concentrations of 0.05 to 0.40 mL/100 g. Correction factors also exist for different alloy compositions because of their greater or lesser sensitivity to hydrogen. The Telegas instrument performs well when it is properly operated, and it has been found to compare very favorably with the vacuum hot extraction analytical method, with a maximum standard deviation of 0.023 mL/100 g.

Although the Telegas instrument is not difficult to operate, the ceramic probes used with this instrument are very fragile. To avoid thermal shock to the probes, they must be preheated and immersed with extreme caution.

Vibrated Vacuum Gas Test (Ref 43). The standard vacuum solidification test provides only a qualitative measure of metal quality as influenced by both hydrogen gas content and inclusions. The vibrated vacuum gas test provides several features that improve upon the standard test and sort out hydrogen effects versus inclusion-nucleated porosity. A larger-capacity pump and more sensitive vacuum gage are used to produce a better and more reproducible vacuum. A preheated outgassed refractory sample cup permits slower solidification. A controlled vibrator assists the nucleation of gas bubbles, promotes coalescence, and reduces the surface tension of the molten sample.

Results of the vibrated vacuum test have shown good differentiation between the hydrogen content effects (presence of gas bubbles) of filtered (fewer inclusions) versus unfiltered metal (Ref 43). Figure 22 shows the improvement in metal quality at any test pressure for filtered metal, correlating with lower hydrogen content as verified by hot extraction analysis. Therefore, the vibrated vacuum test can provide a more sensitive determination of metal quality as affected by hydrogen alone.

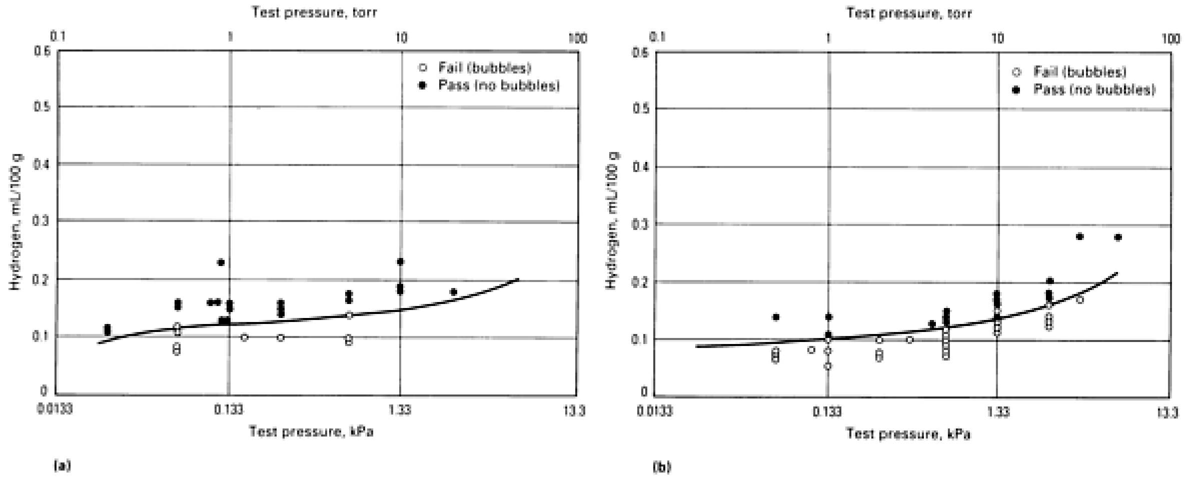

Fig. 22 Hydrogen content as a function of vibrated vacuum gas test pressure for unfiltered (a) and filtered (b) aluminum alloy. Source: Ref 43.

Methods of Degassing

Several methods are available for degassing aluminum. The simplest method is to hold the metal at a lower temperature for some period of time during which the hydrogen solubility is lower and thus provide for natural outgassing. In addition, casting conditions that permit solidification with natural expulsion of hydrogen without the attendant porosity are also desirable. However, neither of these is always possible. Deliberate degassing of the melt can be accomplished in the following ways:

- Gas purging or gas flushing
- Tableted flux degassing
- Mechanical mixer degassing

Gas Purging. The simplest method of degassing molten aluminum is by injecting a purging gas or gas mixture under pressure through a flux tube, pipe, lance, or wand. The tubes themselves are either ceramic-coated cast iron or steel pipe, or more often graphite.

A purge gas serves to collect hydrogen because of the lower partial pressure of the hydrogen afforded by the collector bubble versus the surrounding melt. Hydrogen diffuses into the purge gas bubble, which rises to the surface of the melt and is expelled into the atmosphere.

Purge gas can be either inert (argon or nitrogen) or reactive (chlorine and Freon 12). Reactive gases are used in small concentrations of under 10% along with an inert gas. Reactive gases undergo an actual chemical reaction with the melt. Chlorine reacts with molten aluminum to form a gaseous $AlCl_3$, which then serves as the purging gas. In the case of Freon, fluorine reacts to form AlF_3 a solid phase.

Both chlorine and fluorine have very favorable effects on bubble surface tension and in wetting out inclusions from the melt. Therefore, gas purging that uses either of these two elements can be expected to improve degassing efficiency through more effective coalescence of hydrogen and hydrogen inclusion complexes. However, although chlorine is very effective as a purge gas, it is also very noxious, and considerable effluent may result. Therefore, it is almost always used with an inert gas.

A mixture of nitrogen, chlorine, and carbon monoxide (CO) has been successfully used for degassing (Ref 44). This trigas mixture and Freon are both reported to have lower gaseous emissions or effluent than either chlorine alone or chlorine plus inert gas mixtures (Ref 44, 45).

Results of Hydrogen Removal With Purging Gas. In general, chlorine gas or mixtures with chlorine are more beneficial than inert gases or Freon alone. Figure 23(a) shows the relative effects of three different purging gases or mixtures, while Fig. 23(b) compares the degassing achieved with argon and nitrogen.

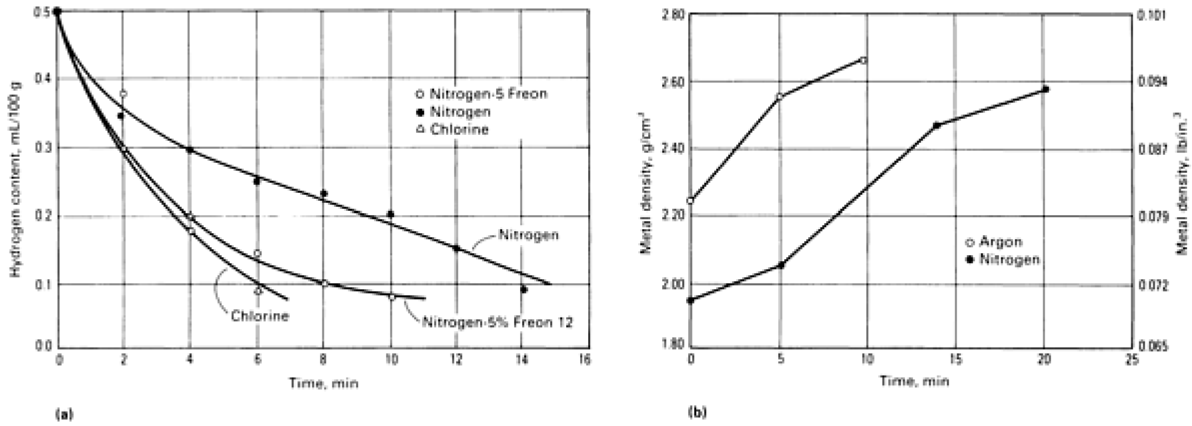

Fig. 23 Relative efficiencies of purge gases in the degassing of aluminum alloy 356 (a) and aluminum alloy 319 (b) at constant gas flow rates. Metal density in (b) increases as gas content of the metal decreases. Source: Ref 46, 47.

Vacuum fluxing is not used on any significant commercial basis in North America, but is practiced in Europe. Recent results have shown that this technique is beneficial (Ref 48). In large (45 Mg, or 50 ton) melts, a series of alloys (99.5Al, Al0.5Mg-0.5Si, and Al-5Zn-1.1Mg-0.3Cu) was refined using argon fluxing for 30 min through porous plugs. Pressure was maintained at 7 Pa (0.001 psi). Hydrogen contents were reduced from 0.16 to 0.11 ppm, 0.24 to 0.12 ppm, and 0.17 to 0.13 ppm for the three alloys, respectively. One particular advantage of vacuum fluxing is the minimal amount of dross formed.

Hexachloroethane Degassing (Ref 49, 50). Perhaps the most common method of degassing in foundry applications is the use of hexachloroethane (C_2Cl_6) tablets. The tablet decomposes in the aluminum melt to form gaseous $AlCl_3$. The rising $AlCl_3$ gas bubbles then collect hydrogen gas and deliver the gas to the melt surface for release. The tablets may also contain salt fluxes to help wet oxide inclusions within the melt and thus enable some removal of the hydrogen gas associated with inclusions.

To be fully effective, the tablets must be kept dry and should be plunged with clean, dry tools (preferably a perforated bell-shaped plunger to permit easy gas bubble escape). The plunge should be to the full depth of the melt, and the tablets should be held in position until a gentle bubbling on the melt surface subsides. If this is not done, the lighter-density tablets will rise and float on the melt surface during decomposition, providing little or no effective degassing of the entire melt.

Tableted products are available for virtually any melt size, although their principal application is for smaller furnaces and ladles within the foundry casting industry. When properly used, C_2Cl_6 provides very effective degassing. However, the somewhat noxious odor of the raw tablet--as well as the sometimes strong effluent during use, particularly improper use--creates environmental difficulties that have forced many foundries to discontinue use of the tablets.

Rotary Degassing. The use of simple gases or gas mixtures in lance or flux tube degassing, although reasonably effective, is not necessarily fully efficient. The ability of this simple process to degas depends on the bubble size generated and the amount of contact area between the degassing bubbles and the melt. The bubbles are often large, and very little mixing occurs in large melts or vessels when flux tubes or lances are used.

A significant improvement was the development of rotary gas injection systems. These systems originated in the aluminum primary and mill products casting industry and are used as in-line treatment systems in auxiliary vessels between furnace and ladle or furnace and casting pit.

The principle of the rotary injector system (Fig. 24) is that gas is injected into the column or shaft of a rotating member and is released through fine openings at the base or rotor. When rotating at speeds of 300 to 500 rpm, the disperser shears the incipient gas bubble released, producing a wide dispersion of very fine bubbles for degassing. The high surface-area-to-volume ratio of degassing bubbles provides greatly increased contact area and therefore increased reaction kinetics, resulting in more efficient degassing. The rotating member also disperses the bubble array more uniformly within the reaction vessel to provide more thorough mixing of metal with the purge gas. Figure 25 shows a typical rotary degassing system used in primary and mill products casting operations. Such systems are sized according to metal volume and flow rate conditions, and either single gases such as argon, nitrogen, and chlorine or mixtures of these are used in the gas mixing and control system. The level of hydrogen removal depends on gas flow rate and initial hydrogen content as well as metal flow rate, but most commercial systems can achieve final hydrogen contents well below 0.15 mL/100 g (Fig. 26).

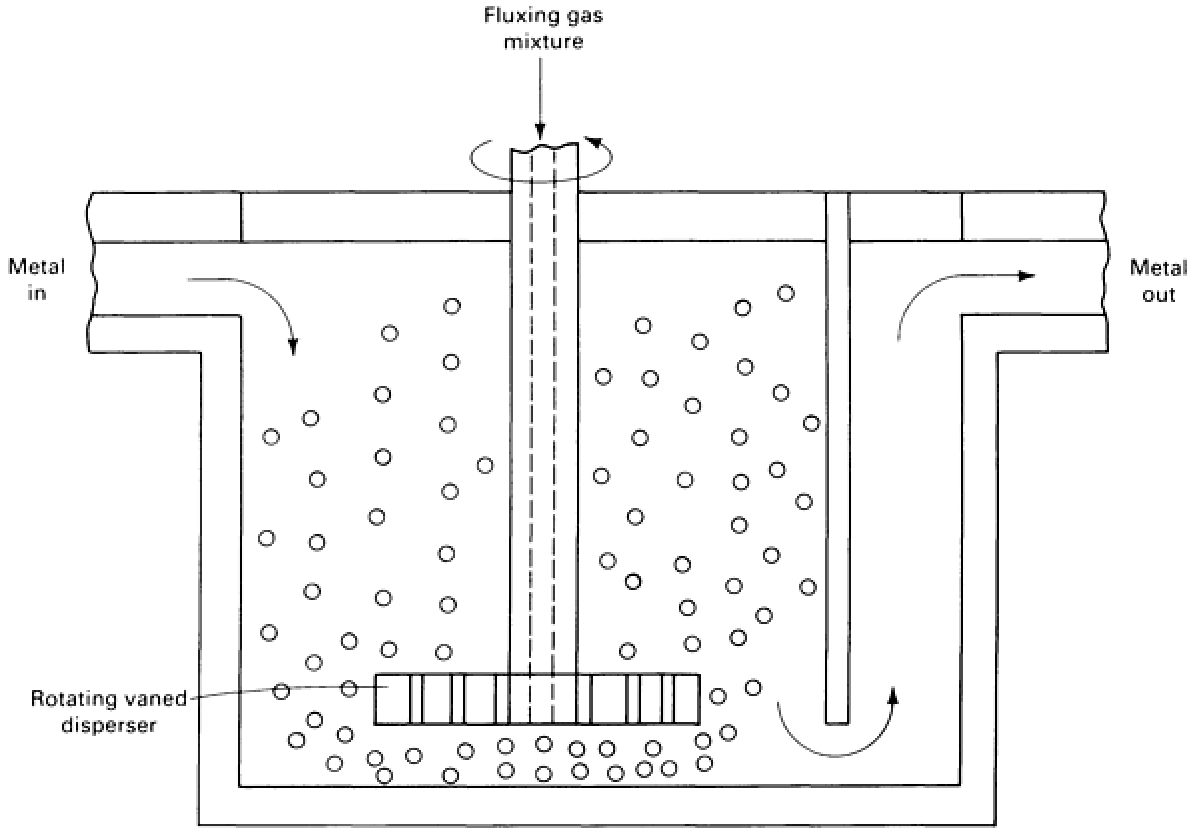

Fig. 24 Schematic of an in-line rotary degassing unit.

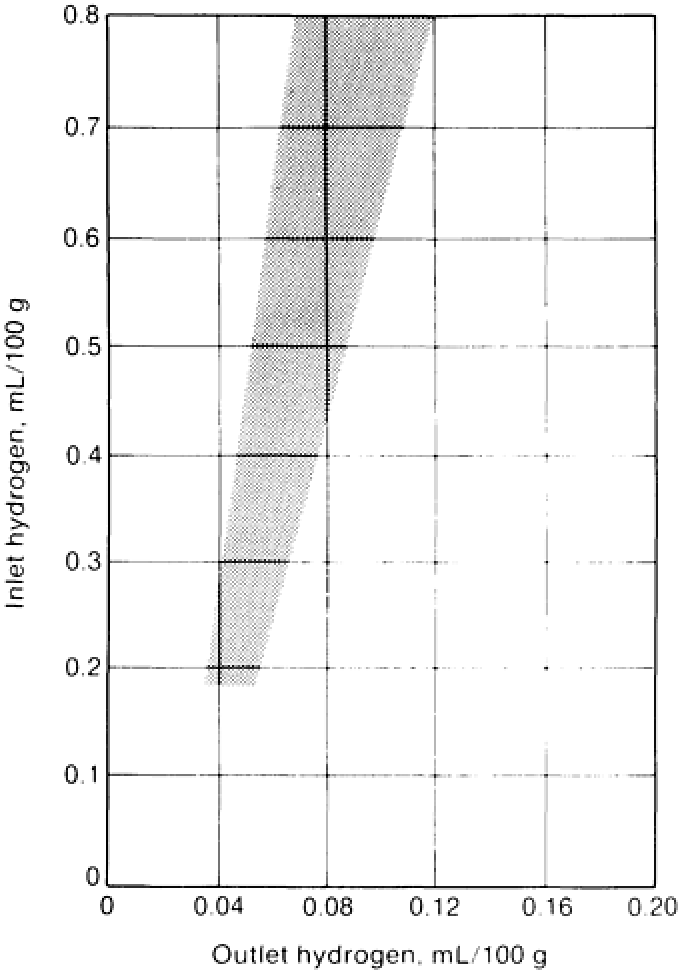

Fig. 26 Hydrogen removal results with the SNIF rotary degasser shown in Fig. 25. Similar results can be obtained with comparable commercially available equipment. Source: Ref 51.

Degassing performance is determined by several interrelated factors, including initial hydrogen content, metal flow rate, vessel size (which determines residence time in conjunction with flow rate), purge gas flow rate, mixing capability, and specific alloy (thermodynamic factors and mass transfer coefficients). In general, all such systems have achieved satisfactory degassing results (Ref 51, 52, 53, 54, 55, 56).

Rotary degasser systems have recently been downsized for foundry applications with good results (Ref 47, 57). The degassing system is inserted directly into a crucible or ladle of metal, and the metal is degassed in a batch process before pouring.

There are optimum combinations of purge gas volume, ratio of impeller diameter to crucible diameter, and shaft revolutions per minute for best efficiency of degassing without excessive turbulence. An impeller/crucible diameter ratio of 20 to 25%, a 350 to 450 rpm shaft speed, and a gas flow rate of 18 to 20 standard cubic feet per hour (SCFH) have been found to be appropriate for one unit. Variations in impeller design, however, may alter these parameters. Gas removal results achieved with rotary degassing compare very favorably with those achieved by lance treatment. This is illustrated in Fig. 27 for a 180 kg (400 lb) heat of Alloy A357.

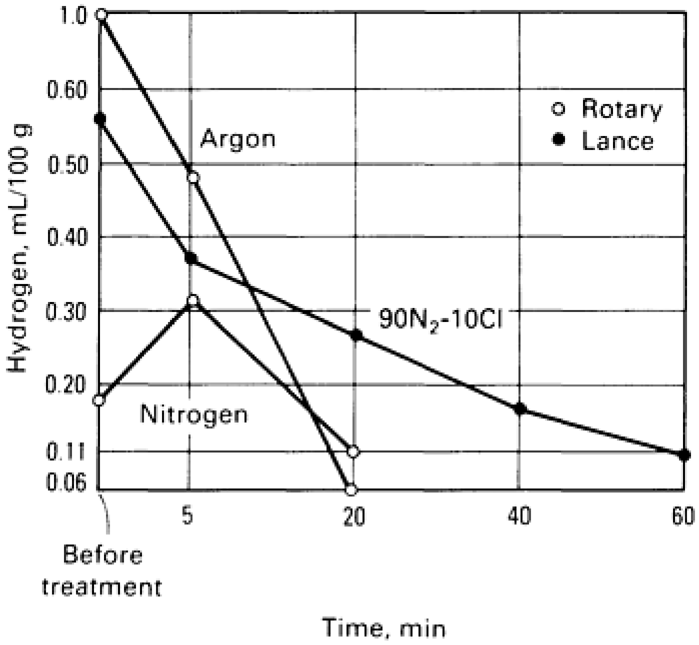

Fig. 27 Comparison of efficiency of rotary degassing and lance degassing of aluminum alloy A357. The rotary system used a 150 mm (6 in.) rotor at 375 rpm. Melt weight: 180 kg (400 lb). Source: Ref 57.

Other Mechanical Degassing Systems. The circulation gas injection pump (see the section "Demagging of Aluminum" in this article) can also be used for degassing. The high speed (600 to 1100 rpm) of the impeller shears the gas bubbles exiting the injection tube and creates a very fine and widely dispersed bubble pattern. In large reverberatory furnaces, the melt can be degassed through the injection and pumping action without the need for additional furnace fluxing with wands. In this manner, degassing efficiency and energy efficiency are both improved because furnace doors need not be opened, as in flux tube or lance fluxing. Large (45 Mg, or 50 ton) melts have been successfully degassed to levels of 0.15 mL/100 g and below with the gas injection pump.

Another device being used for degassing in the primary industry is a swirling tank reactor. The metal flows in a swirling pattern counter to gas flow. The gas is injected through a series of nozzles, as shown schematically in Fig. 28. Typical results obtained with this process are shown in Fig. 29.

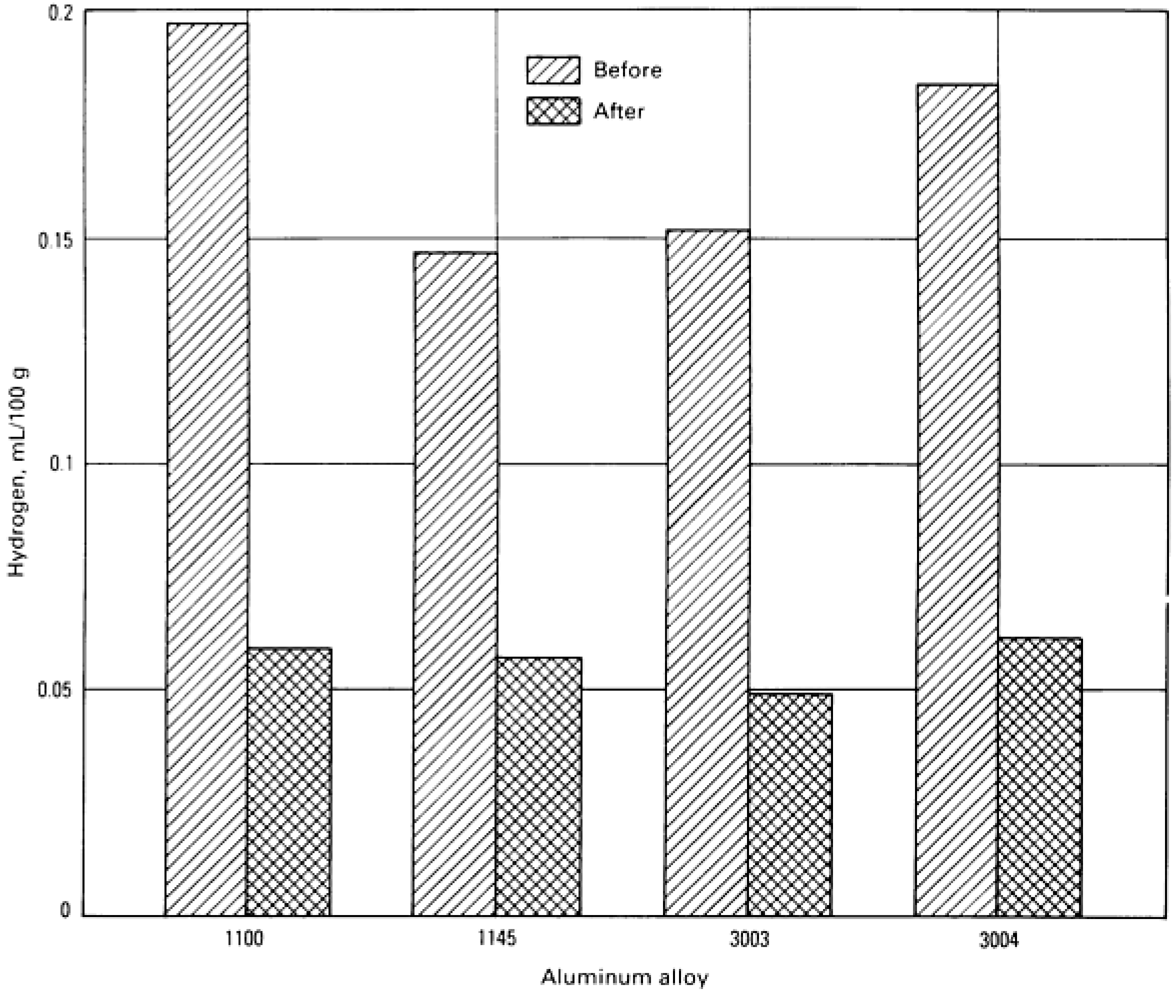

Fig. 29 Efficiency of the MINT III degassing system shown in Fig. 28 using a gas mixture of Ar-0.5/2Cl. Source: Ref 58.

Porous Plug Degassing. Another method that can be used to degas by creating fine bubbles is the use of a porous disperser on the end of a flux tube or a fixed porous plug (Fig. 30). Porous plugs are graphite or ceramic materials with a very fine, interconnected porosity through which gas can be conveyed. These plugs can be installed into ladle bottoms, furnaces, or auxiliary treatment vessels. The fine porosity of the plug material allows a fine bubble size to be generated (comparable to that of rotary degassers). However, degassing efficiency is strongly related to bubble residence time, gas flow rate, depth of the melt, size of the vessel, and the ability to keep the pores in the plug open for full gas emission. Porous plug degassing can be more economical than rotary degassing systems, in which the rotors and shafts, usually graphite, require periodic replacement as they wear and oxidize.

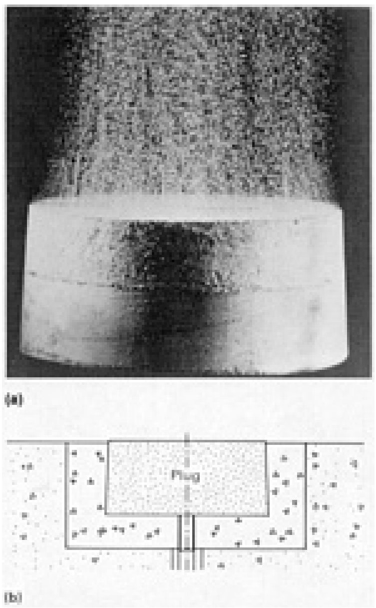

Fig. 30 Porous plug degassing unit (a) showing fine bubbles produced in water. (b) Plug installation in vessel bottom.

Figure 31 compares the degassing obtained by using identical gas flows for porous plug, lance, and rotary degassing systems. The porous plug is more effective than a lance, and satisfactory degassing results can be obtained in many applications by controlling vessel size, gas flow rate, and residence time.

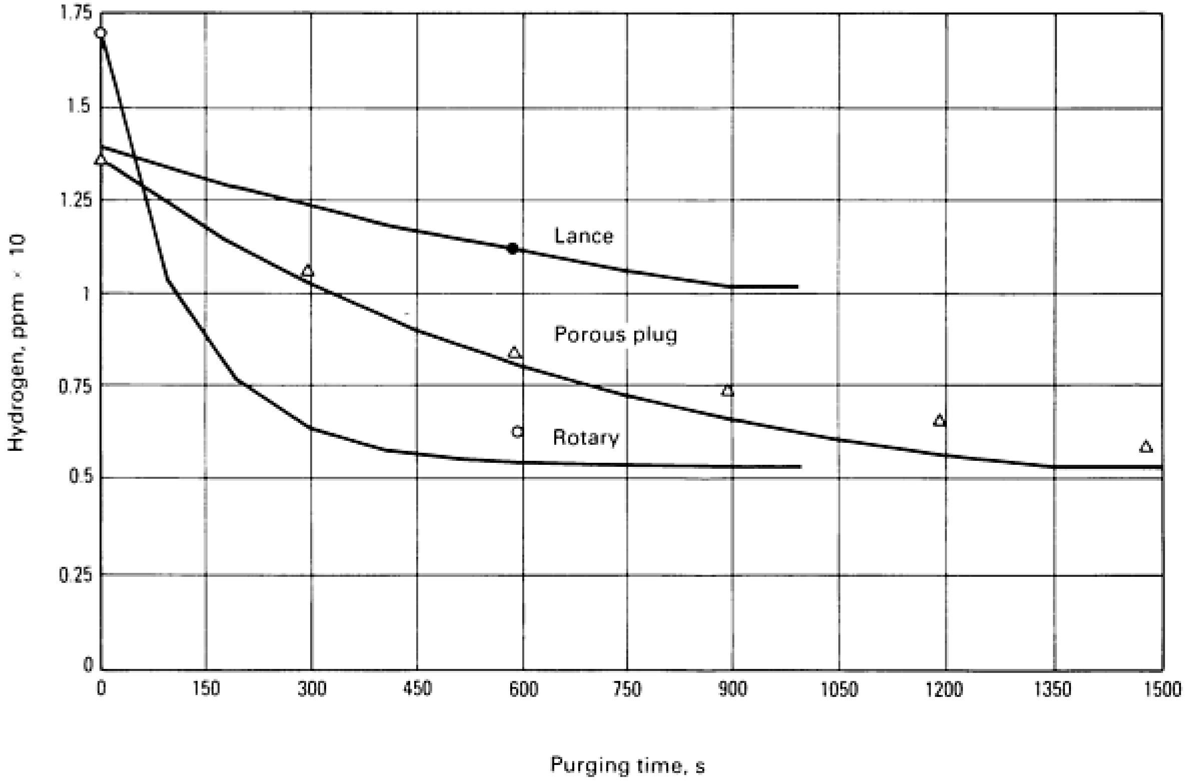

Fig. 31 Comparison of lance, porous plug, and rotary degassing efficiencies for identical gas flows. Source: Ref 36.

A combination in-line degassing/filtration system using porous plugs has recently been introduced (Ref 59). The degassing chamber is designed to accommodate all the above-mentioned variables. This system (Fig. 32) has produced final hydrogen contents of 0.06 mL/100 g at low metal flow rates (40 kg/min, or 90 lb/min) and 0.14 mL/100 g at flow rates near 330 kg/min (725 lb/min).

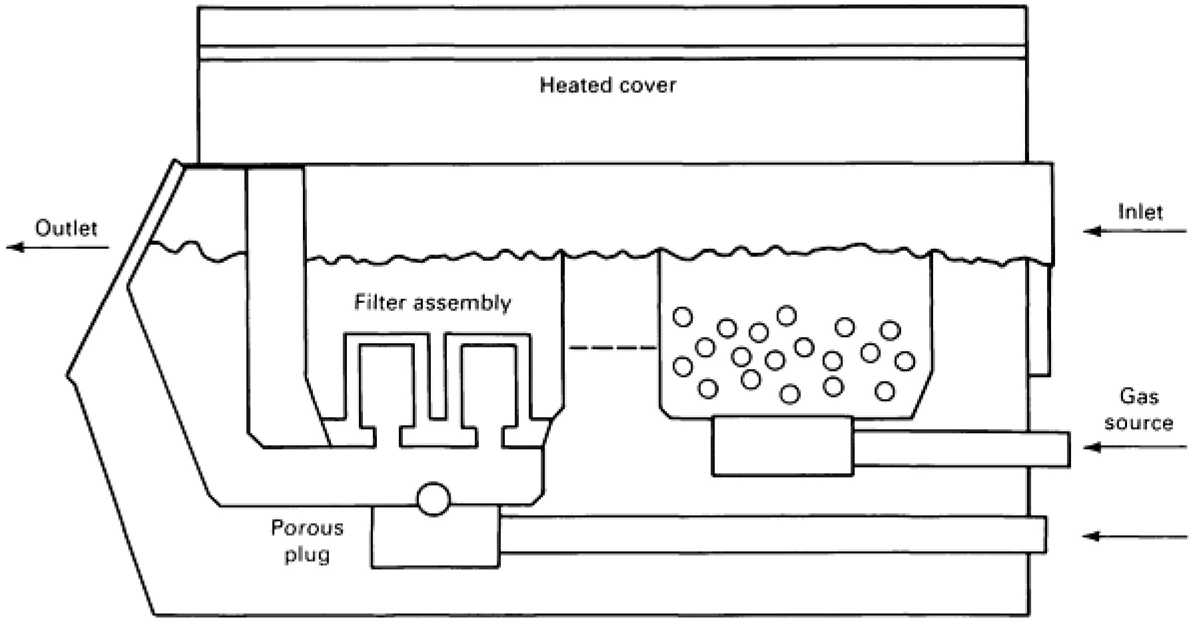

Fig. 32 Schematic of proprietary combination in-line degassing/filtration system. Source: Ref 59.

Degassing of Magnesium

Magnesium behaves similarly to aluminum in its ability to dissolve hydrogen easily in the molten state (Fig. 33). It too will suffer from porosity when cast if the hydrogen is not removed or naturally expelled during solidification. Aluminum and zinc, which are typical alloying elements in magnesium alloys, lower this solubility somewhat. Figure 34 indicates that much more gas is evolved from magnesium alloys containing zinc and aluminum than from pure magnesium upon solidification. Gas porosity occurs in solidified castings when the residual hydrogen exceeds 15 mL/100 g.

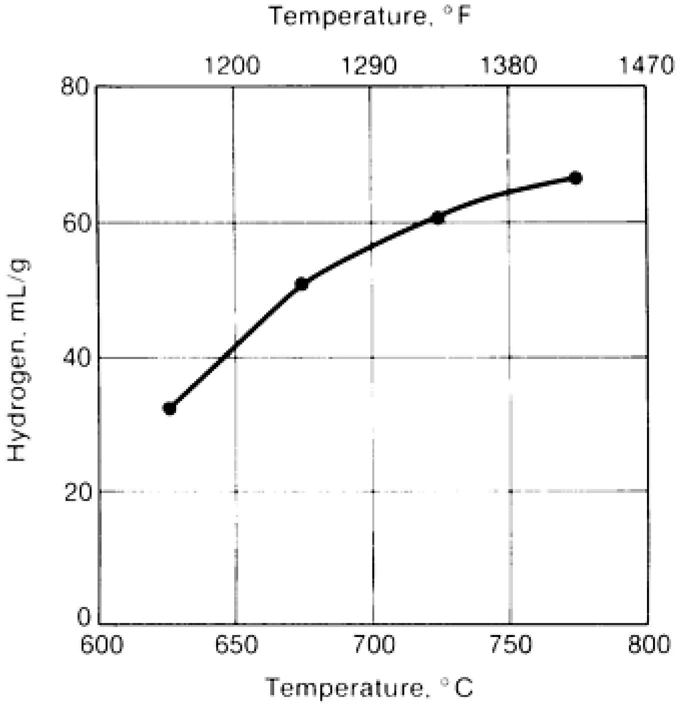

Fig. 33 Solubility of hydrogen in molten magnesium at 101 kPa (760 torr). Source: Ref 7.

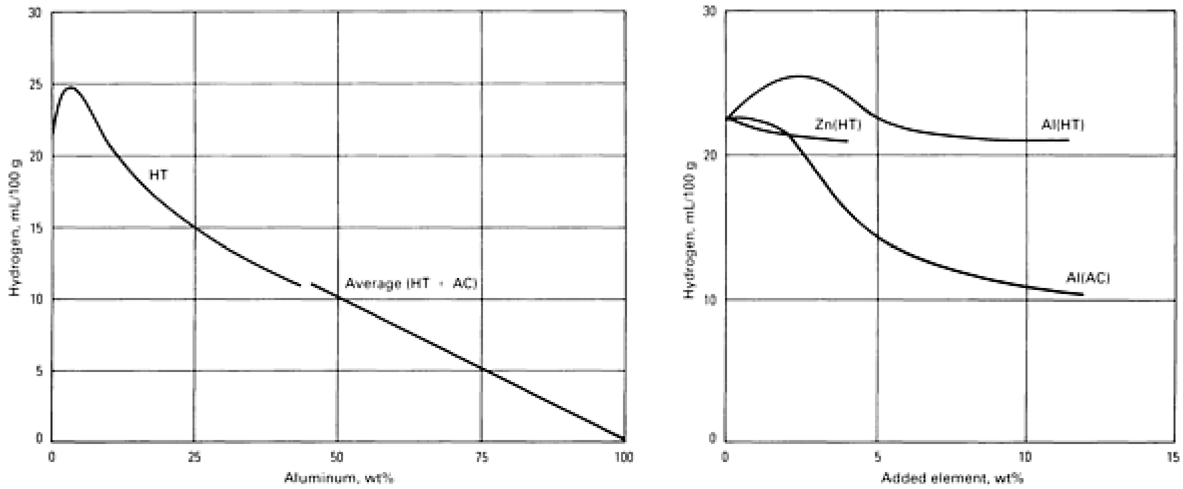

Fig. 34 Effect of alloying elements on hydrogen solubility in liquid magnesium. AC, as-cast; HT, heat treated. Source: Ref 7.

Zirconium is also a major constituent of certain magnesium alloys and has a marked effect on hydrogen solubility. Hydrogen solubility decreases as the zirconium content of the alloy increases (Ref 7). Because of this low solubility even in the liquid state, hydrogen porosity is minimal in castings of magnesium-zirconium alloys. However, excess hydrogen in the melt readily precipitates as zirconium hydride, thus depleting the alloy of zirconium in solid solution. It is therefore advisable to minimize hydrogen absorption into the melt and/or to employ degassing methods even with this alloy.

Sources of gas in magnesium alloy melts are the same as those for aluminum--atmospheric conditions, fluxes, tools, and so on. Flux covers or antiburning agents do not necessarily preclude hydrogen absorption during melting.

Like aluminum alloys, molten magnesium metal and alloys can be degassed with hexachloroethane, chlorine, or nitrogen. Hexachloroethane has the added advantage of supplying carbon through the decomposition of the hexachloroethane, with

the carbon serving as a grain refiner (see the section "Grain Refining of Magnesium Alloys" in this article). Chlorine or chlorine/nitrogen gas purging is optimally performed at temperatures of 725 to 750 °C (1335 to 1380 °F). In this range, liquid $MgCl_2$ will also be formed, which will retard burning on the surface. Liquid $MgCl_2$ wets the oxides and the magnesium melt surface, facilitating hydrogen escape. Pure chlorine provides for more liquid $MgCl_2$ formation than either gas mixtures or hexachloroethane and therefore creates better degassing. Fluxes higher in $MgCl_2$ that are used as covers during degassing also aid in hydrogen desorption at the flux/metal interface and in subsequent expulsion to the atmosphere (Ref 60).

The degassing of magnesium alloys in crucible or pot-type furnaces should be carried out with clean, dry lances, preferably graphite, with thorough mixing for 5 to 10 min. Pressures and volumes should not exceed those required to achieve a mild, gentle roll or small bubble (≤25 mm, or 1 in., in diameter) on the melt surface. Rare earth containing magnesium alloys should only be degassed when required with nitrogen or argon, because chlorination will readily remove these expensive alloying elements.

Degassing of Copper Alloys

In the melting and casting of many copper alloys, hydrogen gas absorption can occur because of the generous solubility of hydrogen in the liquid state of these alloys. The solid solubility of hydrogen is much lower; therefore, the gas must be rejected appropriately before or during the casting and solidification process to avoid the formation of gas porosity and related defects (excessive shrink, pinholing, blowholes, and blistering). These defects are almost always detrimental to mechanical and physical properties, performance, and appearance. Different copper alloys and alloy systems have varying tendencies toward gas absorption and subsequent problems. Other gases, particularly oxygen, can cause similar problems (see the section "Deoxidation of Copper Alloys" in this article).

Sources of Hydrogen Porosity

There are many potential sources of hydrogen when melting copper alloys. For the most part, these are identical to the sources of hydrogen in aluminum melting (see the section "Sources of Hydrogen in Aluminum" in this article).

Gas Solubility

Hydrogen is the most obvious gas to be considered in copper alloys. Figure 35 shows the solubility of hydrogen in molten copper. As in aluminum and magnesium alloys, solubility is reduced in the solid state; therefore, the hydrogen must be removed prior to casting or rejected in a controlled manner during solidification. Alloying elements have varying effects on hydrogen solubility (Fig. 36).

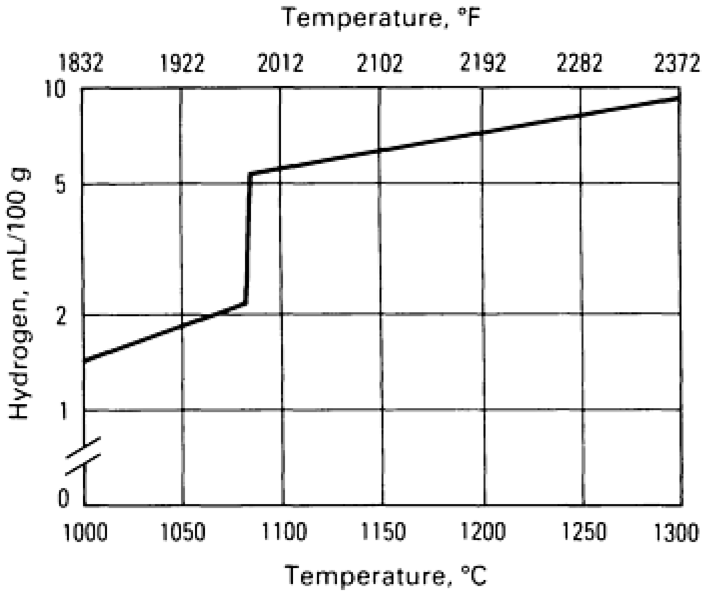

Fig. 35 Solubility of hydrogen in copper. Source: Ref 61.

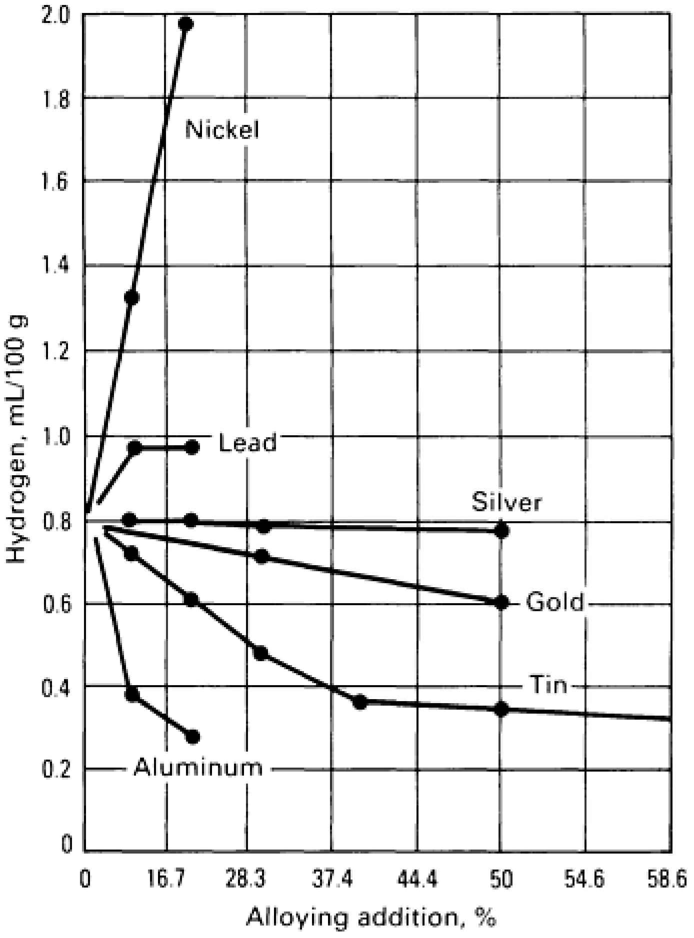

Fig. 36 Effect of alloying elements on the solubility of hydrogen in copper. Source: Ref 62.

Oxygen also presents a potential problem in most copper alloys. In the absence of hydrogen, oxygen alone may not cause problems, because it has limited solubility in the melt. However, it forms a completely miscible liquid phase with

the copper in the form of cuprous oxide (Fig. 37). During solidification, the combination of cuprous oxide and hydrogen can give rise to casting porosity resulting from the steam reaction (discussed later).

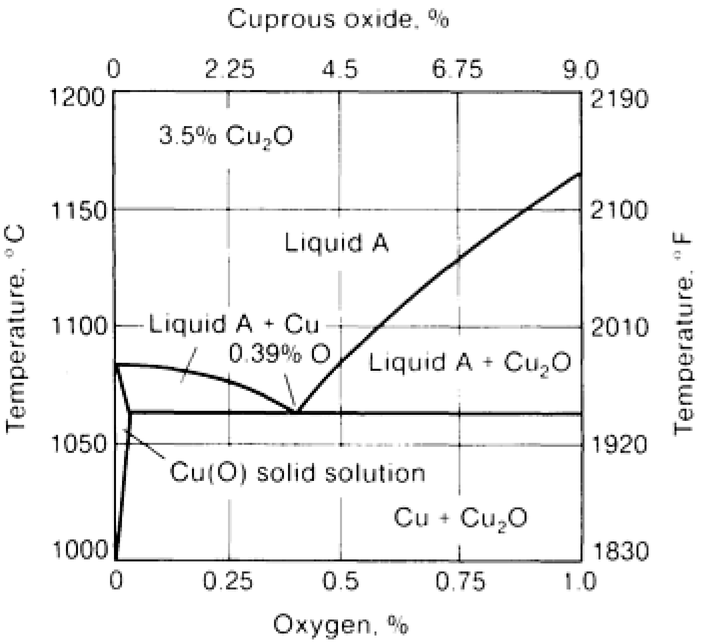

Fig. 37 Copper-oxygen phase diagram. Source: Ref 62.

Sulfur gases have significance in primary copper through the smelting of sulfide ores and in the remelting of mill product scrap containing sulfur-bearing lubricants. Sulfur dioxide is the most probable gaseous product. Foundry alloys and foundry processing usually do not experience sulfur-related problems unless high-sulfur fossil fuels are used for melting.

Carbon can be a problem, especially with the nickel-bearing alloys. The nickel alloys have extensive solubility for both carbon and hydrogen. Carbon can be deliberately added to the melt, along with an oxygen-bearing material such as nickel oxide. The two components will react to produce a carbon boil, that is, the formation of CO bubbles, which collect hydrogen as they rise through the melt (Ref 63). If not fully removed, however, the residual CO can create gas porosity during solidification.

Nitrogen does not appear to be detrimental or to have much solubility in most copper alloys. However, there is some evidence to suggest that nitrogen porosity can be a problem in cast copper-nickel alloys (Ref 64).

Water vapor can exist as a discrete gaseous entity in copper alloys (Ref 61, 65, 66). Water vapor is evolved from solidifying copper alloys, which always have some residual dissolved oxygen. When the oxygen becomes depleted, hydrogen is produced as a separate species.

The type and amount of gas absorbed by a copper alloy melt and retained in a casting depend on a number of conditions, such as melt temperature, raw materials, atmosphere, pouring conditions, and mold materials. Table 4 lists the gases that can be found in a number of copper alloy systems.

Table 4 Summary of gases found in copper alloys

Alloy family	**Gases present**	Remarks
Pure copper	Water vapor, hydrogen	**Approximate hydrogen/water vapor ratio of 1. Higher purity increases the amount of water vapor and lowers hydrogen.**

Copper-tin-lead-zinc alloys	Water vapor, hydrogen CO	**Lead does not affect the gases present. Higher tin lowers total gas content. Increased zinc increases the amount of hydrogen, with a loss in water vapor.**
Aluminum bronzes	Water vapor, hydrogen, CO	**The presence of 5 wt% Ni in alloy C95800 causes CO to occur rather than water vapor. Lower aluminum leads to higher total gas contents.**
Silicon brasses and bronzes	Water vapor, hydrogen	**Approximate hydrogen/water vapor ratio of 0.5. Increased zinc decreases hydrogen and increases water vapor.**
Copper-nickels	**Water vapor, hydrogen, CO**	**All three gases are present up to 4 wt% Ni, after which only CO and hydrogen are present. Hydrogen increases with increasing nickel up to 10 wt% Ni, but is decreased at 30 wt% Ni.**

Testing for Gases

There are essentially three ways to determine the presence of gas in a copper alloy melt. The easiest and simplest is a chill test on a fracture specimen. In this method, a standard test bar is poured and allowed to solidify. The appearance of the fractured test bar is then related to metal quality standards (Ref 67).

The second method is a reduced-pressure test similar to the Straube-Pfeiffer test used for aluminum alloys. In recent years, considerable development and definition have been given to this test as adapted for copper alloys, because the different classes of copper alloys have different solidification characteristics that affect the response to the test (Ref 61, 68, 69, 70). The objective of the test is to use a reduced pressure only slightly less than the dissolved gas pressure so that the surface of the sample mushrooms but does not fracture (Fig. 38). The test apparatus is shown schematically in Fig. 39. The key to establishing controllable results, that is, unfractured but mushroomed test sample surfaces, is to provide wave front freezing. This is accomplished by proper selection of vessel materials to achieve the correct solidification characteristics. Because the freezing ranges of copper alloys vary from short to wide, different materials must be used. The various material combinations that have proved successful are described in Ref 61.

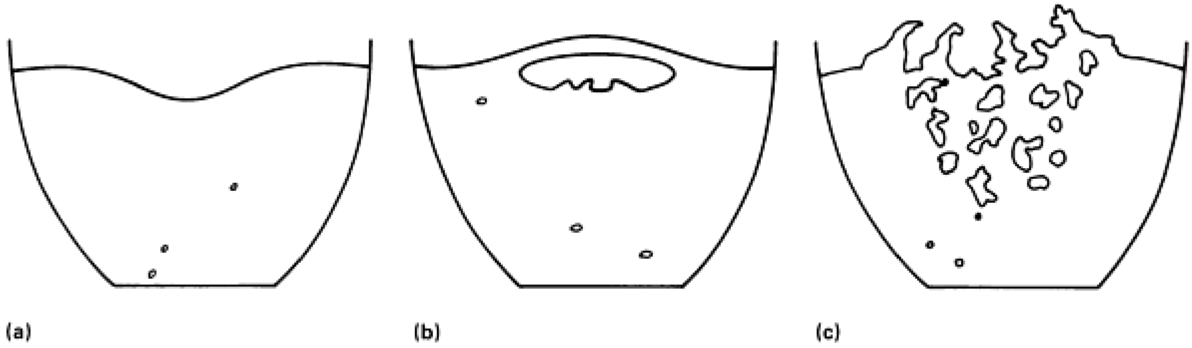

Fig. 38 Effect of pressure on the appearance of copper alloy reduced-pressure test samples containing the same amount of gas. (a) Pressure of 7 kPa (55 torr) results in surface shrinkage. (b) At 6.5 kPa (50 torr), a single bubble forms. (c) Boiling and porosity occur at 6 kPa (45 torr).

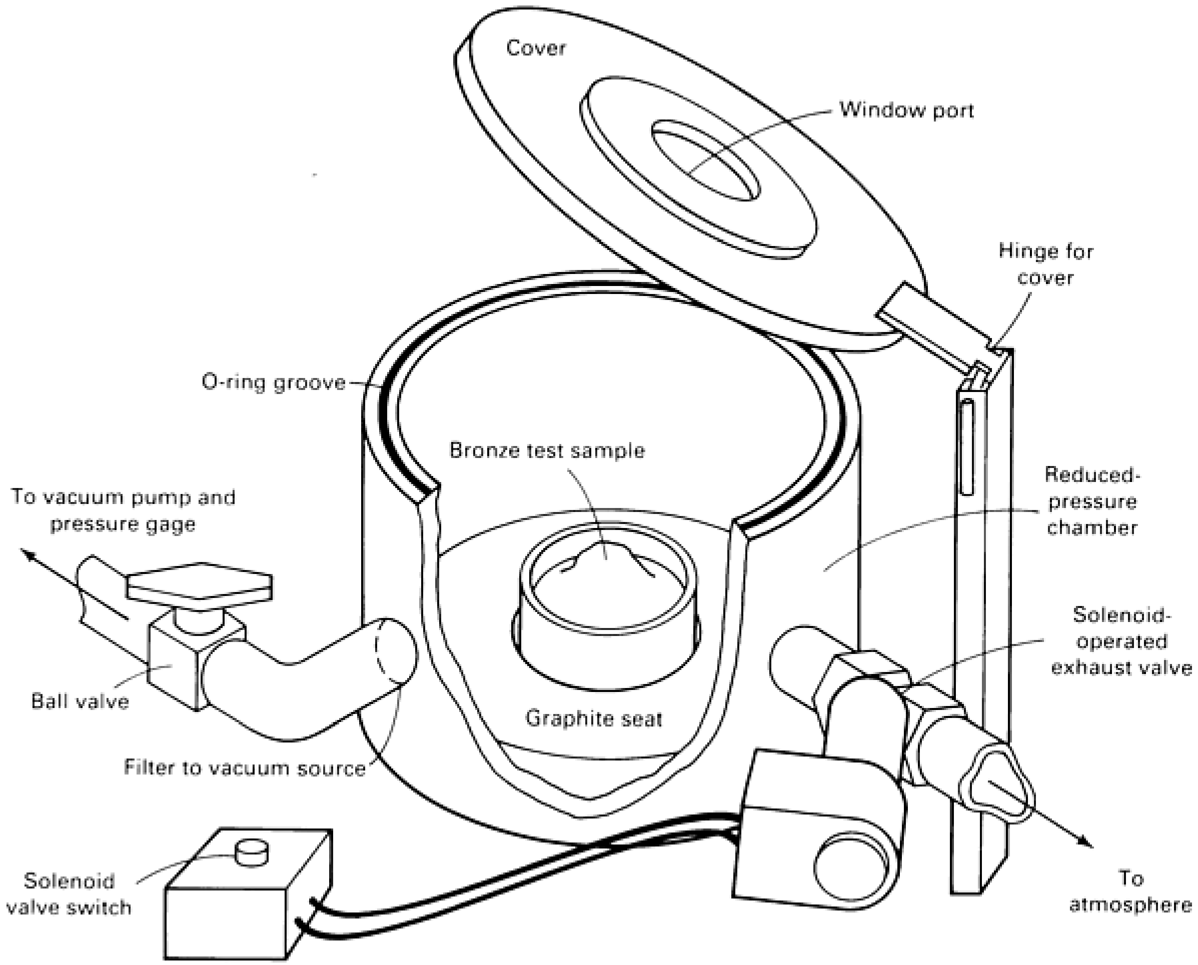

Fig. 39 Schematic of the reduced-pressure test apparatus used to assess amounts of dissolved gas in copper alloys.

Degassing Methods

Oxidation-Deoxidation Practice. The steam reaction previously mentioned is a result of both hydrogen and cuprous oxide being present in the melt. These constituents react to form steam, resulting in blow-holes during solidification as the copper cools:

$$2H + Cu_2O \rightarrow H_2O \text{ (steam)} + 2Cu$$

The proper deoxidation of a copper alloy melt will generally prevent this steam reaction, although excessive hydrogen alone can still cause gas porosity if it is not expelled from the casting before the skin is completely solidified. Fortunately, there is a mutual relationship between hydrogen and oxygen solubility in molten copper (Fig. 40). Steam is formed above the line denoting equilibrium concentration, but not below. Consequently, as the oxygen content is raised, the capacity for hydrogen absorption decreases. Therefore, it is useful to provide excess oxygen during melting to preclude hydrogen entry and then to remove the oxygen by a deoxidation process to prevent further steam reaction during solidification.

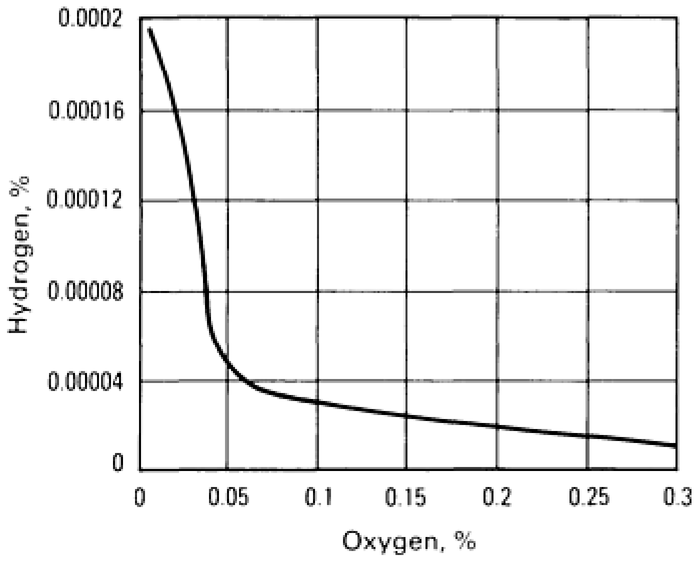

Fig. 40 Hydrogen/oxygen equilibrium in molten copper. Source: Ref 61.

This relationship gave rise to the Pell-Walpole oxidation-deoxidation practice for limiting hydrogen, especially when fossil fuel fired furnaces were used for melting. The melt was deliberately oxidized using oxygen-bearing granular fluxes or briquetted tablets to preclude hydrogen absorption during melting. The melt was subsequently deoxidized to eliminate any steam reaction with additional hydrogen absorbed during pouring and casting.

Zinc Flaring. The term zinc flare applies to those alloys containing at least 20% Zn. At this level or above, the boiling or vaporization point of copper-zinc alloys is close to the usual pouring temperature, as shown in Fig. 41 (Ref 62). Zinc has a very high vapor pressure, which precludes hydrogen entry into the melt. Zinc may also act as a vapor purge, removing hydrogen already in solution. Furthermore, the oxide of zinc is less dense than that of copper, thus providing a more tenacious, cohesive, and protective oxide skin on the melt surface and increasing resistance to hydrogen diffusion. In zinc flaring, the melt temperature is deliberately raised to permit greater zinc vapor formation. Because some zinc loss may occur, zinc may have to be replenished to maintain the correct composition.

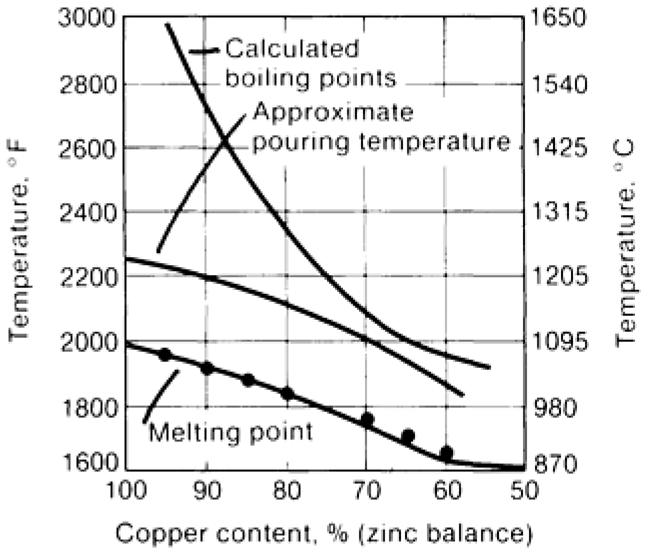

Fig. 41 Influence of zinc content on boiling point or vapor pressure in copper alloys. Source: Ref 62.

Inert Gas Fluxing. With gas fluxing, an inert collector or sparger gas such as argon or nitrogen is injected into the melt with a graphite fluxing tube. The bubbling action collects the hydrogen gas that diffuses to the bubble surface, and the hydrogen is removed as the inert gas bubbles rise to the melt surface. The reaction efficiency depends on the gas volume, the depth to which the fluxing tube or lance is plunged, and the size of the collector gas bubble generated. Again, finer bubble sizes have higher surface-area-to-volume ratios and therefore provide better reaction efficiencies. Figure 42 depicts the amount of purge gas necessary to degas a 450 kg (1000 lb) copper melt. Figure 43 shows the response of an aluminum bronze alloy to nitrogen gas purging. The curve for oxygen purging is also shown.

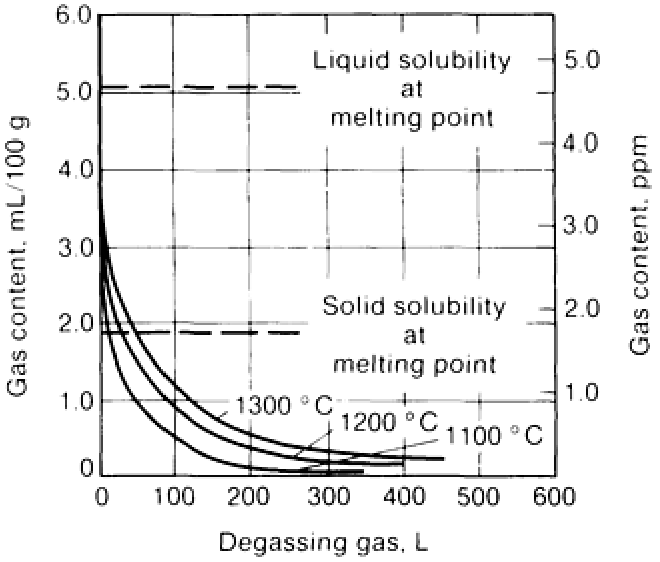

Fig. 42 Amount of purge gas required to degas a 450 kg (1000 lb) copper melt. Source: Ref 70.

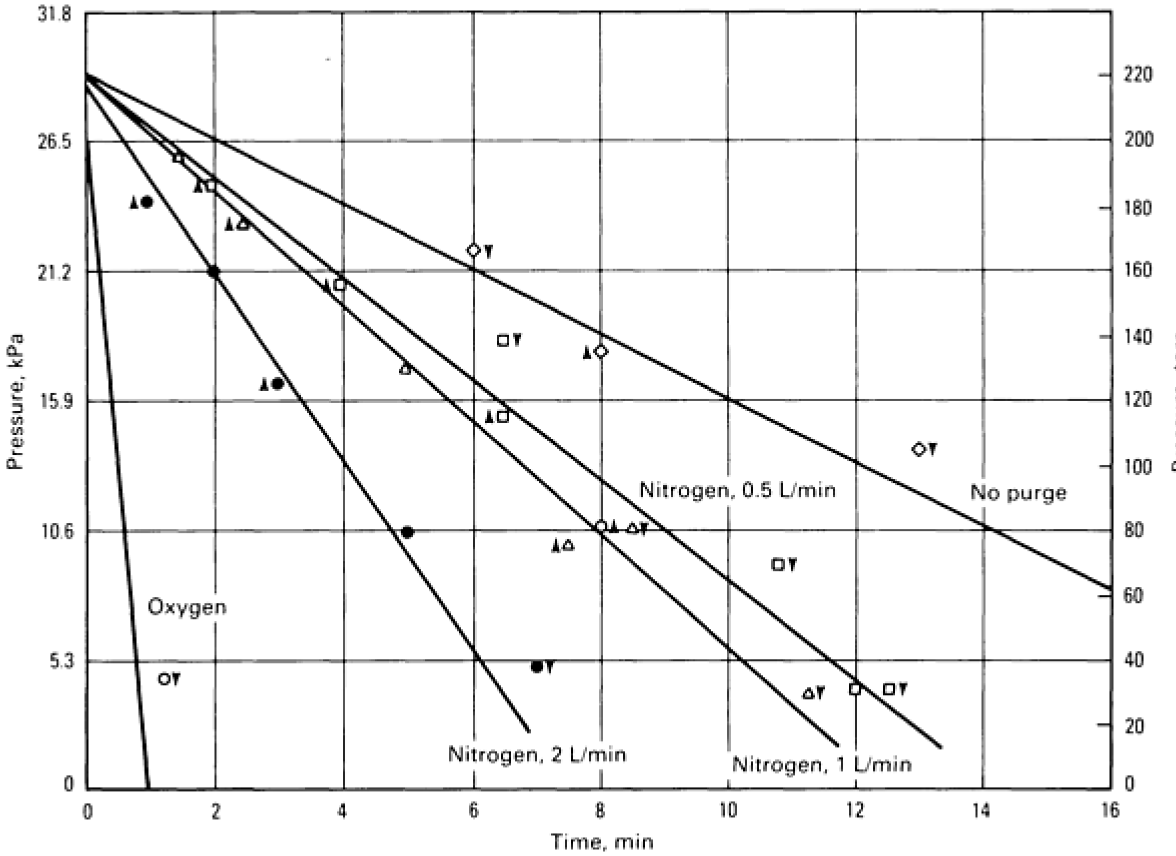

Fig. 43 Effect of nitrogen flow rate during purging on the residual gas pressure remaining in an aluminum bronze melt. The cure for oxygen purging is also shown. Source: Ref 69, 71.

Solid Degassing Fluxes. Other materials can be used to provide inert gas purging. A tabletted granular flux such as calcium carbonate ($CaCO_3$), which liberates CO_2 as the collector gas upon heating, has been successful in degassing a wide variety of copper alloys. This type of degassing is simpler than nitrogen, but must be kept dry and plunged as deep as possible into the melt with a clean, dry plunging rod, preferably made of graphite. This type of degasser may also have the advantage of forming the collector gas by chemical reaction *in situ.* This results in an inherently smaller initial bubble size than injected gas purging for better reaction efficiency. Such an advantage can be inferred from Fig. 44, although after 5 min of degassing the end results are the same.

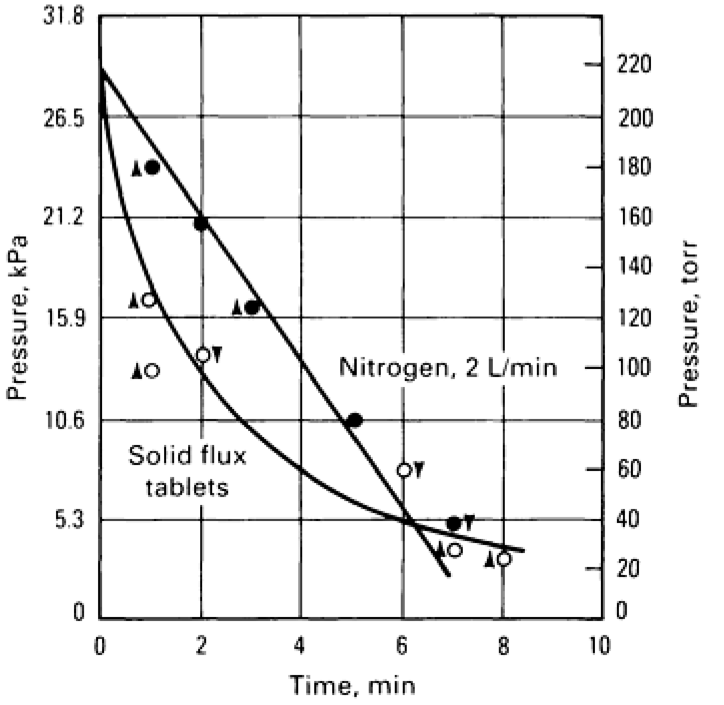

Fig. 44 Comparison of the effectiveness of solid degassing flux versus nitrogen purging. Source: Ref 71.

Other solid degassers in the form of refractory metals or intermetallic compounds, such as calcium-manganese-silicon, nickel-titanium, titanium, and lithium, are effective in eliminating porosity due to nitrogen or hydrogen by their ability to form stable nitrides and hydrides. Again, maintaining dry ingredients, deep plunging, and stirring or mixing will enhance their effectiveness. For best results and optimum reaction efficiency, such degassers should be wrapped or encapsulated in copper materials to provide controlled melting when plunged. Alternatively, copper master alloys containing these elements are available.

For both inert gas fluxing and solid degassing additions, the sparging gas reaction should not be so violent as to splash metal and create an opportunity for gas reabsorption. Furthermore, a melt can be overdegassed; an optimum amount of residual gas remaining in the melt helps to counter localized shrinkage in long freezing range alloys such as leaded tin bronzes.

Vacuum degassing is not generally applied to copper alloys, although it can be very effective. However, the cost of the equipment necessary is relatively high, and there may be a substantial loss of more volatile elements having a high vapor pressure such as zinc and lead. Furthermore, significant superheat (up to 150 °C, or 300 °F) may be required to accommodate the temperature drop during the degassing treatment, further aggravating the vapor losses.

Auxiliary Degassing Methods. There are other ways to degas a copper alloy melt than using a specific treatment. The technique of lowering the melt superheat temperature, if possible, and holding the melt (in a dry, minimal gas environment) provides outgassing simply by lowering the equilibrium liquid state solubility of the gas. During casting, the use of chills to provide directional solidification, particularly for the long freezing range alloys such as the red brasses and tin bronzes, results in less tendency for gas porosity.

In the mold-metal reaction, previously degassed and deoxidized metal containing excess phosphorus or lithium deoxidants can react with green sand containing moisture. Hydrogen is liberated and absorbed as the metal comes into contact with the sand. This can be minimized by correct deoxidant additions (discussed in the following section in this article). In addition, finer facing sands or mold coatings (inert or reactive such as sodium silicate or magnesia) can be used; these confine any reaction to the mold/metal interface area and retard hydrogen penetration into the solidifying skin of the cast metal.

Deoxidation of Copper Alloys

All copper alloys are subject to oxidation during most melting operations. Oxygen reacts with copper to form cuprous oxide, which is completely miscible with the molten metal. A eutectic is formed at 1065 °C (1950 °F) and 3.5% Cu_2O, or 0.39% O, as shown in the copper-oxygen phase diagram in Fig. 37.

Therefore, cuprous oxide exists within the melt as a liquid phase and is not generally separated by gravity alone. If not removed, this liquid phase will cause discontinuous solidification during casting, resulting in considerable porosity and low mechanical strength. Thus, some type of deoxidation process is required. In addition, proper deoxidation of all melts enhances fluidity and therefore castability.

Of course, deliberate oxidation treatments (the oxidation-deoxidation process previously described) are still employed. These are designed to preclude hydrogen pickup in copper alloy melts.

Phosphorus Deoxidation. Most copper alloys are deoxidized by a phosphorus reduction of the cuprous oxide. Although several other oxygen scavengers are possible according to the free energy of oxide formation, phosphorus is usually the easiest, most economical, and least problematic deoxidant. The phosphorus is usually added in the form of 15% phosphor copper master alloy, either in granular shot or briquetted waffle form. Care must be taken to ensure that the deoxidant is dry. The deoxidant is often added to the bottom of the ladle before pouring so that during pouring the deoxidant reacts with the cuprous oxide contained in the melt. The turbulence created during pouring is sufficient to ensure adequate mixing. The phosphorus copper deoxidant should not be simply thrown onto the surface of the ladle after pouring, because little mixing will result. When the deoxidant is added directly to the furnace, however, it should be

completely stirred into the melt using clean, dry tools, and pouring should begin as soon as possible so that the effect is not lost.

Use of phosphorus deoxidation results in the formation of a liquid slag of cuprous phosphate [$2P + 4Cu + 7O \rightarrow 2Cu_2O \cdot P_2O_5$]. This product easily separates from the rest of the melt; therefore, the phosphorus effectively scavenges the oxygen, delivering the product to the surface dross phase, where it can be easily skimmed.

Phosphorus is usually added at a rate of 57 g (2 oz) of 15% master alloy per 45 kg (100 lb) of melt. In cases where oxidation of the melt is deliberately employed to reduce hydrogen absorption, double this amount can be required for full deoxidation. This is usually sufficient to deoxidize completely a melt saturated with 0.39 wt% O. However, the recovery of phosphorus is less than 100% and may be as little as 30 to 60% (Ref 72). It is desirable to maintain a residual level of at least 0.01 to 0.015% P in the melt, especially during pouring, so that reoxidation and potential steam reaction problems are alleviated.

Each foundry must determine the proper addition rate for a given set of conditions. Furthermore, with foundry returns, a certain residual amount of phosphorus is usually already present. A routine addition of phosphor copper for deoxidation could then actually result in excessive phosphorus. If the phosphorus content is too high during melting or pouring, the lack of oxygen may invite hydrogen entry and result in the steam reaction during casting. Adding more phosphorus to control the steam reaction can therefore actually aggravate the condition. In addition, when the phosphorus content is 0.03% and beyond, excessive metal fluidity can result in penetration of the molding sand or burn-in during casting.

Phosphorus copper is an effective deoxidant for the red brasses, tin bronzes, and leaded bronzes. However, phosphorus should not be used for deoxidizing high-conductivity copper alloys, because of its deleterious effect on electrical conductivity (as will be discussed shortly), and it should not be used for copper-nickel alloys. In these materials, the presence of phosphorus results in a low-melting constituent that embrittles the grain boundaries. A silicon addition of 0.3% and a magnesium addition of 0.10% serve to deoxidize and desulfurize copper-nickel melts. For nickel-silver alloys (copper-nickel-zinc), the use of 142 g (5 oz) copper-manganese shot per 45 kg (100 lb) of melt, and 57 g (2 oz) manganese coupled with 85 g (3 oz) of 15% P-Cu, is a recommended deoxidation technique.

The yellow brasses, silicon bronzes, manganese bronzes, and aluminum bronzes usually do not require deoxidation *per se*, because of the oxygen-scavenging effects of their respective alloy constituents.

High-Conductivity Copper (Ref 72, 73, 74, 75). Where the high-copper alloys (pure copper, silver copper, cadmium copper, tellurium copper, beryllium copper, chromium copper) are employed and electrical conductivity is a desirable property, phosphorus copper cannot be used as a deoxidant. Moreover, the strong oxide formers beryllium and chromium serve as their own deoxidants.

Figure 45 shows the effects of a variety of elements on the electrical conductivity of copper. Clearly, phosphorus even in small amounts significantly decreases conductivity; therefore, alternative deoxidants must be used. Fortunately, both boron and lithium are capable of deoxidizing high-conductivity copper without appreciably affecting electrical conductivity.

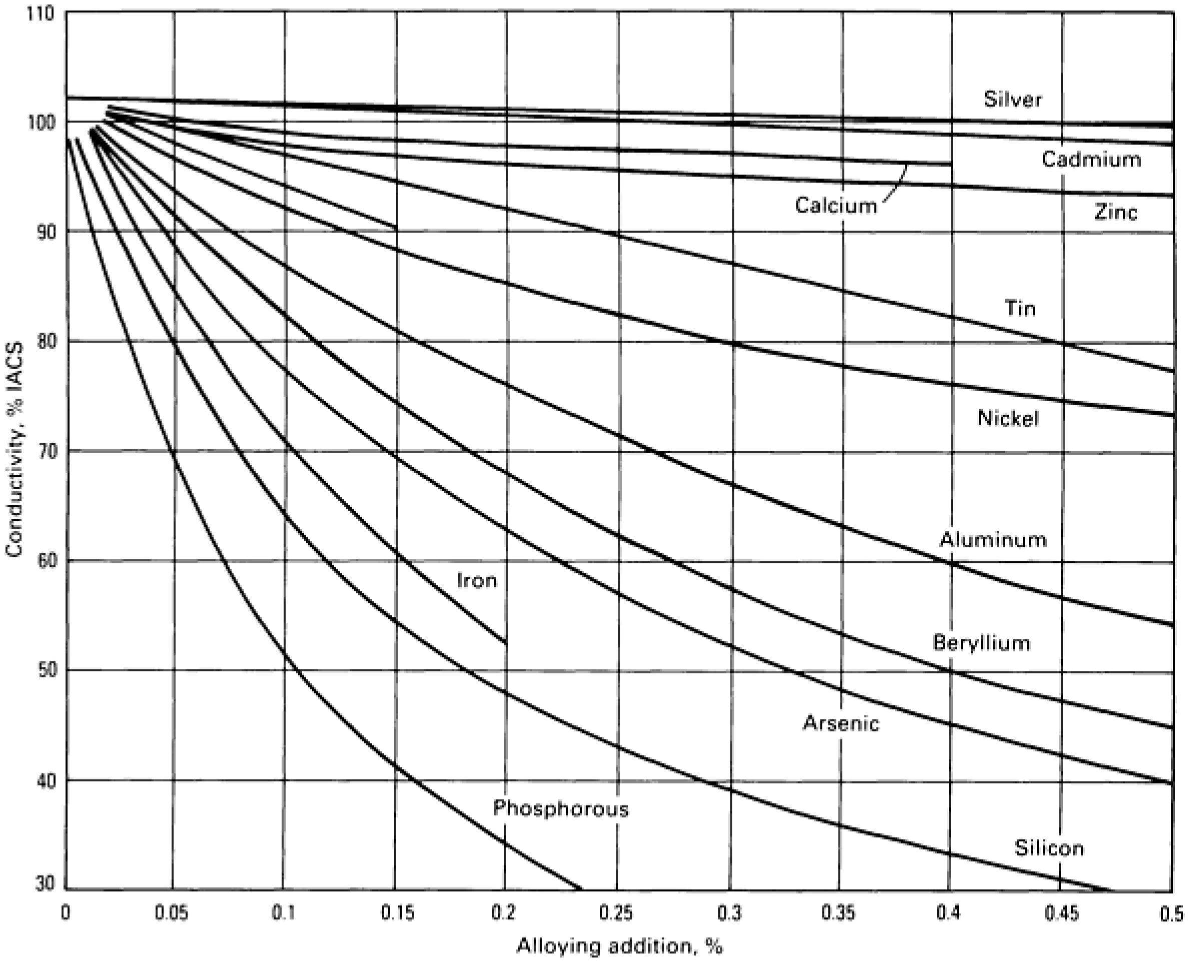

Fig. 45 Effect of alloying elements on the electrical conductivity of copper. Source: Ref 73.

Boron Deoxidation. Boron is available either as a copper-boron master alloy or as calcium boride (CaB_6). The boron probably forms a copper-borate slag of the general form $2Cu_2O{\cdot}B_2O_3$ in much the same fashion as phosphorus produces a cuprous oxide phosphate slag (Ref 72). Theoretically, the boron combines with 60% more oxygen than the stoichiometric amount required to form B_2O_3 and therefore appears to be superefficient. However, practical experience has shown that this theoretical efficiency is not always achieved and that lithium is more effective, as shown in Fig. 46 (Ref 72). Therefore, lithium is often preferred, although there are greater precautions attendant upon its use.

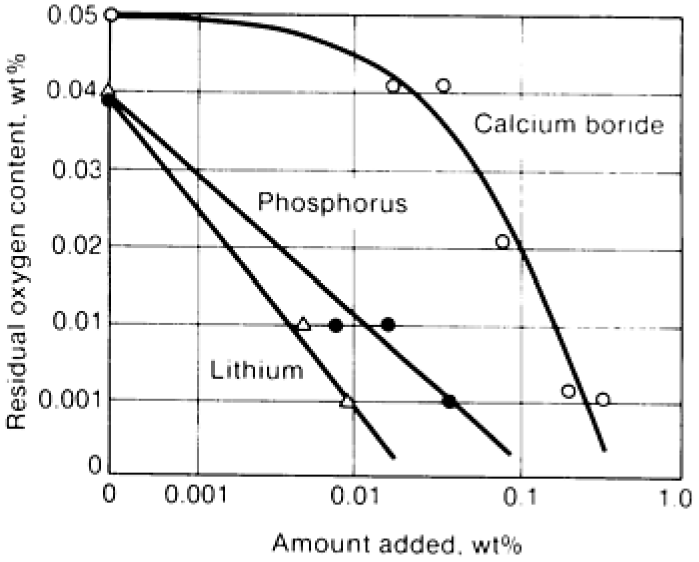

Fig. 46 Deoxidant efficiency in copper alloy melts. Source: Ref 72.

Lithium Deoxidation (Ref 62, 73, 74, 75, 76). Lithium has the advantage of serving as both a deoxidant and a degasser because it reacts readily with both oxygen and hydrogen. Lithium is soluble in molten copper but insoluble in the solid state. There is very little residual lithium contained in the casting or in scrap for remelt.

Because lithium metal is very reactive in air, bulk lithium metal must be stored in oil. For foundry applications, lithium is supplied in sealed copper cartridges. These cartridges must be stored in a safe, dry environment and must be preheated (to above 105 °C, or 225 °F) before use to drive off any surface moisture. These preheated cartridges should then be carefully yet firmly and quickly plunged to the bottom of the reacting vessel (furnace or ladle) to achieve full intimate contact and reactivity with the bulk of the melt. Only clean, dry, preheated plunging tools should be used for this task. Graphite rods are usually preferred.

Lithium-copper cartridges are generally available in various sizes ranging from 2.25 g (0.09 oz) for 23 kg (50 lb) melts to 108 g (4 oz). Thus, lithium additions can be made at maximum efficiency.

The specific chemical reactions that can occur with lithium include:

$$2Li + CU_2O \rightarrow 2Cu + Li_2O \text{ (deoxidation)}$$

$$Li + H \rightarrow LiH \text{ (degassing)}$$

$$LiH + CU_2O \rightarrow 2Cu + LiOH \text{ (recombination)}$$

$$2Li + H_2O \rightarrow Li_2O + H_2 \text{ (reaction during pouring)}$$

The lithium oxide (Li_2O) and lithium hydroxide (LiOH) products separate cleanly as a low-density fluid slag suitable for skimming (Ref 73). The lithium hydride that forms initially if hydrogen is present is unstable at normal copper melting temperatures and recombines with cuprous oxide (recombination).

When lithium is added in excess of the amount of cuprous oxide present, it will react with moisture in the air during pouring and can therefore generate sufficient hydrogen to regas the melt. This can result in unanticipated additional gas porosity and unsoundness during solidification.

Because lithium is such an effective deoxidant, it can also reduce residual impurity oxides (FeO, P_2O_5, and so on) in high-conductivity copper melts. This allows these elements to redissolve in the molten metal to the extent of their solubility limit and thus reduce electrical conductivity according to Fig. 45. Furthermore, lithium can form intermetallic compounds

with silver, lead, tin, and zinc when the residual lithium exceeds that required for deoxidation. These intermetallic compounds, while reducing solid solubility, may improve mechanical properties and electrical conductivity.

Occasionally, it may be desirable to practice a duplex deoxidation treatment using the less expensive phosphorus, followed by a lithium treatment (Ref 73, 75, 76). Care must be taken to do this quickly and not allow phosphorus reversion to occur by letting the copper phosphate deoxidation slag remain on the melt for an extended period of time.

Magnesium Deoxidation. Magnesium behaves similarly to lithium, but may be stored in air rather than oil. It is actually a stronger deoxidant in terms of its free energy of oxide formation (Ref 77), and it is used to deoxidize (and desulfurize) copper-nickel alloys. The deoxidation product (magnesia) is a stable refractory, unlike lithium compounds, but it forms a tenacious oxide skin and can result in inclusions in copper casting alloys.

Testing for Proper Deoxidizer Addition. As stated previously, each foundry should assess its own casting practice for a given alloy and set of melting conditions and should determine the optimal addition of deoxidizer. However, there are two tests that can be used to determine whether a given amount of deoxidizer is adequate.

In the first test, a test plug or shrink bar of metal approximately 75 mm (3 in.) in diameter by 75 mm (3 in.) deep is poured. If a shrinkage cavity results, the metal is deoxidized and ready for pouring, which should then be done immediately. Shrinkage will not occur until about 0.01% residual phosphorus is present (Ref 77). A puffed-out or mushroomed cap on the test plug indicates that deoxidation is incomplete and that more should be added.

The second test involves a carbon or graphite rod immersed in the melt. When the rod surface reaches the molten metal temperature, if there is oxygen present, the rod will vibrate because of the reaction ($2C + O_2 \rightarrow 2CO$) occurring on the bar surface. The intensity of the vibration is a function of the oxygen content, and an experienced foundryman can readily determine the point at which the reaction becomes negligible, that is, when the melt is sufficiently deoxidized. The vibration decreases near the level of 0.01% residual phosphorus, as expected for a deoxidized melt (Ref 77).

Relative Effectiveness of Copper Deoxidizers. Various elements capable of scavenging oxygen from copper alloy melts have been described. The theoretical relative capabilities of several deoxidizers are listed below:

Deoxidizer	**Reaction products**	Amount of deoxidizer required to remove 0.01% oxygen	
		g/100 kg	oz/100 lb
Carbon	CO	7.5	**0.12**
Carbon	CO_2	3.8	**0.06**
Phosphorus	P_2O_5	7.5	**0.12**
Phosphorus	$2Cu_2P_2O_5$	5.6	**0.09**
Cu-15P	P_2O_5	49.3	**0.79**
Cu-15P	$2Cu_2P_2O_5$	36.8	**0.59**

Boron	B_2O_3	4.4	**0.07**
Boron	$2Cu_2OB_2O_3$	2.5	**0.04**
Cu-2B	B_2O_3	224.5	**3.60**
Cu-2B	$2Cu_2OB_2O_3$	134.7	**2.16**
Lithium	Li_2O	8.7	**0.14**
Magnesium	**MgO**	**15.0**	**0.24**

In practice, selection of the deoxidizer must be based on actual efficiency, economics, ease of use, and the specific metallurgical requirements of the alloy in question.

Melt Refining of Aluminum Alloys

The principal elemental impurities in molten aluminum are alkali metals (lithium, sodium, and calcium) in very small concentrations (<20 ppm) and magnesium in large concentrations (0.20 to 1.5%). In the latter case, the magnesium is commonly removed by demagging processes (see the section "Demagging of Aluminum Alloys" in this article). Phosphorus is sometimes present as an impurity when remelting phosphorus-treated hypereutectic aluminum-silicon alloys, but is generally removed by conventional fluxing processes.

The alkali metals lithium, sodium, and calcium are true impurities arising from primary aluminum production and can have detrimental effects on solidification and casting integrity if not removed. Residual lithium originates from certain electrolytic reduction cell practices in the production of primary aluminum, where lithium salts are used to enhance energy efficiency in the Al_2O_3 reduction process. In the new aluminum-lithium alloys, the element is a deliberate addition (2 to 4%). However, as these alloy products are scrapped, remelt contamination of nonlithium alloys can become a problem, especially for the secondary smelting industry. Sodium may also be present as an impurity, dissolved by the molten aluminum from the cryolite used in the reduction process. Calcium may originate from the Al_2O_3, refractory vessel deterioration, or as an impurity in other additives.

Removal of Alkali Metals

The removal of these impurities is rendered thermodynamically favorable when the halogens chlorine or fluorine are introduced into the melt. Figure 47 shows the free energy of formation of various chloride compounds. It can be seen that the chlorination of aluminum will result in the preferential formation of chlorides of lithium, sodium, potassium, and calcium.

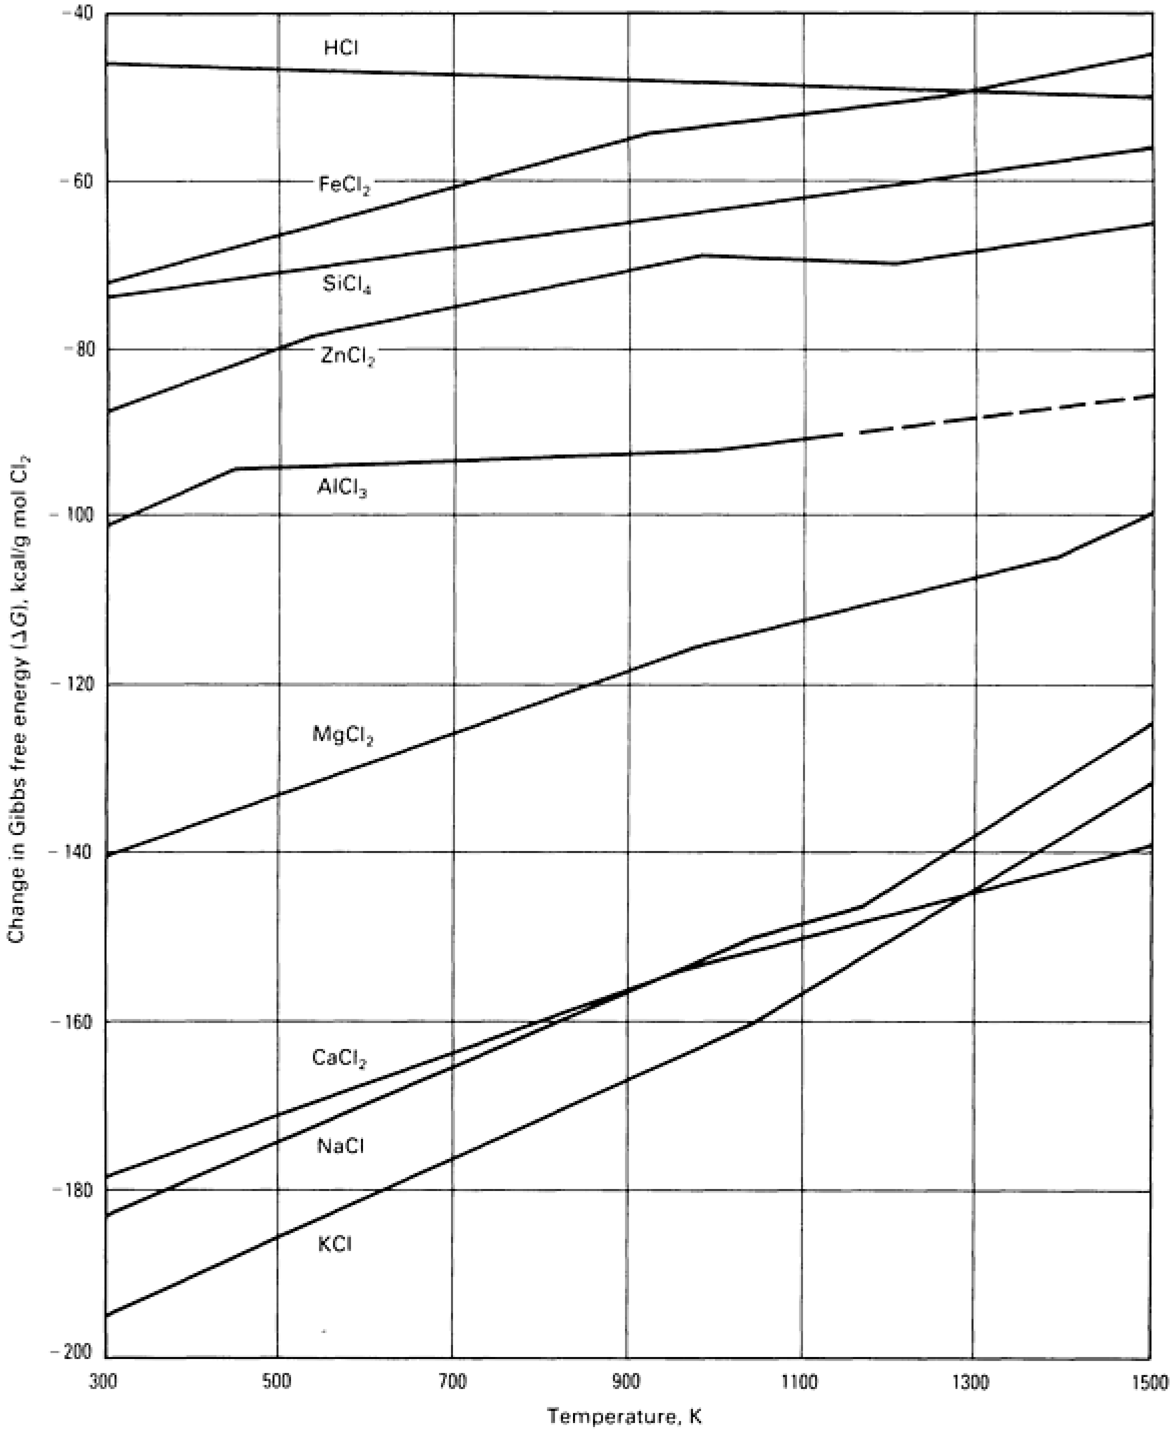

Fig. 47 Thermodynamics of metal chloride formation in aluminum alloys. Source: Ref 78.

Various methods are available for removing these impurities. Simple gas fluxing or gas or solid flux injection coupled with rotating dispersers can be used. Most of these mechanical processes apply to the primary, secondary, or mill products industries, although flux injection is also applicable to foundry operations.

The TAC process, or the treatment of aluminum in crucible (Fig. 48), employs the injection of AlF_3 powder into a crucible of metal that is stirred with a cast iron paddle mixer. Critical process parameters include mixer paddle design, position within the crucible, amount of flux added, and proper speed (revolutions per minute) to achieve optimum reaction capability and performance (Ref 80). Favorable reactions between dissolved alkali metals and the decomposed

fluorides occur to form complex metal fluoride compounds. Figure 49 shows the alkali removal results obtainable with this process.

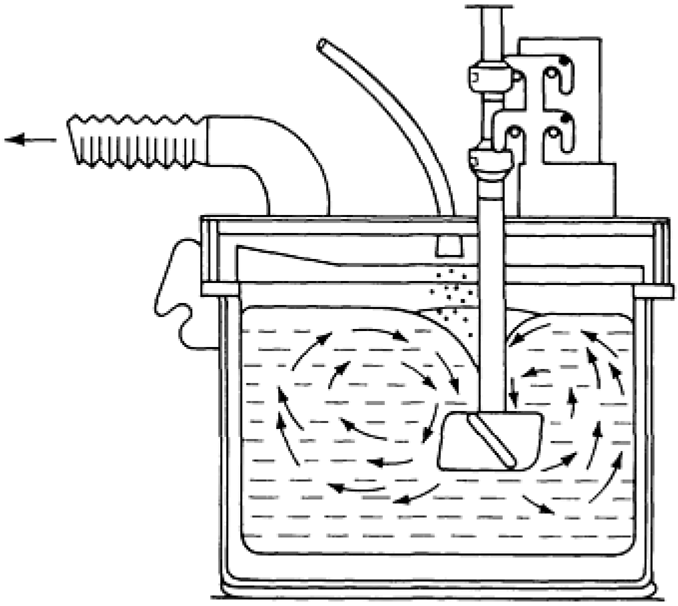

Fig. 48 Schematic of the TAC process for the removal of alkali metal impurities from aluminum. Source: Ref 79.

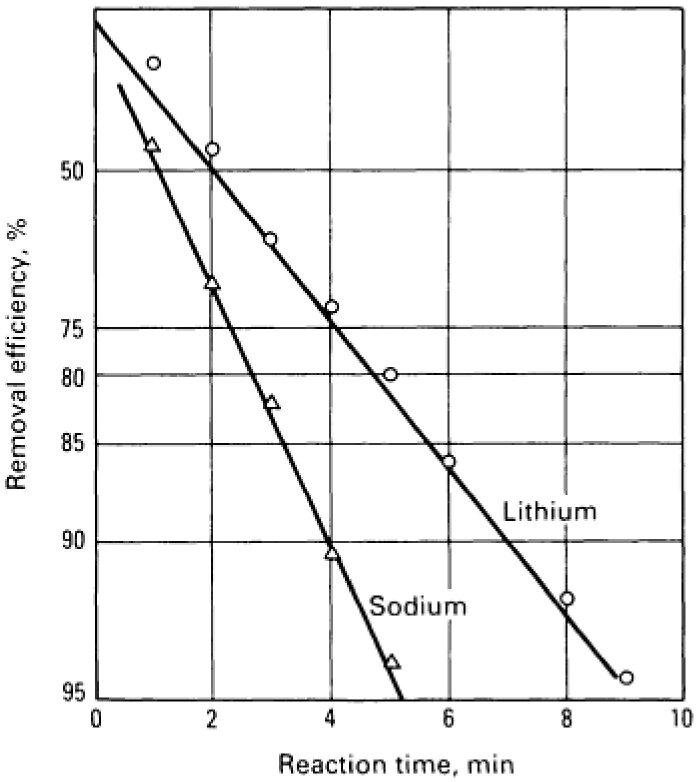

Fig. 49 Efficiency of TAC alkali metal removal versus time. Temperature: 800 °C (1470 °F); AlF_3 addition: 2 kg/Mg (4 lb/ton); rotor speed: 150 rpm. Source: Ref 81.

Other rotating injection systems are also used in-line between the melting or holding furnace and the casting equipment. In general, each of these processes involves chlorine plus an inert carrier gas such as argon or nitrogen, and similar results are obtained. Information on these processes can be found in Ref 47, 52, and 55, which discuss the SNIF, Alcoa, and Alpur processes, respectively.

The metal in-line treatment (MINT) system (Fig. 28) operates with the metal flow counter to the flow of the purge gas being injected through a series of nozzles, thus creating a swirling tank reaction without the use of other moving parts. Table 5 lists the alkali removal capabilities of this system using argon plus 1 to 2% Cl at a rate of 0.4 L/lb/min for metal flow rates near 590 kg/min (1300 lb/min).

Table 5 Removal of alkali metals from aluminum alloys using the MINT system

General Principles of Gas Injection Refining. A relatively recent investigation has shown how calcium can be removed by chlorination in a stirred tank reactor typical of many in-line metal treatment technologies and has demonstrated several fundamentals that apply to other melt-refining and degassing (hydrogen removal) reactions (Ref 82, 83):

- In each stirred tank reactor, there are limits of fluxing gas, flow rate, and rotor speed, varying with reactor size and geometry, beyond which efficiency is reduced
- Fluxing gas average bubble size in stirred tank reactors varies with fluxing gas flow rate and rotation speed (Fig. 50)
- The fluxing gas interfacial area is the primary reaction rate controlling parameter in these systems
- An increase in the total fluxing gas interfacial area (that is, reduced bubble size and increased bubble numbers) increases the reaction rate more significantly than increasing chlorine concentration alone (Fig. 51)

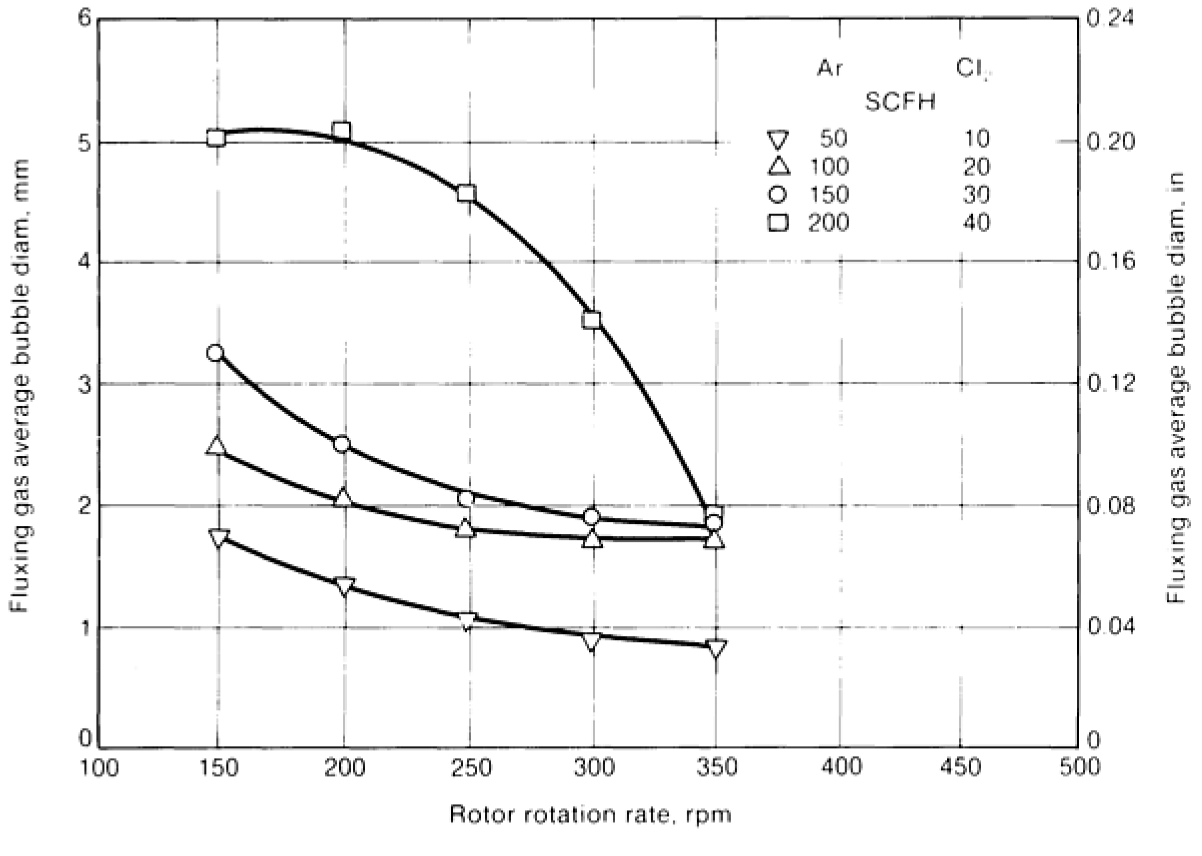

Fig. 50 Effect of gas flow rate (in standard cubic feet per hour, SCFH) and rotor speed on bubble size of a stirred tank reactor. Melt weight: 1500 kg (3300 lb); alloy: aluminum plus calcium; fluxing gas: 16.7% Cl. Source: Ref 82.

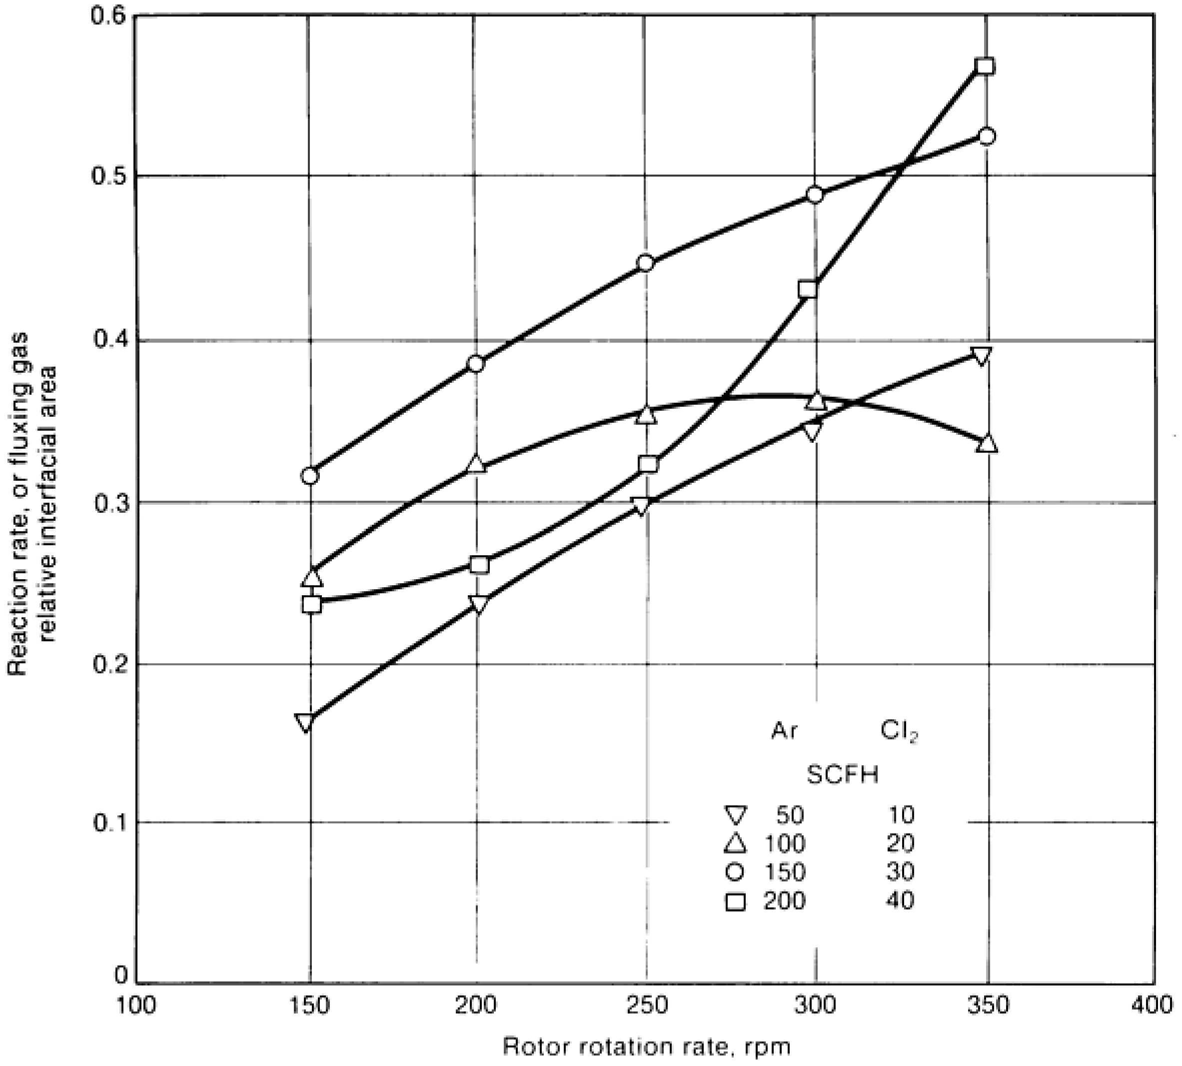

Fig. 51 Effect of gas flow and rotor speed on the reaction rate for a stirred tank reactor. Same alloy and parameters as given for Fig. 50. Source: Ref 82.

It has also been found that increased chlorine concentration as a reactive gas may not always produce better trace element removal. This may be related to an already minimized gas bubble size; increased gas volume is beneficial only if mass transfer is not the rate-limiting step.

Filter Bed Refining Process. Another method of removing alkaline impurities is to use a bed filter. One such technique employs petrol coke, which most likely removes alkali metals through the formation of salts or metal carbon compounds such as Li_2C_2, LiC_4, and $NaC_{64}NaC_{12}$ (Ref 84). The process equipment (Fig. 52) consists of a bed of petrol coke and corundum. Argon gas is sparged to flow counter to the molten aluminum. A sodium reduction of up to 75% or down to as little as 1 to 3 ppm can be achieved. Lithium has been removed at rates up to 60%. Removal rate and efficiency increase with metal temperature and decrease with metal flow rate (Ref 84). Efficiency also decreases as the petrol coke becomes saturated.

Demagging of Aluminum Alloys

Many useful aluminum alloys contain magnesium in quantities from 0.10 to 5.5%. Wrought alloys in particular contain higher levels of magnesium, and casting alloys 518 and 520 also contain 8 and 10% Mg, respectively. These materials constitute a significant portion of the scrap market and are therefore largely available for recycling/remelting. Mill recyclers often need to produce new alloy product with lower magnesium content, and secondary smelters producing die cast and foundry ingot also need to produce very low magnesium content alloys (generally <0.2%). Therefore, there may be a need to demag aluminum scrap during these remelting/alloying operations.

Fortunately, the demagging of aluminum alloy scrap is possible during remelting. There are three general types of processes that can be used to remove magnesium from aluminum: chlorination, use of solid chlorine-containing fluxes, and electrolytic demagging (Ref 85). Although electrolytic demagging does not yet exist commercially, it is worthy of mention because it eliminates the potential environmental problems associated with chlorination. Demagging by chlorination or fluxing is discussed further in the section "Chlorination and Fluxing Processes" in this article.

Principles of Demagging

Magnesium can be removed from molten aluminum alloy by adding halogen compounds containing chlorine and/or fluorine. The reaction between magnesium and chlorine or fluorine occurs because it is thermodynamically favorable; that is, there is a preferred chemical affinity between magnesium and the halogen at normal molten aluminum operating temperatures. Although both halogens can be used, commercial practice, economics, and availability usually favor the use of chlorine.

Figure 47 shows the thermodynamics of metal chloride formation; it can be seen that indeed $MgCl_2$ formation is favorable. Accordingly, when gaseous chlorine is introduced into molten aluminum, $AlCl_3$ is formed; this is a gaseous phase, and it further decomposes to react with the magnesium present. The resultant product--$MgCl_2$--forms as a liquid phase above 712 °C (1313 °F). It is less dense than aluminum and therefore ultimately rises to the surface or dross phase, where it can be removed by skimming. However, favorable thermodynamics alone do not guarantee that magnesium will be efficiently removed. Kinetic factors (rate of mixing, contact area) also have pronounced effects. Therefore, adding chlorine alone does not guarantee effective magnesium removal, particularly if it is injected simply by lances or fluxing tubes.

Figure 53 shows free energy changes for various reactions in the demagging process as a function of magnesium content. The change in free energy ΔF is negative; that is, the demagging reaction is thermodynamically favorable throughout the entire range of magnesium levels to 1% (and beyond although this is not shown). Kinetic factors, however, determine whether or not the reaction will occur. The most important kinetic factors are the size and residence time of the $AlCl_3$ bubbles. Finer bubble sizes have higher surface-area-to-volume ratios; this results in more contact area and therefore higher reaction rates. Accordingly, processes that provide for finer bubble sizes and better mixing are desired for effective and efficient demagging.

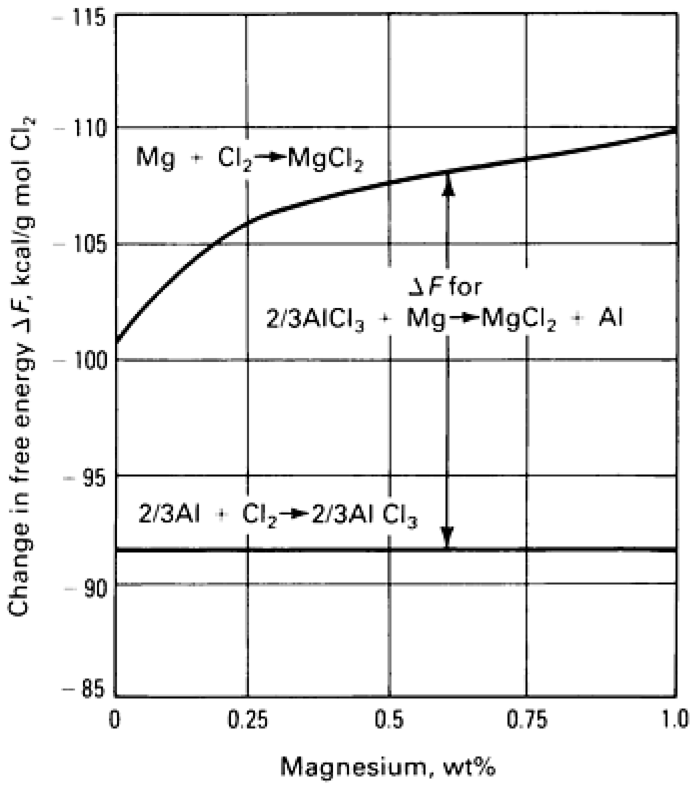

Fig. 53 Free energy changes for reactions occurring during the demagging of aluminum at 700 °C (1290 °F). Source: Ref 86.

Demagging Efficiency. For a perfect (100% efficient) reaction, 1.34 kg (2.95 lb) of chlorine is required to remove 0.45 kg (1 lb) of magnesium. If process factors are such that the reaction is not completely efficient, substantially more chlorine may be required. Inefficient reactions waste time and chlorine and usually result in substantial emissions and fuming, creating environmental hazards and corrosion problems. It is therefore useful to express actual demagging efficiency as a percentage of the stoichiometry of a complete reaction. Thus:

$$\textit{Demagging}\ \text{efficiency}(\%) = \frac{2.95}{\text{Actual chlorine used per pound of magnesium}}$$

When the above-mentioned kinetic factors are not sufficiently satisfied, the reduction of $AlCl_3$ is incomplete. Effluent from the reaction chamber, which contains $AlCl_3$, will react with moisture in the air to form aluminum oxychlorides and chlorohydrates plus aluminum oxide and hydrochloric acid.

Demagging efficiency also varies with magnesium concentration. Figure 54 shows a decreasing efficiency at lower magnesium levels, following the concept of Henry's law for lower free energy available for reaction at low or dilute levels of solute (in this case, magnesium in aluminum). Therefore, reducing magnesium from 1.0 to 0.3% is much easier than reducing it from 0.3 to 0.1%.

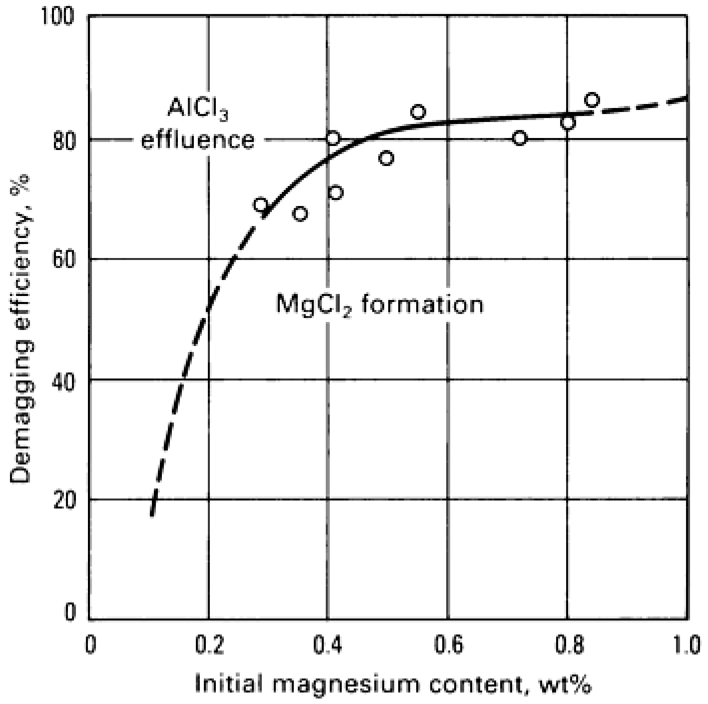

Fig. 54 Efficiency of demagging versus initial magnesium content. Source: Ref 86, 87.

Chlorination and Fluxing Processes

Flux Tube Demagging. The simplest method of demagging is the use of flux tubes for chlorination. However, flux tube demagging is not particularly efficient, because the bubble size generated is not sufficiently fine and the effluent may be extensive. Figure 55 illustrates magnesium loss during the simple flux tube chlorination of aluminum melts. As shown, the efficiency for pure chlorine is temperature dependent, optimizing near the melting point of $MgCl_2$ (710 °C, or 1310 °F).

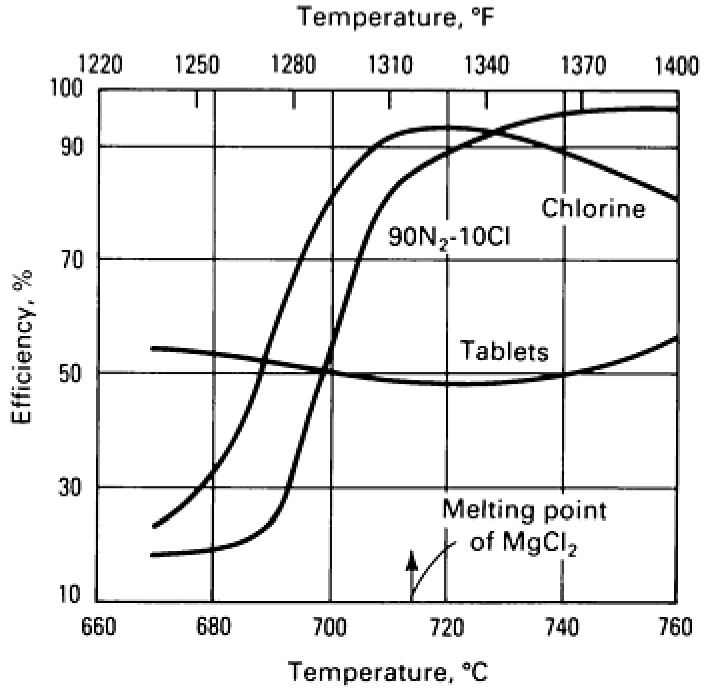

Fig. 55 Effect of temperature on the efficiency of flux tube demagging process associated with the formation of

liquid $MgCl_2$. Source: Ref 88.

The Bell process is based on the injection of chlorine gas into molten aluminum under a cast iron bell submerged into the melt. The favored chlorine partial pressure under the bell maximizes the reaction time, and the chloride fumes generated and the unused chlorine gas are mostly trapped within the bell. However, a scrubber system and a settling pond are often required to handle the effluent in most applications. Consequently, the Bell process has largely given way to other demagging methods with better environmental acceptance (Ref 87).

The Derham process uses a flux layer, usually chloride salts and/or cryolite, that traps the $AlCl_3$ fumes generated by chlorine injection. This flux layer creates a further reaction between the $AlCl_3$ and the magnesium-bearing molten aluminum. However, a large amount of dross can be created in the process, resulting in disposal problems as well as the emission of salt fumes.

The Derham and Bell processes have been commonly used in the secondary industry and have achieved better than 97% efficiency at magnesium levels of 0.10%. However, the need for close control of chlorine injection and the flux disposal problems of the Derham process, as well as the mechanical system complexities of the Bell process, have limited the usefulness of these systems in modern secondary smelting operations (Ref 87).

Channel Injection Process. The channel induction-injection furnace uses chlorine injection into the loop or throat of the induction furnace. Small gas bubbles are generated by the electromagnetic induction stirring action of the furnace (Ref 89). Excellent magnesium removal results have been reported, but the system has not achieved significant commercialization, possibly because of high energy costs and lack of flexibility. Furthermore, the channel induction melting of scrap aluminum and the accompanying problems with dross formation may pose significant operating and maintenance difficulties.

The ALCOA process is often used as an in-line demagging treatment in the production of mill products production (Ref 52). This process is similar to rotary degassing, and it consists of a reactor vessel with one or more rotating dispersers. A flux gas consisting of chlorine plus nitrogen is introduced, and the disperser(s) ensures good mixing. Excellent removal rates and process efficiencies (now 99%) have been achieved with this type of unit, but it is expensive and is primarily suitable for the recycling of mill products.

The gas injection pump has become the most widely used demagging method in secondary smelting operations. Combining forced convection molten metal circulation with chlorine injection through a flux tube discharging just ahead of the rotating impeller, the pump allows the *in situ* demagging of high-magnesium aluminum scrap during the melting process. Demagging efficiencies with this device have been reported to be virtually 100% when the molten metal bath temperature is kept at 760 °C (1400 °F) or slightly above (Ref 87).

The principal advantage of the gas injection pump is its ability to provide demagging directly during the melting process. Figure 56 illustrates the effect of the gas injection pump in the demagging of aluminum scrap in a 68 Mg (150,000 lb) furnace. The magnesium content was continuously reduced during the time the scrap was being charged into the furnace, resulting in a low final magnesium content without a separate treatment.

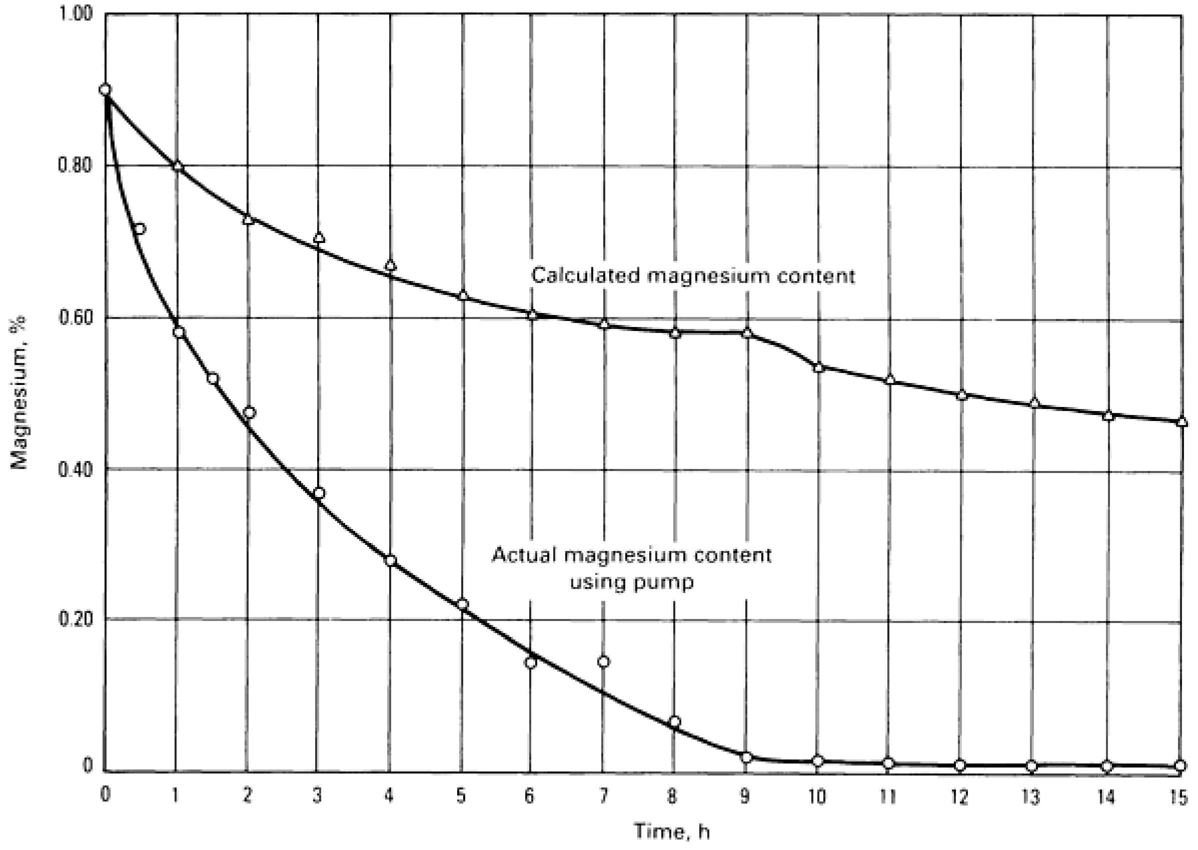

Fig. 56 Demagging of aluminum scrap using a gas injection pump during melting in a 68 Mg (150,000 lb) furnace. Source: Ref 87.

A tremendous quantity of aluminum used beverage container (UBC) scrap is being generated. Recycling of UBC scrap has therefore become a significant commercial enterprise. The gas injection pump is capable of demagging UBC scrap to levels of approximately 0.05% (Ref 87).

Melting of Lead Alloys

Lead and its alloys constitute a small but commercially important segment of the nonferrous metal casting industry. Principal lead alloys and their areas of importance include Pb-60Sn (solders), antimony-lead and calcium-lead (battery grids), and Pb-7Sn (terne plating).

The melting and casting of pure lead and foundry alloys pose fewer problems than with other nonferrous systems. The major lead alloys have relatively low melting points (315 to 425 °C, or 600 to 800 °F) and are not susceptible to hydrogen absorption and the attendant gas porosity to any great extent. Dross formation can be a problem, especially with alloy constituents, so simple cover fluxes such as graphite or vermiculite are sometimes used. However, oxidation is relatively minor unless temperatures are excessive.

In the terne plating industry, where lead-tin coatings are applied by hot dipping steel articles, principally for use in fuel systems, a cover flux is often used. This is similar to the flux used in galvanizing--a $ZnCl_2$-NH_4Cl mixture, often with other chloride salts such as KCl. The flux used in terne plating serves to preclean the steel, to absorb pretreatment pickling residue, to prevent spitting as the articles enter the plating bath, to alleviate bath dross formation, and to prewet the article being coated.

In the die casting of lead alloy acid battery grids, no treatment is usually necessary at the die cast machine melting pot itself, although a melt cover can be used for heat insulation purposes and to prevent dross buildup. In remelt pots, where trim scrap and other scrap is melted, chloride-base drossing fluxes can be used. Pitch, sawdust, or wood chips are used to agglomerate the residues that accumulate on the surface.

The lead is usually first softened (refined) in the production of the newer calcium-lead-tin alloys used for maintenance-free battery grids from either primary metal or recycled scrap. Calcium is then added as an alloy, often under a protective cover such as sawdust, wood chips, or resin to prevent oxidation at the usual higher temperature at which alloying is facilitated.

Refining of Lead

A number of fluxing procedures and refining processes are used in the smelting and refining of primary and secondary lead production. Several of these involve chemical flux-refining techniques somewhat analogous to those used with other nonferrous metals. Figure 57 is a flow chart showing a number of important sequential process steps in the refining of lead. These steps will be briefly discussed here and are covered in greater detail in Ref 90.

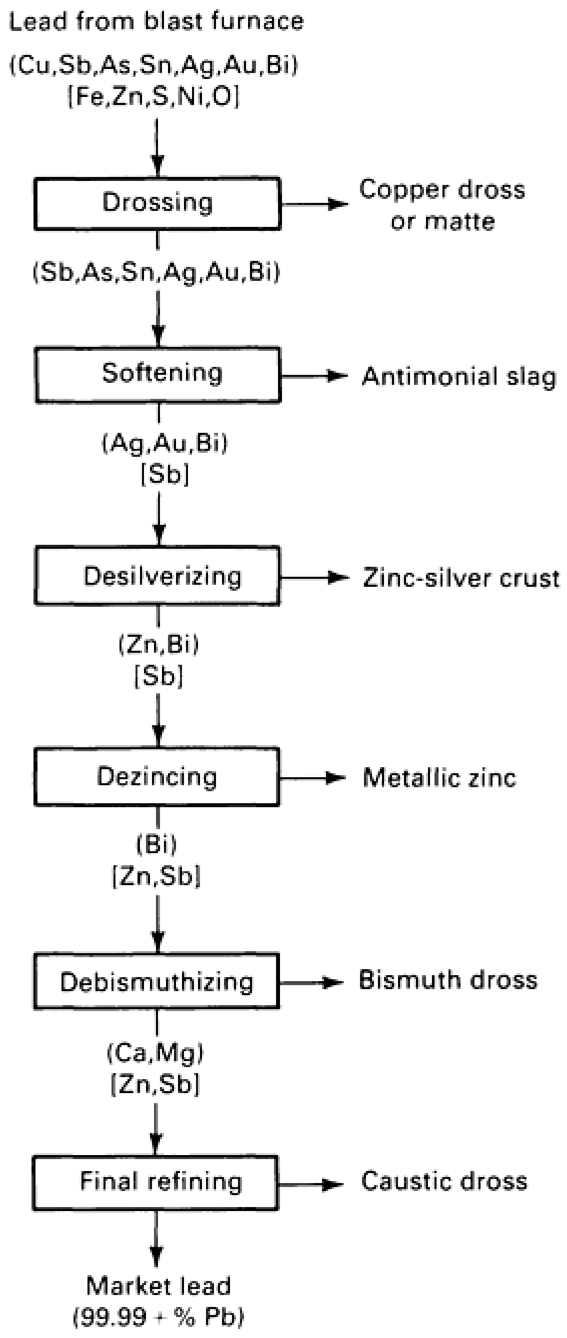

Fig. 57 Flow chart showing steps in the lead-refining process. Impurities remaining are shown in brackets after each step. Source: Ref 90.

Copper Drossing. In copper drossing, the first step, the elements copper, iron, nickel, cobalt, and zinc can be removed, if present, by cooling the lead almost to its freezing point. The liquid solubility of these elements at that temperature is very low; thus, they can be removed as an intermetallic dross as they separate from the heavier lead melt.

Copper will precipitate with any sulfur, arsenic, antimony, or tin, in that order. Lead sulfide may also form.

These drosses are usually intimately intermingled with the lead metal phase. A molten phase (copper-lead sulfide) may form, and when the newer calcium lead battery scrap is remelted, calcium may be present in this phase, lowering the lead content. If oxides are present, there is also a slag phase, and silica can be added to increase its fluidity, resulting in the creation of iron, zinc, and lead silicates.

It is also possible to remove copper from lead down to a level of 0.05% by stirring sulfur into the lead melt at temperatures near the freezing point. When silver or tin is present, copper can be reduced to even lower levels, but a reversion (copper reentering the metallic phase) can occur if stirring is excessive (over 10 min) or if temperature is increased (Fig. 58).

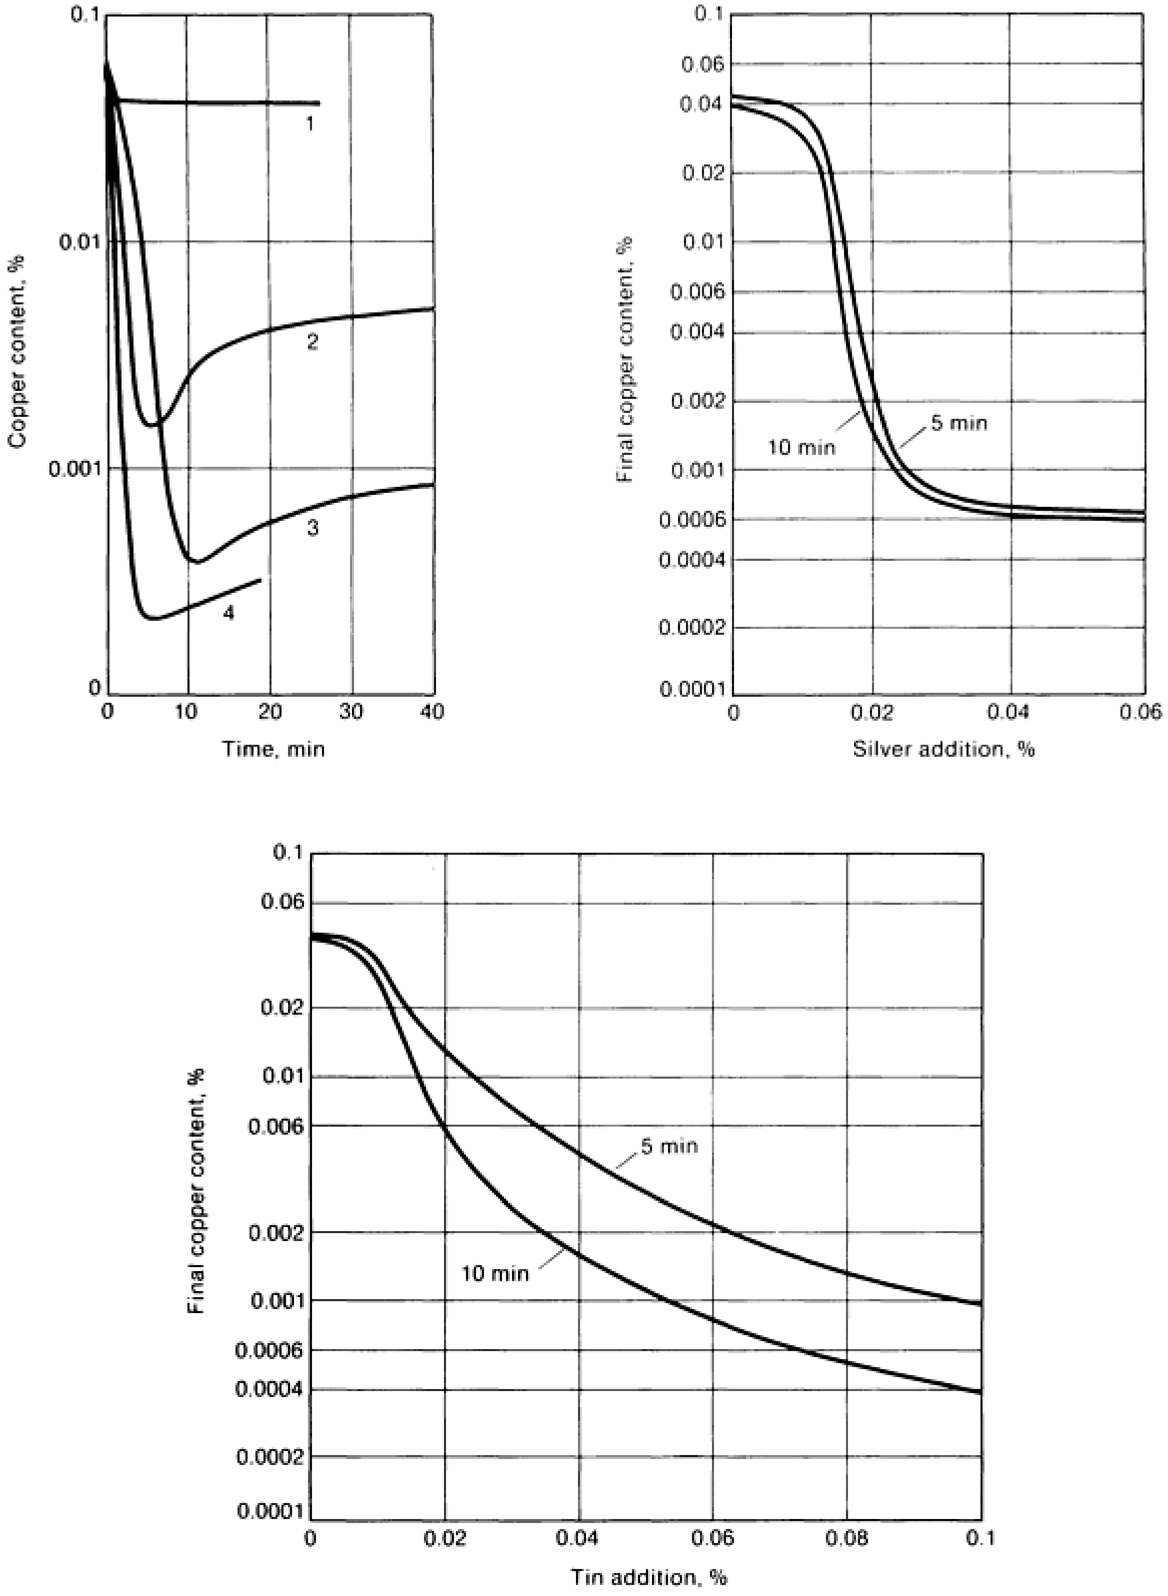

Fig. 58 Decoppering of lead. (a) Effect of sulfur. Curve 1 represents the copper content of silver-free lead as a function of time while stirring in 0.1% S at 330 °C (625 °F), and curve 4 represents similar conditions for a lead containing 0.04% Ag. Curve 2 resulted when only 0.05% S was added, and curve 3 when a total of 0.1% S was

added as ten equal additions of 0.01% S each, at 1 min intervals, approximating plant practice in which the sulfur is added gradually over ten minutes. (b) Effect of silver. (c) Effect of tin. Source: Ref 90.

Softening. In softening, the second process step, elements more readily oxidized than lead are removed by oxidation. These include tin, arsenic, antimony, and indium, whose free energies of oxide formation are greater than that of lead. The term softening relates to the effect these elements have on lead. When present, they contribute to solid-solution strengthening; thus, their removal results in softening.

The Harris process of softening consists of oxidizing the impurities, converting them to sodium salts, and collecting them in a caustic soda melt slag phase that rejects molten lead, providing for relatively easy physical separation. Temperatures of best reactivity are fairly high (700 to 800 °C, or 1290 to 1470 °F), and thorough mixing of the metal with the salt flux is required.

Tellurium, arsenic, and tin can be reacted directly with caustic soda to form lower sodium salts. A further oxidation reaction, employing sodium nitrate ($NaNO_3$) as the oxidizing agent, forms the higher sodium salts (arsenates, stannates, and antimonates). The intermixed metallic oxide products produced by these reactions are then removed and separated by various wet processing and recipitation methods.

A simple softening process involves the refining of lead by oxygen at a somewhat reduced temperature (650 °C, or 1200 °F) directly in a refining kettle. A 22.5 Mg (25 ton) lead melt containing 0.6% Sb was refined to a level of just 0.02% by blowing 10 m^3 (350 ft^3) of oxygen for 1.5 h (Ref 91). Moreover, approximately 100 kg/m^2 (20 lb/ft^2) of antimony was oxidized with oxygen injection, versus a rate of only 10 kg/m^2 (2 lb/ft^2) using air. Because this is in excess of the expected stoichiometric ratio, the oxygen must also act catalytically.

Desilvering is the term applied in lead refining to the removal of elements more noble than lead--silver, gold, and bismuth. These elements can be coprecipitated with lead and zinc by the Parkes process, which is the addition and mixing of zinc with the lead at a temperature just above the freezing point of lead (~320 °C, or 610 °F). Because there is substantial metal value contained by silver- or gold-bearing precipitate residues, technologies (pressing, liquation, and zinc distillation, for example) have evolved for separating the noble metals from the precipitate.

Zinc Removal. Zinc can be removed preferentially from the base lead metal by preferential oxidation or chlorination or by the Harris process without the use of an additional oxidizing agent:

$$Zn + 2NaOH \rightarrow Na_2ZnO_2 + H_2$$

Vacuum dezincing, however, provides much higher zinc recoveries than any of these techniques and is therefore preferred.

Bismuth Removal. Bismuth is more noble than lead and therefore cannot be removed by chemical fluxing techniques. Fractional oxidation or crystallization can yield liquid slag and solid crystals that are purer than the starting metal. Bismuth can also be precipitated from lead by adding alkali or alkaline earth metal reagents, such as calcium and magnesium (the Kroll-Betterton process). Magnesium metal and Pb-5Ca master alloy are stirred into the bismuth-containing molten lead at 420 °C (790 °F). As the lead is cooled back to its freezing point, $CaMg_2Bi_2$ crystals precipitate, leaving the lead refined of bismuth. The precipitate is intermixed with lead, and the latter can be removed by liquation by adding the mixture to the next batch and raising the temperature once again. Further reduction of bismuth is possible by stirring in antimony (or antimonial lead) in the presence of residual calcium and magnesium in the melt after the initial $CaMg_2Bi_2$ precipitate has been removed. The antimony addition forms a similar precipitate, which facilitates easier formation and substitution of bismuth for antimony in the precipitate at more dilute concentrations of bismuth.

Final Refining. Before casting, a final refining step is carried out on the molten lead, using a modified Harris process at 450 to 500 °C (840 to 930 °F). Caustic soda or $NaNO_3$ at the rate of 0.1% is stirred into the lead to decrease the zinc and antimony that may remain after previous refining steps to less than 1 ppm each, as shown in Fig. 59 (Ref 90). Arsenic, tin, calcium, magnesium, and iron will also be removed to very low levels with or before the antimony. The softened and highly purified lead thus produced is required in the production of battery alloys, whose electrochemical performance is highly dependent on the removal of impurities.

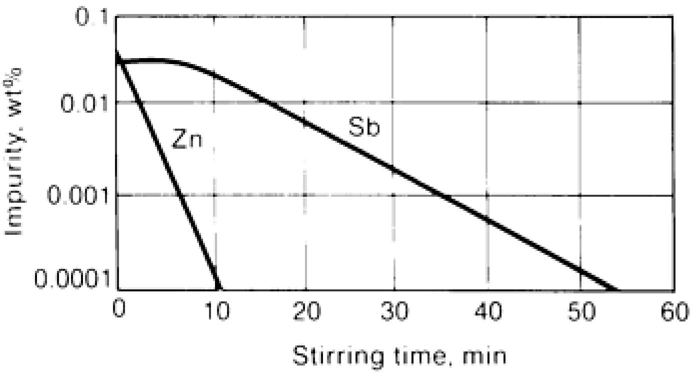

Fig. 59 Final lead refining using the modified Harris process. Source: Ref 90.

Grain Refining of Aluminum Alloys

Grain refining is widely practiced in the commercial production of virtually all aluminum alloys, whether wrought or cast. Although many alloys contain alloying constituents that provide for fine-grain cast structures by virtue of their specific compositional effects, other alloys, especially those containing silicon, do not readily develop a fine grain size without assistance.

Benefits of Grain Refining

Grain refining is a necessary processing step in the production of most wrought shapes and foundry castings because:

- Mechanical properties and high-temperature properties are usually enhanced with finer grain structures; heavy-section properties are also improved by deliberate grain-refining practices
- Better castability results from the finer grain structure provided by creating more nuclei as the melt solidifies. Shrinkage porosity and hot tearing of castings is usually minimized. Better feeding characteristics usually mean improved casting soundness
- Better control and uniformity of response to heat treatment occur with finer grain size because there is more alloy homogeneity throughout the cast structure
- Finer grain structures result in enhanced extrudability, sheet formability, and machinability. Surface-finishing operations such as polishing and anodizing are also easier and more successful with finer grain structure

Measuring Grain Size

Grain size can be measured by a number of procedures, which are detailed in ASTM E 112. The grain size of finished castings or cast or wrought products can be determined metallographically. Grain size can be compared with a known and measured set of standards associated with a particular alloy or alloy family.

In the wrought industry, many producers have developed their own specific grain size tests correlating with their specific practices. These tests are designed to simulate the specific solidification conditions found in typical direct chill casting for large ingots and have been found to correlate well one with another.

Another, simpler test has recently evolved with great application for aluminum foundry casting purposes. In the ring test, samples of molten aluminum are poured into one or more iron rings 75 mm (3 in.) in diameter by 25 mm (1 in.) high set on a block of fused silica and allowed to solidify. Three surfaces of each test sample exhibit the grain structures to be found in most aluminum casting methods. The ring itself provides an immediate chill; therefore, the side of the test

casting exhibits a grain structure typical of permanent mold casting. The top of the test casting, open to the atmosphere, cools slowly; its grain structure is considered to be indicative of a sand casting. The bottom surface of the test casting is in contact with the insulating and smooth fused silica and will exhibit a grain structure resembling a direct chill cast shape casting (Ref 6, 92).

The test can be used to compare the capabilities of various grain refiners or differing amounts. It can also be used as a process control check with each furnace heat or during prolonged holding times when delays in casting are experienced. Because the effects of grain refinement can be diminished with prolonged holding time, additional grain refiner may need to be added, and this simple test will monitor that need.

The use of thermal analysis has recently found application as a method of determining both sufficient grain size and silicon phase modification treatment immediately before casting. This will be discussed in the section "Modification of Aluminum-Silicon Alloys" in this article.

Grain-Refining Methods

Several methods are used to achieve grain refinement--for example, rapid cooling, mechanical agitation, growth-hindering additions, and addition of nucleating agents (Ref 93).

Rapid cooling produces finer grain size in most aluminum alloys. The mechanisms may involve reduced grain growth, reduced critical size of the nucleus, activation of additional nucleants, increase in nucleation sites, homogeneous nucleation, and recrystallization (Ref 93). Rapid cooling has a significant effect on the other aspects of a cast structure that influence properties, such as decreased dendritic arm spacing, increased solid solubility, decreased segregation, and the appearance of metastable phases. However, additional, deliberate grain refinement may still nevertheless be sought.

Mechanical agitation can be achieved by manual or electromagnetic stirring, gas purging, or ultrasonic vibration. Such motion in the molten metal induced by these techniques most likely breaks up or bends growing dendrite arms. The amount of refinement obtained usually increases with the mechanical energy put into the melt up to a point. Although other benefits such as reduced segregation can result, the high cost, labor, or complexity of the equipment required has precluded the large-scale use of such grain-refining methods in actual practice.

Growth-hindering additions are usually alloying elements or solutes in an alloy system in which constitutional supercooling can take place during solidification. Figure 60 illustrates this phenomenon in a binary phase diagram; in this diagram, as an alloy of composition C_0 solidifies, the solute concentrates in the liquid ahead of the growing solid. As a consequence, there is a zone in which the actual temperature is lower than the equilibrium freezing temperature, yet the liquid metal persists. This is the undercooled or supercooled zone, in which the solute enrichment or supersaturation facilitates nucleation and therefore smaller grain size. The lower the eutectic temperature and the smaller the amount of solute element needed, the more effective this means of grain refinement. Copper alloys, with relatively small amounts of the solute that causes this effect, are therefore usually quite adequately grain refined by alloying alone. Although aluminum alloys exhibit similar behavior when solute is added (Fig. 61), additional methods of producing grain refinement are always employed commercially.

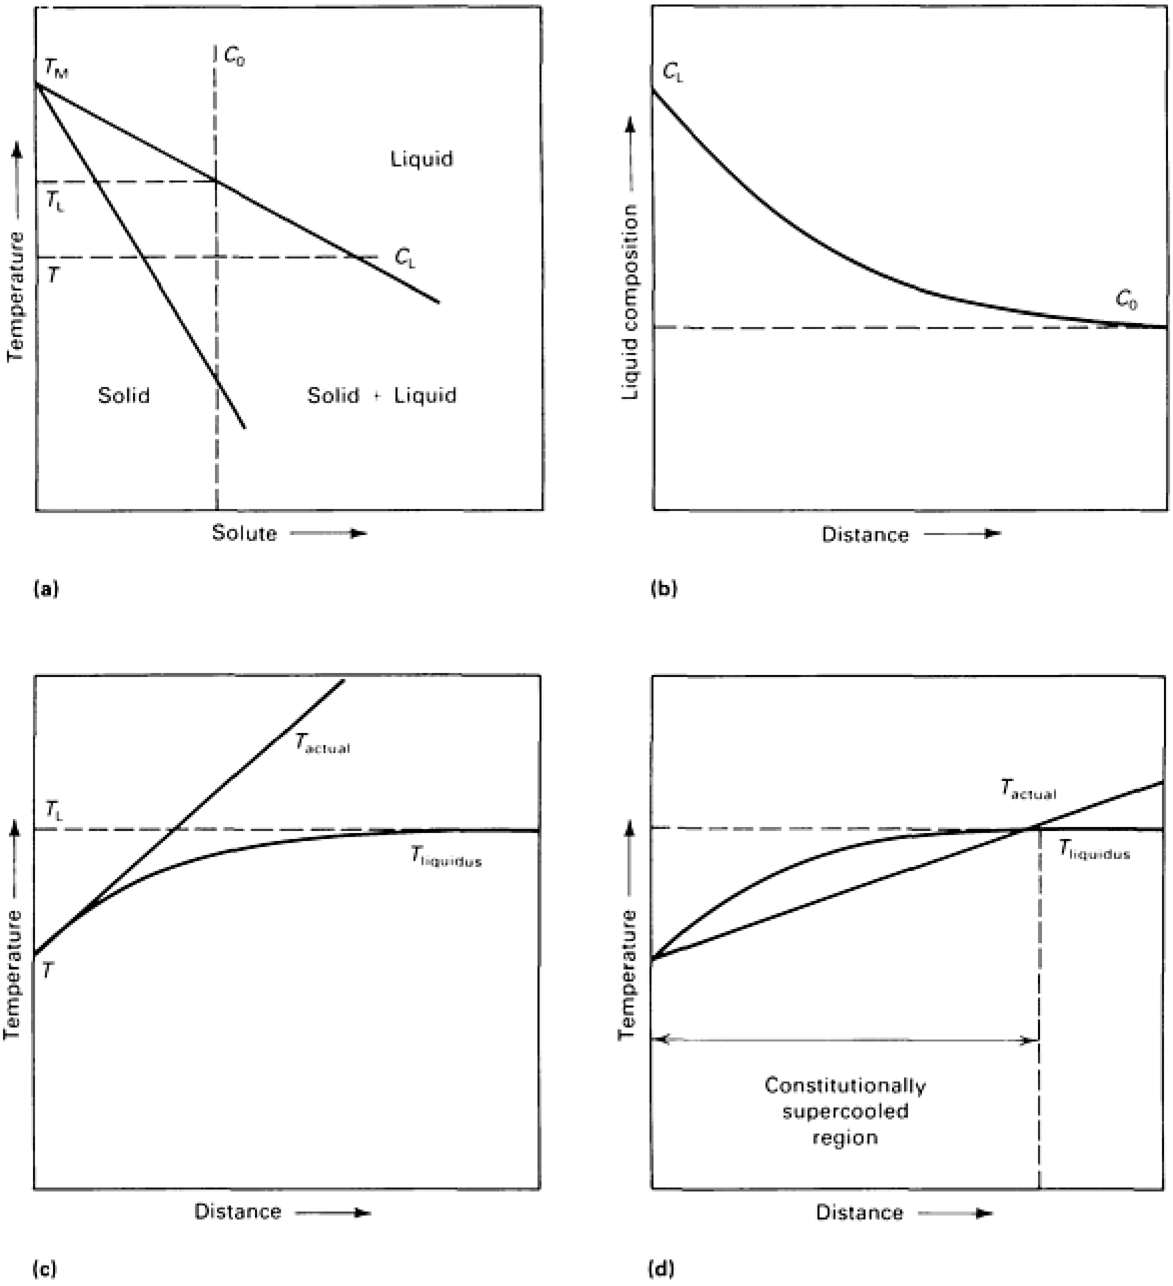

Fig. 60 Constitutional supercooling during solidification of alloy with composition C_0. (a) Phase diagram. (b) Solute-enriched layer ahead of solid/liquid interface. (c) Stable interface. (d) Unstable interface. Source: Ref 94.

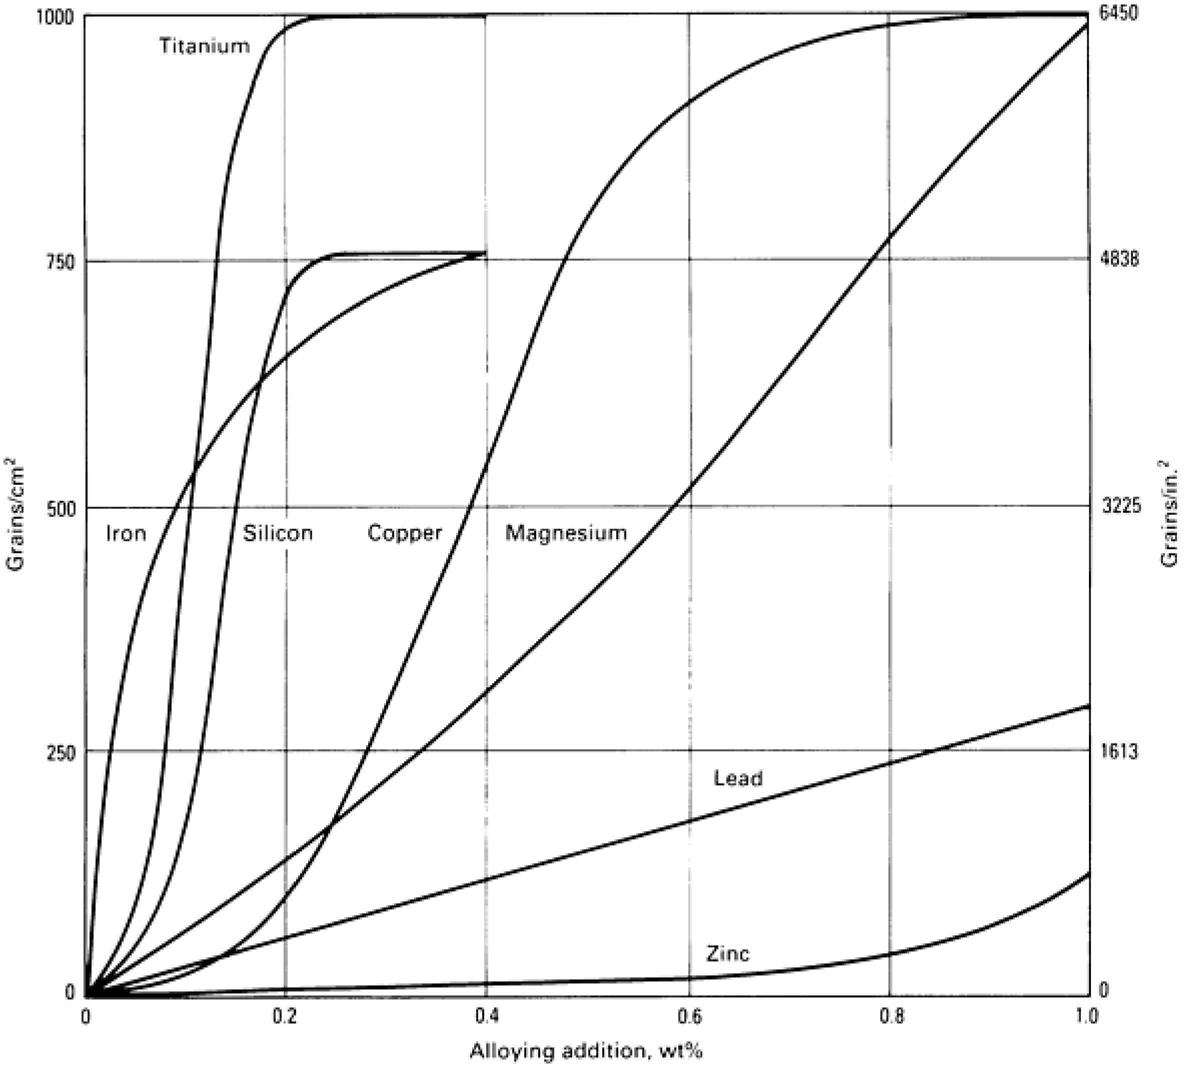

Fig. 61 Effect of alloying elements on the grain size of aluminum. Source: Ref 95.

Types of Nucleating Additions. By far the most common method of achieving grain refinement in aluminum is the use of specific nucleating additions--salts or master alloys. Grain-refining agents such as titanium, boron, and zirconium are added singly or in combination to aluminum melts in very small quantities that do not alter the base composition of the melt to any great degree. These additions have historically been made as salts (often tabletted) or as master alloys (hardeners) with aluminum in the form of shot, waffles, or briquettes. Carbon (graphite) can be an effective grain refiner in the presence of carbide-forming elements such as titanium (Ref 96).

Salt Flux Grain Refining. Grain-refining elements can be introduced by fluoride and double fluoride salts that react with the melt (Ref 1, 95).

$$3K_2TiF_6 + 4Al \rightarrow 3Ti + 4AlF_3 + 6KF$$

$$2KBF_4 + 3Al \rightarrow AlB_2 + 2AlF_3 + 2KF$$

$$3K_2TiF_6 + 6KBF_4 + 10Al \rightarrow 3TiB_2 + 10AlF_3 + 12KF$$

Various other fluxing salts can be included to improve fluidity and reactivity, and both boron and titanium salts can be included in the same product. Some fluxes may also contain carbon to enhance carbide formation, because carbides will also serve as effective grain nuclei (Ref 96). In addition, it is now known that intermetallic compounds formed by titanium and aluminum (for example, $TiAl_3$) play a major role as grain-nucleating agents.

Master alloys, or hardeners, are alloys of aluminum with certain amounts of titanium and/or boron. Master alloys are usually produced in induction furnaces and are cast as ingot, waffle, sheared rod, or shotted product.

Binary aluminum-titanium hardeners contain only 3 to 10% Ti because of their relatively high melting points even at this low level. Even at such low concentrations, gravity segregation is difficult to control. When boron is added to these alloys, the boron content is kept equally low (0.5 to 3%) because titanium diborides have an even greater tendency to segregate due to their higher density relative to liquid aluminum.

Use of Grain Refiners

The first issue to settle when considering a grain-refining treatment is to determine the degree of refinement needed for each application and then to choose from the variety of grain-refining compositions available. Factors to be considered include economics; the effect of titanium and boron residuals on composition, specifications, and properties; and end use of the products.

In foundry applications, grain refiner is usually added by salt flux tablet or master alloy waffle, sheared rod, or shot to the furnace. The grain-refining capabilities are diminished by degassing or fluxing treatments and by prolonged holding. This loss of refining capability is due to agglomeration of the nucleating particles, dissolution at high temperatures, and the formation of complex compounds with other alloying elements and fluxing agents. It is therefore essential that grain refiner be added immediately before pouring and casting. In general, the amounts to be added are 0.05 to 0.15% Ti, 0.04% B, or 0.01 to 0.08% Ti plus 0.003% B, even though foundry ingot as received from the smelter is usually prerefined.

Grain refinement is diminished by the subsequent remelting of scrap castings, gates and risers, and so on (Ref 95, 97). In general, increased pouring temperature and holding time result in coarser grain size for most types of grain-refiner additions (Fig. 62).

Fig. 62 Effect of pouring temperature (a) and holding time (b) on the grain size of several aluminum casting alloys. Source: Ref 95.

Grain refining as a specific treatment does not have great value for die casting and certain permanent mold processes. This is because the high rate of solidification and turbulent flow into the mold in these processes serve to increase the number of grain nuclei.

Shape Casting. In the production of foundry ingot or aluminum cast shapes, grain-refiner additions are made with master alloys either by furnace addition of waffle or briquette or by a rod (9 to 10 mm, or 0.35 to 0.4 in., in diameter) into the casting launder. The specific choice of which type to add depends on requirements, economics, and alloy composition.

In the traditional furnace method, the master alloy is added about 30 min before casting to ensure ample time for contact and dissolution. Potential problems with the furnace addition method include inadequate mixing in a full furnace charge and the settling and agglomeration of the heavier titanium diboride particles to form a sludge.

The second method--adding master alloy in rod form with a wire rod feeder directly into the casting launder--permits a lower addition rate, but relies on the use of a master alloy with a short dissolution or contact time. Depending on the casting route and the type of filter used, the time available between addition and eventual metal solidification varies from 30 s to 10 min (Ref 98). Consequently, the contact time available (determined by the flow distance and metal flow rate) and the efficiency achieved will often dictate which type of grain refiner to add. Figure 63 illustrates the efficiency of three types of grain-refining additions. Clearly, the Al-5Ti-1B alloy addition would be preferred in rod-feeding applications in which minimal contact time is available.

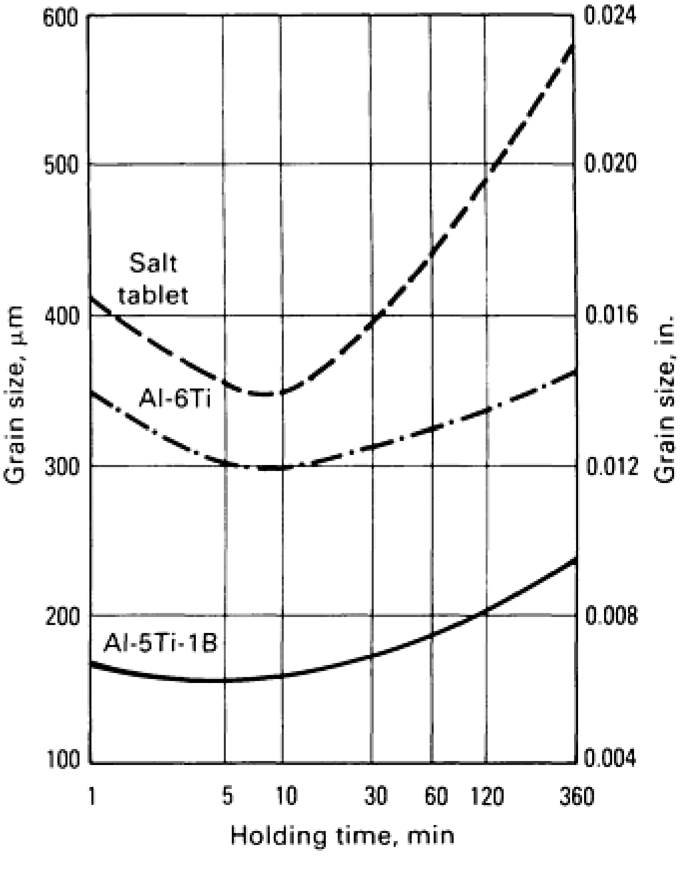

Fig. 63 Comparison of efficiency of three grain-refining additions to 99.7% Al. Source: Ref 98.

Proper positioning of a casting launder grain-refining addition (before or after a filter) is currently a subject of debate. Filtering can remove or agglomerate grain-refining nuclei. Filtration can also remove impurity constituents from the

grain-refiner rod itself and thus have a positive effect. Available contact time, type of product being cast, and properties and experience with a particular grain refiner should determine the flexibility of where the addition point can be positioned in the casting sequence. In many cases, grain refiner is added directly into rotating disperser metal treatment systems in which the increased agitation facilitates thorough mixing and dissolution.

Fade is the decline in grain-refining properties that takes place in both cast foundry alloys or wrought cast aluminum alloys. It occurs with prolonged holding times before casting and may also be aggravated by intervening fluxing or degassing. Fade is usually thought to result from the agglomeration and settling of TiB_2 particles, but it may also be due to a submicron precipitation poisoning effect on particle surfaces, rendering them unsuitable or sluggish in serving as effective nuclei for aluminum grains during solidification. In addition, the gradual dissolution of nucleating particles with prolonged holding at higher temperature may reduce effective grain-refining nuclei.

Figure 64 shows the effects of various boron addition levels on fading in a 99.99% Al melt. Higher addition levels (in this case, 0.008% B to 0.15% Ti) prolong grain-refining effects (that is, retard the fading behavior). For this reason, most secondary smelter foundry ingot production, which in turn is remelted by the foundry, contains boron and titanium as grain-refining agents.

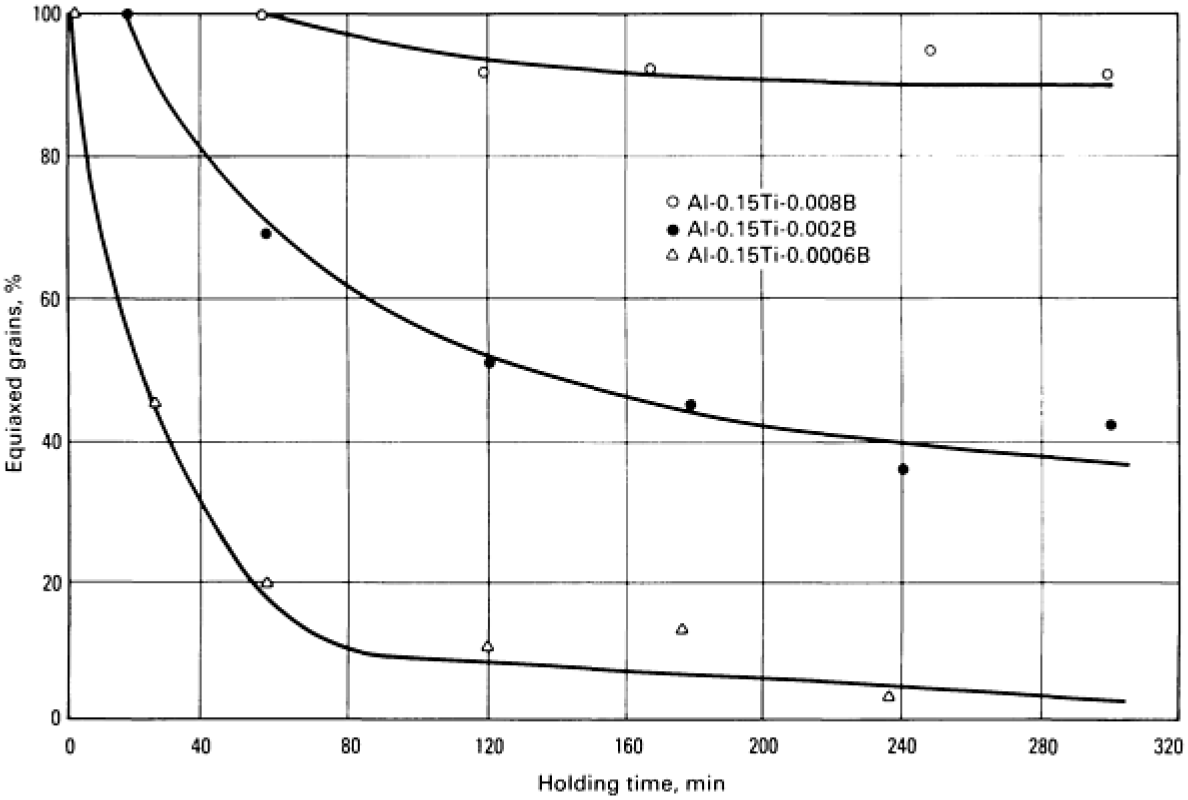

Fig. 64 Effect of various residual boron levels on the fading behavior of a 0.15% Ti grain-refining addition. Source: Ref 97.

Grain Refining of Foundry Alloys

In foundry alloys with 7% Si, salts or aluminum-titanium master alloy have usually been used for grain refining. An addition level of 0.10 to 0.25% Ti as a specification usually ensures adequate grain refinement. The specific nuclei, in the absence of boron, are $TiAl_3$ particles.

Despite the successful use of titanium as a grain refiner for foundry alloys, it has recently been found that boron alone may be a more effective refiner than titanium in aluminum-silicon alloys (Ref 99). Figure 65 compares the grain size achieved with additions of boron, titanium, and a titanium-boron mixture on Alloy 356. Similar results are reported in Ref 100.

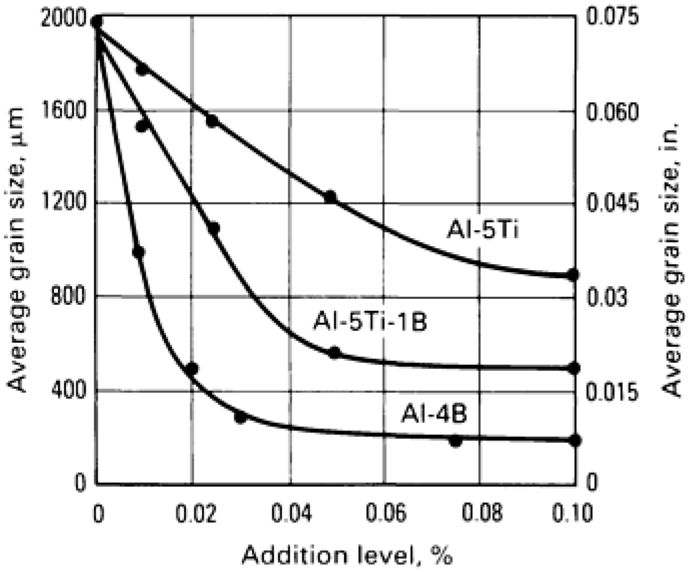

Fig. 65 Comparison of the effectiveness of various master alloy grain refiners in aluminum alloy 356. Source: Ref 99.

These results are also in contrast to wrought alloy experience, in which aluminum-titanium-boron master alloys are powerful refiners but aluminum-boron alloys alone do not grain refine effectively. In the latter wrought alloys, however, the silicon content is usually less than 0.5%; foundry alloys have 7% Si or greater.

Therefore, it may be that with higher silicon contents the effectiveness of the $TiAl_3$ nucleating particles is poisoned by silicon-titanium compound precipitation (Ref 99). As a consequence, relatively large titanium additions are required to achieve adequate refinement in alloys containing higher silicon.

In melts using aluminum-boron grain refiner alone, the principal refining constituent is an AlB_2 precipitate, which seems to be enhanced with higher dissolved silicon contents. However, the AlB_2 will dissolve and react with residual titanium to form TiB_2, which may settle to the bottom of the furnace as sludge. If this occurs, the grain-refining capabilities are lost. In addition, boron is more expensive than titanium. Consequently, a compromise is sought, employing both titanium and boron, in a master alloy. This yields both AlB_2 and TiB_2 nucleating crystals, comprising a mixed boride $(Al,Ti)B_2$.

Figure 66 demonstrates the effectiveness of Al-2.5Ti-2.5B master alloys to 356 and 319 foundry alloys compared to the Al-5Ti-1B alloys previously used. Clearly, the use of higher levels of boron and lower levels of titanium than those previously used can have substantial benefits for foundry alloys. Figure 67 illustrates the comparison of an adequately grain-refined Al-7Si alloy before and after the grain-refining addition.

Grain Refining of Wrought Alloys

In the grain refining of aluminum alloys that are direct chill or continuously cast as semifinished products (billet, slab, foil, strip, or forging stock), the grain-refining alloy of choice will depend on several factors, as previously discussed. These factors are residence time, available effectiveness, cost, and compositional effects (Ref 101).

Generally, aluminum-titanium-boron refiners are used, except when electrical conductivity is important. In this case, titanium is undesirable, because its presence decreases conductivity. For these alloys, an aluminum-boron master alloy is used.

In wrought alloys, titanium and boron provide more effective grain refinement than either alone. The use of a straight titanium master alloy would require significant concentration (~0.15% Ti). This concentration is unacceptable in wrought aluminum alloys, because it results in the formation of coarse, brittle intermetallic titanides, which interfere with desirable wrought alloy forming properties. Furthermore, an aluminum-titanium addition is subject to considerable fade because Al_3Ti dissolves rapidly above 700 °C (1290 °F). Boron additions retard or delay the fade phenomenon.

A variety of aluminum-titanium-boron grain-refining alloys are currently in use, including Al-10Ti-0.4B, Al-5Ti-1B, Al-5Ti-0.5B, Al-5Ti-0.2B, Al-3Ti-lB, and Al-3Ti-0.2B. These varieties exist because each alloy and application may require a specific grain refiner or addition rate to achieve the desired result. The typical desired grain size is generally 200 μm (0.008 in.) or finer in certain cases. There appears to be an optimum titanium/boron ratio for achieving the finest grain size in individual alloys (Fig. 68 and 69).

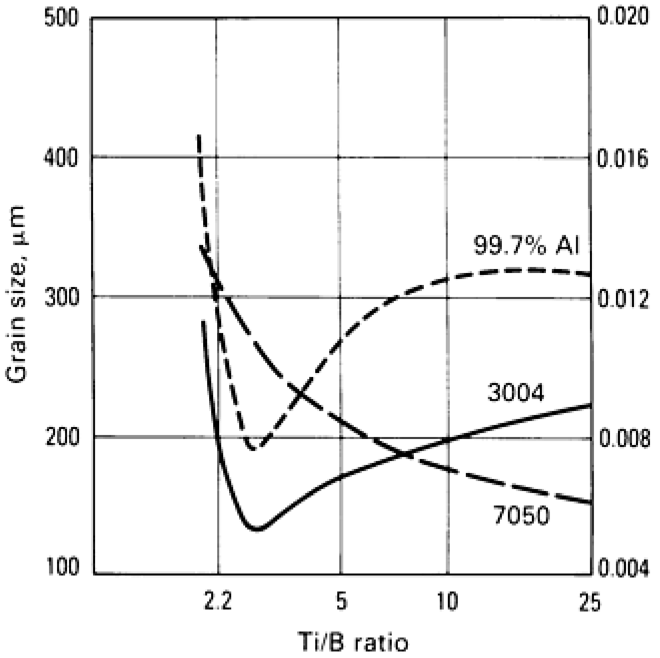

Fig. 68 Effect of titanium/boron ratio on the grain size of three aluminum materials. Source: Ref 97.

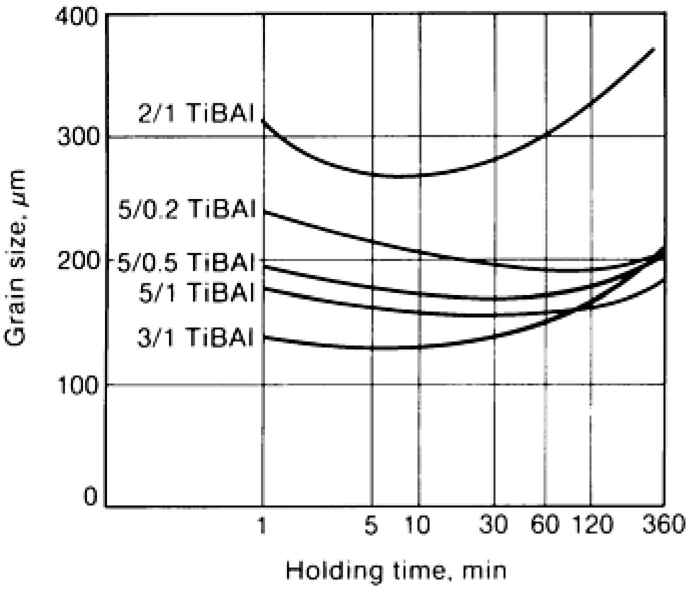

Fig. 69 Effect of addition level and holding time on grain size for 3004 alloy. Source: Ref 98.

Even within a given alloy, more or less grain refiner may be required, depending on alloy composition. Certain levels of alloying elements may influence the amount of grain refiner needed to achieve a specific result. Figure 70 shows the effect of iron level on the grain size of 99.99% Al when a specific Al-5Ti-1B addition is made. As can be seen, additional refiner would be required to achieve the 200 μm (0.008 in.) grain size desired at low iron levels. Similar results have been observed in commercial alloys 3004 and 6063.

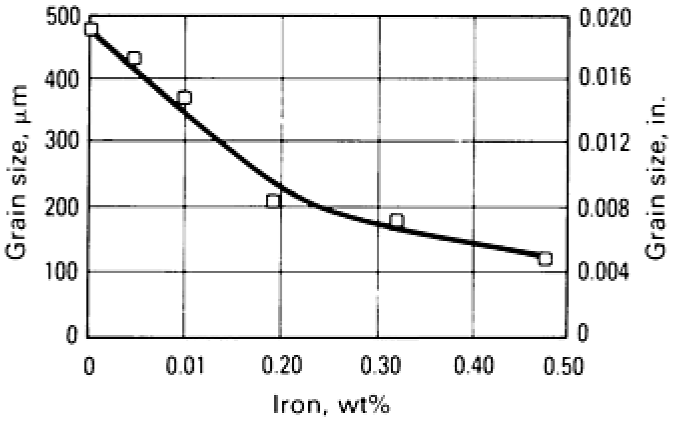

Fig. 70 Effect of iron level in pure aluminum on grain refining using Al-5Ti-1B alloy. Source: Ref 101.

Residual titanium will also influence grain refining when a specific amount of refiner is added. Higher levels of residual titanium result in finer grain size for a given addition. More information on the selection of aluminum alloy grain refiners for specific applications is available in Ref 102 and 103.

Grain Refining of Magnesium Alloys (Ref 104)

Pure magnesium solidifies with a relatively coarse grain structure. In most cases, the common alloying elements--aluminum, zinc, rare earths, and thorium--serve to reduce the as-cast grain size. This is most likely accomplished through typical constitutional supercooling effects.

Zirconium additions (0.1 to 0.2%) have a marked effect on grain size. Magnesium alloys directly alloyed with zirconium exhibit a naturally very fine grain size with the attendant increase in mechanical properties.

Superheating of magnesium-aluminum-zinc alloys produces considerable grain refinement through supersaturation and precipitation upon cooling of preferred grain nuclei. To provide the superheat, the temperature of the melt is raised to between 850 and 925 °C (1560 and 1695 °F). Time required at superheat decreases with increasing aluminum content, proportion of scrap in the charge, and maximum melt temperature, and it increases with crucible size and heating rate. Certain elements, such as zirconium, titanium, and the rare earths, retard the grain-refining effect produced by superheating.

Hexachloroethane. Grain refinement is possible with hexachloroethane, which enables both degassing and grain refining to be accomplished in one step without superheating. Therefore, melting times, crucible wear, and excessive hydrogen absorption through superheating are avoided. Hexachloroethane tablets are plunged carefully into the melt (above any sludge layer) and held for complete reaction. Approximately 0.1% by weight addition is usually sufficient to achieve maximum grain refinement.

The major grain-refining constituent with hexachloroethane appears to be carbon, which forms an Al_4C_3 intermetallic submicroscopic precipitate. Carbon inoculation is probably also active in superheating, where high temperatures corrode steel melting crucibles, thus generating carbon. The use of graphite fluxing tubes may also provide for carbon grain inoculation, where tube wear yields carbon.

Rare-earth alloying elements, which are strong carbide formers, suppress grain refining by limiting the amount of carbon available for Al_4C_3 nuclei formation. Zinc-iron master alloys can be used for grain refining rare earth containing alloys. Methods for grain refining magnesium alloys are summarized in Table 6.

Table 6 Summary of grain-refining methods for magnesium alloys

Alloy	**Grain-refining element or treatment**	**Degree of refinement**	**Probable mechanism**	**Interfering elements**[(a)]	Remarks
Magnesium	Al, Zn, rare earths, Th, Si, Ca, Zr, others	Mild	Concentration gradients	. . .	. . .
Zirconium		Extreme	Nucleation by zirconium or Zr-enriched Mg	Al, Si, Fe, H, Sn, Sb, Co, Ni, (Mn), (Be), (Li), others	. . .

Grain Refining of Copper Alloys

In general, the grain refinement of copper alloys is not practiced as a specific molten metal processing step *per se*, because a certain degree of refinement can be achieved through normal casting processes. As with aluminum alloys, grain refinement in copper alloys can be achieved by rapid cooling, mechanical vibration, or the addition of nucleating or grain growth restricting agents. Further, many commercial copper alloys have sufficient solute (zinc, aluminum, iron, tin) to achieve constitutional supercooling during solidification. In this case, grain nucleation and growth are naturally retarded. Commercially pure copper can be grain refined by small additions (as little as 0.10%) of lithium, bismuth, lead, or iron, which provide constitutional supercooling effects (Ref 105, 106).

Copper-zinc single-phase alloys can be grain refined by additions of iron or by zirconium and boron (Ref 107). In the latter case, the probable mechanism is the formation of zirconium boride particle nuclei for grain formation. In one case, the vibration of a Cu-32Zn-2Pb-1Sn alloy improved yield and tensile strengths by about 15%, with a 10% reduction in grain size from the unvibrated state. In general, the α copper-zinc alloys (<35% Zn) exhibit grain size reduction and greater improvement in properties, while the α-β alloys do not.

Copper-aluminum alloys have been effectively grain refined with additions of 0.02 to 0.05% B; the effective nucleating agent is boron carbide (B_4C). Figure 71 illustrates the improvement in mechanical properties achieved by grain refining a Cu-10Al alloy.

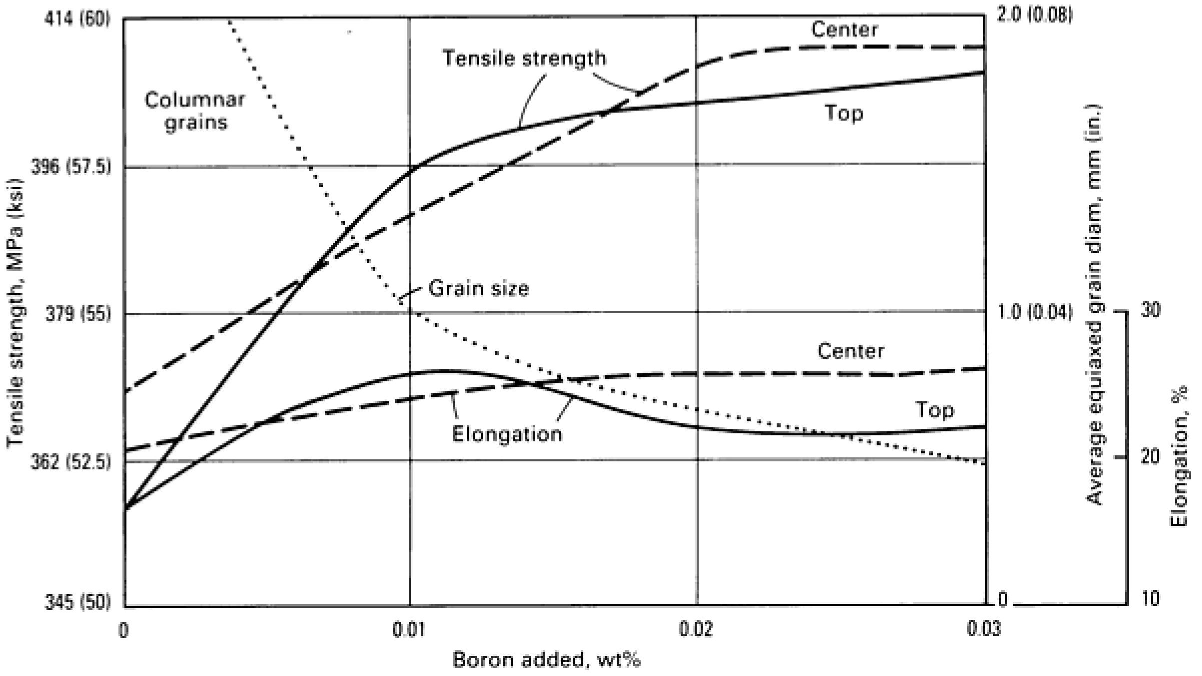

Fig. 71 Effect of boron-refined grain size on the mechanical properties of Cu-10Al alloy. Test specimens were removed from the center or the top of the ingot as indicated. Source: Ref 107.

Tin-bronze alloys have been successfully grain refined by the addition of zirconium (0.02%) and boron master alloys (Ref 108). However, pressure tightness is reduced because in these long freezing range alloys, finer grain size concentrates porosity because of gas entrapment.

Modification of Aluminum-Silicon Alloys

In the aluminum foundry alloy family, the aluminum-silicon alloys form the bulk of the commercially important applications. Silicon is the principal alloying element in these materials. For the purposes of this discussion, these alloys will be grouped as either hypoeutectic (~7% Si) or hypereutectic ($\geq$12% Si).

A two-phase structure exists for both classes. The hypoeutectic alloys consist of a primary α-aluminum matrix plus a second phase based on the silicon eutectic. In the hypereutectic alloys, silicon is the primary phase (Fig. 72). In either case, it is the morphology of the silicon phase that gives rise to the practice of modification. The silicon phase in hypoeutectic alloys, which is the eutectic constituent, solidifies as an acicular or platelike structure. In the hypereutectic alloys, the primary silicon phase is very blocky. These morphologies are detrimental to most aluminum mechanical properties, causing embrittlement, and also result in poor machinability. In addition, unmodified silicon structures are associated with increased porosity in the raw casting.

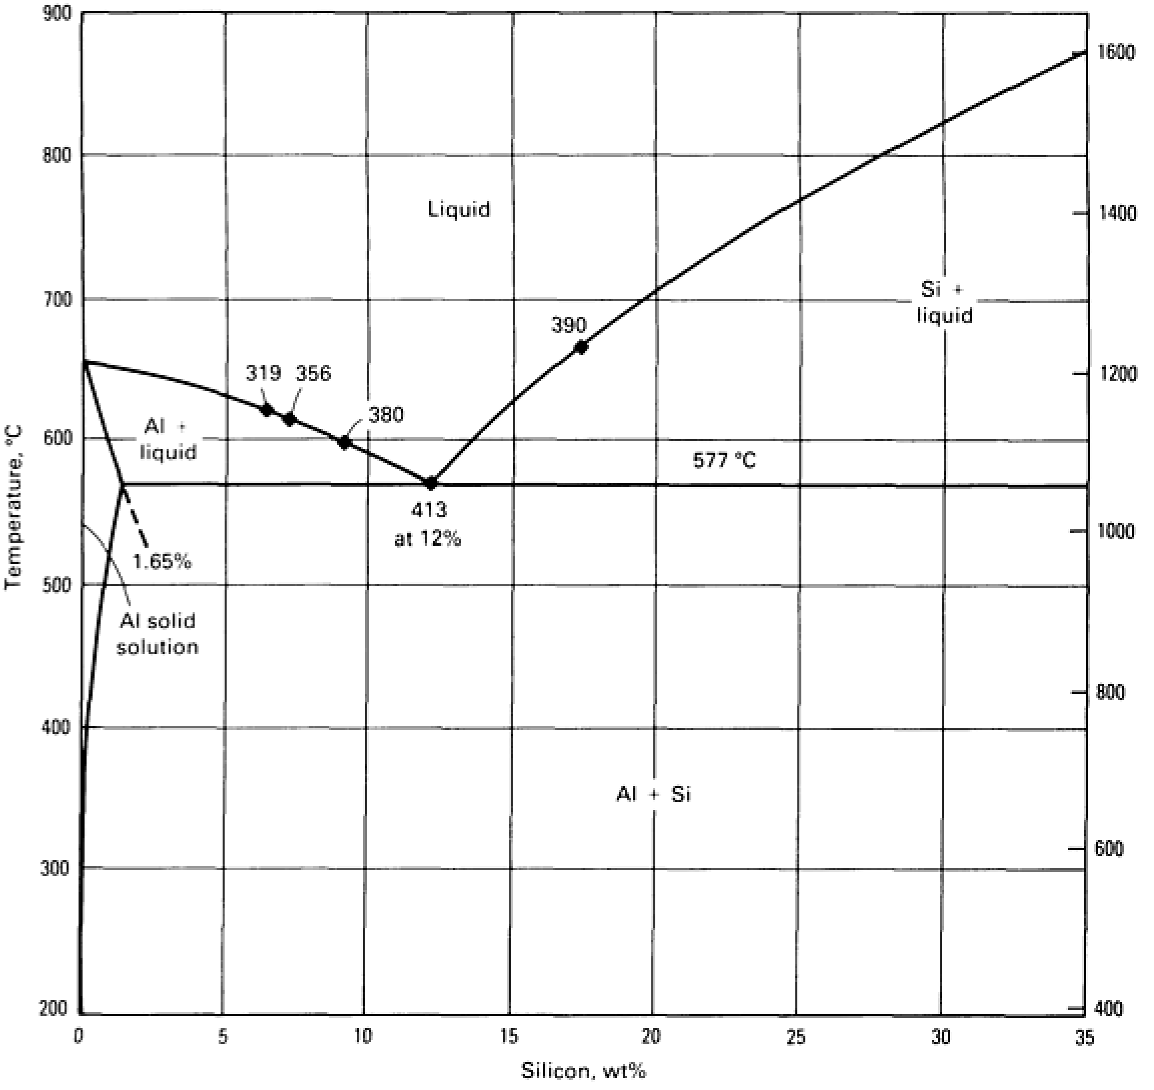

Fig. 72 Aluminum-silicon binary phase diagram showing common foundry and die casting alloy compositions 319, 356, 380, 390, and the eutectic alloy 413. Source: Aluminum Smelters and Refiners Inc.

Therefore, modifiers are deliberately added to the molten metal to change the shape of the silicon phase (eutectic in hypoeutectic alloys, primary silicon in hypereutectic) to a more well-rounded shape that is also more coherent with the matrix. This change also disperses shrinkage during solidification and greatly improves mechanical properties and machinability. Element additives such as sodium, calcium, strontium, and antimony are currently used to *modify* the silicon phase in hypoeutectic alloys, and phosphorus is used to *refine* the silicon phase in hypereutectic alloys.

Theory of Modification

The work of Crossley and Mondolfo (Ref 109) has been instrumental in describing how different impurities nucleate different solid phases. When sodium is present, the nucleation of the eutectic silicon takes place at approximately 3 to 12 °C (5 to 20 °F) undercooling (a factor that thermal analysis takes into account; see the section "Thermal Analysis" in this article). The specific degree of supercooling indicative of complete modification is different for each alloy. For 356 alloy, a typical modified eutectic temperature is about 568 °C (1054 °F). In hypoeutectic alloys, an AlSiNa precipitate appears to serve as the nucleation substrate for the silicon eutectic phase (Ref 110, 111). An AlP precipitate seems to be present even in hypoeutectic alloys (due to residual phosphorus). Sodium neutralizes AlP so that easy nucleation of silicon is prevented.

In the hypoeutectic alloys, another contributing mechanism is thought to be the influence of the modifier element (for example, sodium) on restricting the growth of nuclei by reducing liquid surface tension within the eutectic phase

which consists of a lamellar structure of both aluminum and silicon (Ref 6). The reduction in surface tension increases the contact angle between the aluminum and the silicon, permitting the aluminum to wet the silicon phase overall more easily and therefore restrict favored growth along one particular axis. Sodium apparently reduces the rate of diffusion of silicon in the liquid, thus restricting nuclei and grain growth.

Hypereutectic Alloys. Silicon phase modification in these alloys by phosphorus, which is referred to as refinement, is theoretically a nucleation phenomenon that influences the size and shape of the primary silicon only. Phosphorus reportedly combines with aluminum to form submicroscopic AlP precipitate whose crystallographic characteristics are similar to those for silicon and that permit the primary silicon crystal to nucleate more easily and grow evenly during solidification. It is also apparent that metal casting temperature, mold temperature, overall metal composition, and turbulence of the flowing metal all play a role in determining the extent of modification (Ref 6, 112, 113).

Thermal Analysis

Thermal analysis is used to predict or analyze the anticipated degree of modification to be expected from a melt (Ref 114). The principles are based on the thermal arrests and degree of undercooling that take place when a melt sample is allowed to solidify under carefully controlled conditions. A thermocouple is placed in a precise position within a mold containing a melt sample, and it monitors the temperature as a function of time as the sample solidifies. A characteristic curve can be obtained, as illustrated in Fig. 73 for an unmodified alloy. The break in the curve occurs at the eutectic temperature T_e when a two-phase liquid plus solid mixture X or B phase solidifies to α plus β. The beta is the eutectic silicon. In the presence of a modifier, the eutectic temperature is depressed, as shown in Fig. 74, and this depression can be correlated with the amount of modification that can be expected to take place in the full casting if the same solidification conditions are met.

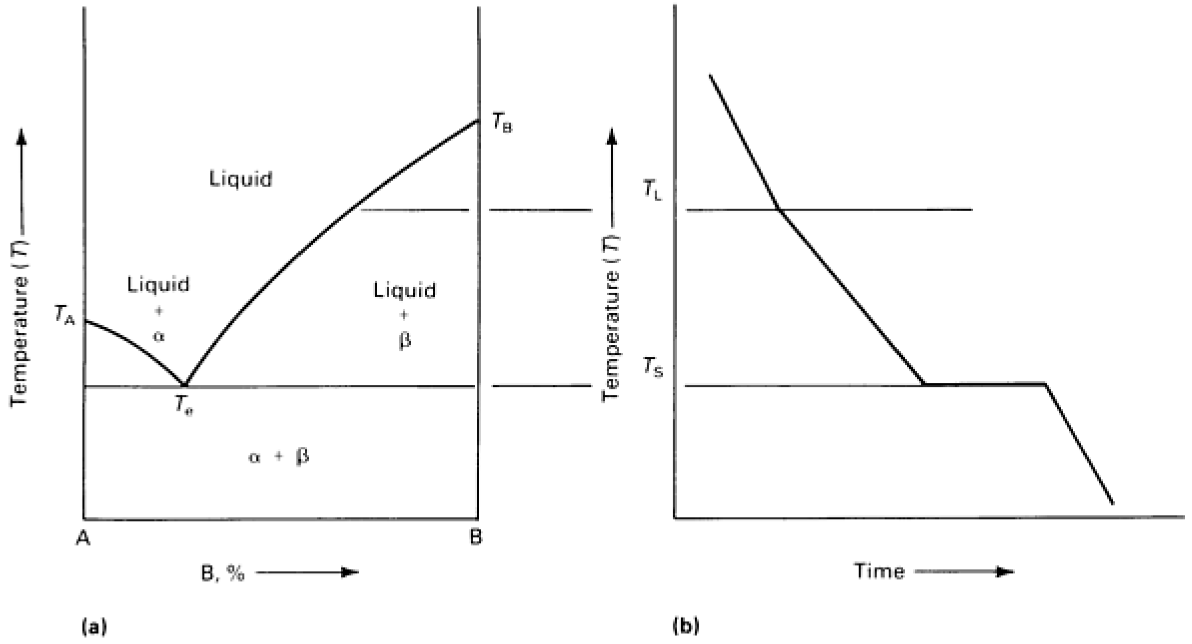

Fig. 73 Binary phase diagram (a) and thermal analysis curve (b) for an alloy having complete solubility in the liquid state and incomplete solubility in the solid state. Source: Ref 112.

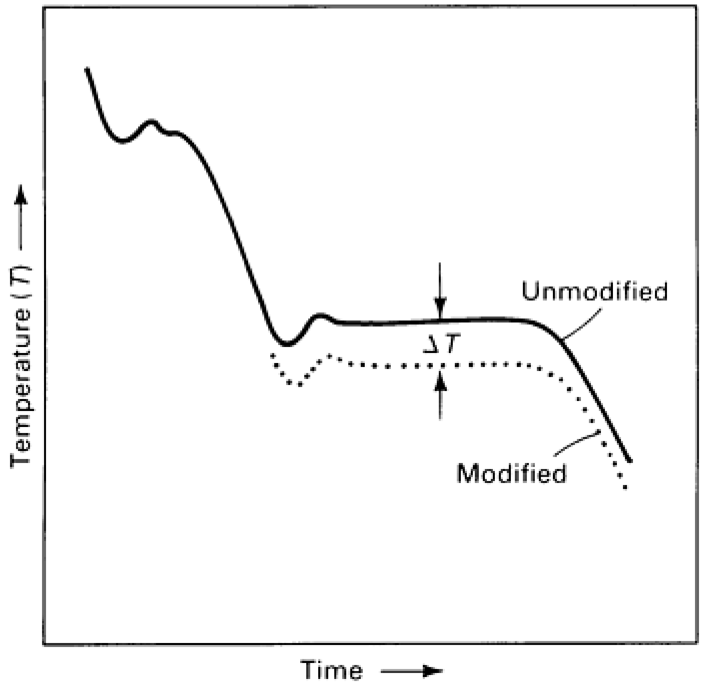

Fig. 74 Characteristic thermal analysis curve showing temperature depression that occurs after modification. Source: Ref 114.

Other features of thermal analysis that can be monitored are the times associated with each thermal change. The eutectic temperature depression is influenced by alloy content, with T_e = 1.1 (Mg) + 0.25 (Cu) + 0.18 (Fe) (Ref 114). The temperature excursions and the times associated with the thermal features can be related to grain size and modification (Ref 115). The thermal arrest T_L associated with the liquidus curve (Fig. 73) can be correlated with grain size. The longer the undercooling time, the lower the nucleation potential and the larger the grain size. Figure 75 indicates the correlation of grain size with several grain-refiner additions as obtained with the one thermal analysis instrument.

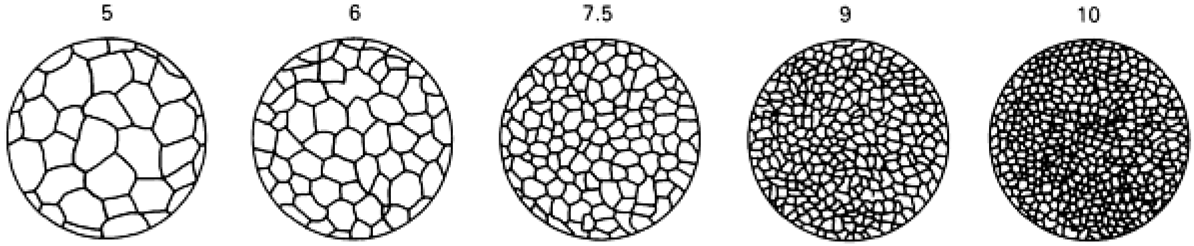

Fig. 75 Schematic showing aluminum grain size (ASTM E 112) as evaluated and displayed by one thermal analysis instrument. Source: Ref 116.

Two principal instruments are commercially available for thermal analysis. Both consist of a sample cup, thermocouple, and microprocessor unit. Regardless of the instrument used, it is important that the test be conducted consistently each time for accurate results (Ref 114, 115, 116, 117).

Alternate Techniques to Determine Modification

There are other nondestructive techniques capable of assessing the degree of modification in a solidified casting or in regions of a casting. Such an analysis can serve as a useful foundry check. Electrical resistivity or conductivity has been found to correlate well with degree of modification (Ref 118 and 119). Conductivity has been found to increase linearly

with degree of modification in Alloys A444 and A356, but detection capability decreases as the magnesium level increases. Surface finish is also a major factor. Polished surfaces display greater sensitivity and response to this technique than as-cast or even machined surfaces. Ultrasonic measurement has also been investigated, but thus far the technique has not been found to provide adequate sensitivity.

Modifier Additions

Most aluminum foundry ingot is modified before shipment to the foundry. However, modification is subject to fade, as with grain refinement, and additional modification is therefore usually necessary.

Hypoeutectic alloys are modified by additions of sodium, strontium, calcium, or antimony, as described below.

Sodium is usually added in metallic form, encapsulated in an aluminum can to retard its natural burning in air. The sodium should be plunged into the melt and stirred gently for a short time to provide good dissolution and dispersion. Alternatively, several commercial salt flux tablets are available whose decomposition yields sodium for modification. The usual precautions apply regarding proper storage and the use of clean, dry tools. Fade, or loss of modification, increases with excessive agitation, degassing, prolonged holding periods, or excessively high temperatures (Ref 6).

In general, a sodium addition of 0.015 to 0.020% is required for adequate modification, which results in a residual level of sodium in the casting of about 0.002%. Sodium should not be used with alloys containing more than 1% Mg, because of possible embrittlement.

Strontium presents no special storage or handling problems, as does sodium, and is usually added in the form of Al-10Sr-14Si or aluminum-strontium master alloy ingots or waffles. An Al-10Sr rod is also available, which dissolves more easily. Additions of 0.01 to 0.02% in foundry castings are sufficient, particularly when melting returns where typical residual 0.008% Sr is available. Overall, strontium modification seems more resistant to fade than sodium.

Calcium is also added as a modifier in the form of a master alloy that also contains 5% Si. Nominal addition levels for modification are about 0.01%. Calcium also seems more resistant to fade than sodium, although prolonged holding will result in calcium loss (Ref 120).

Antimony is a modifier that is used predominantly in Europe and Japan. It is added at about the 0.12% level and serves as a permanent alloy constituent of the aluminum alloy. It is therefore added by the supplier of foundry ingot and does not require any make up addition at the foundry. Antimony is reported to be unaffected by holding time, remelting, or degassing. Alloys modified with antimony are distinguished by lower gas susceptibilities than those containing sodium or strontium. However, cross contamination problems are possible, and antimony is more toxic.

Hypereutectic Alloys. Although various elements have been found to be capable of modifying (refining) hypereutectic alloys, only phosphorus is used commercially. Other elements, such as magnesium, tungsten, sulfur, and lanthanum, have been reported to be effective modifiers (Ref 113) but thus far none has achieved commercial importance.

Phosphorus is available for the refinement of hypereutectic alloys in the form of master alloys (phoscopper), aluminum phosphide, or silicon phosphide; as phosphorus pentachloride; or as various proprietary salt mixtures. Additions usually range from 0.020 to 0.025% P. Addition should be made carefully, with the customary precautions to ensure completely dry materials and tools.

Modifier Comparisons and Interactions

Dissolution. With the advent of strontium modification for hypoeutectic alloys and the increased use of foreign castings modified with antimony, many questions have arisen concerning the merits, problems, and interactions between sodium, strontium, and antimony. Strontium modification has been examined in several recent papers, and the nature of the strontium addition has been found to be quite important (Ref 121, 122, 123). An oxide-free strontium surface increases the rate of dissolution and minimizes the so-called hydrogen pickup that has sometimes been associated with strontium additions (Ref 122).

In general, the strontium master alloys perform better than strontium-bearing salts, and sheared rod produces faster dissolution than waffle ingot. Strontium dissolution is characterized by an exothermic reaction that results in the formation of intermetallic compounds (Ref 121, 122). The rate of this reaction, which is temperature dependent, determines the effectiveness of strontium recovery and therefore the degree of modification achieved.

It has been found that when elemental strontium is present, as in a 90Sr-10Al master alloy, the exothermic reaction proceeds at about 725 °C (1340 °F). However, at lower temperatures, the reaction is slowed, and an intermediate intermetallic precipitate, $SrAl_2Si_2$, forms with good dissolution characteristics. Therefore, lower temperature provides better recovery than higher temperature (Fig. 76a).

Fig. 76 Comparison of dissolution rates for strontium additions made with 90Sr-10Al (a) and 10Sr-90Al (b) master alloys. Source: Ref 123.

On the other hand, lower strontium master alloys such as 10Sr-90Al dissolve by simple dissolution; therefore, recovery increases at higher temperatures (Fig. 76b) because the dissolution rate is greater (Ref 123). A certain amount of time (10 to 20 min) may be necessary for optimal recovery, which is dependent on temperature and the specific strontium alloy addition (Ref 124).

Sodium dissolution occurs more simply and rapidly, providing almost immediate optimal modification. Antimony appears to behave similarly. All modifiers increase the eutectic suppression. At equivalent levels of suppression, strontium yields better modification than sodium.

Fade. It is well known that sodium modification fades; that is, sodium is lost through oxidation and reaction within the melt, perhaps forming some sodium-aluminum-silicon complex that retards the ability for sodium to modify. Degassing or melt agitation easily destroys sodium modification, while such stirring does not seem to affect strontium modification (Ref 125).

Contamination. The recycling of scrap castings poses the problem of intermingling of different modifiers and possible detrimental consequences. Sodium and strontium have been found to be compatible with each other in the range of 0.007 to 0.012% Na and 0.007 to 0.019% Sr (Ref 124, 126). The strontium presence overcomes the effect of sodium fade for up to nearly 2 h. Therefore, strontium can be used to modify melts that may contain some sodium from recycled scrap.

Antimony, however, poisons both sodium and strontium modifications. In the case of sodium, at normal sodium addition levels near 0.01%, the presence of 0.02 to 0.05% Sb eliminates modification. A level of 0.01% Sb might be tolerated, but requires up to 0.04% Na to avoid fade and to retain modification after 1 h (Ref 126). It is thought that this negative interaction is a result of a sodium-antimony (possibly Na_3Sb) intermetallic compound that forms, depleting the alloy of sodium available for modification.

Antimony has a similar negative effect on strontium modification. Figure 77 shows a change in antimony content when it is present as a contaminant in strontium-modified melts. There is reasonably clear evidence that a Mg_2Sb_2Sr intermetallic forms concurrently as the strontium dissolves. This precipitate, having a higher density than molten aluminum, forms a sludge at the bottom of the melting vessel. Figure 78 indicates that much higher amounts of strontium are needed to achieve modification when antimony is present.

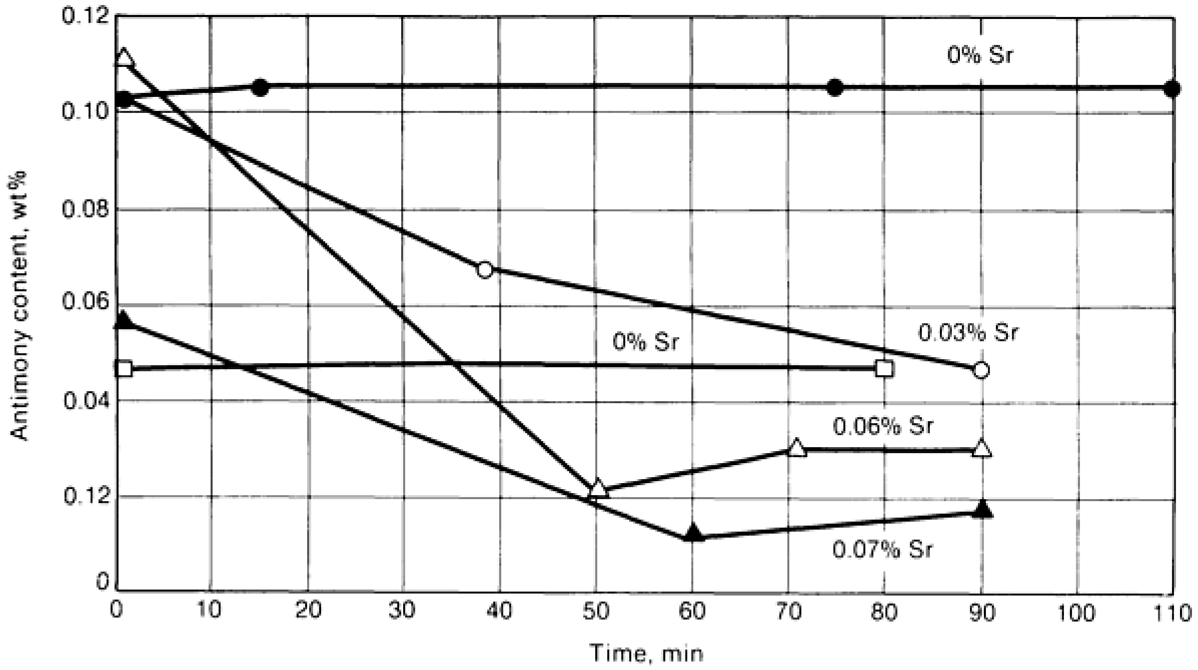

Fig. 77 Interaction between antimony and strontium present in A356 alloy as a function of time. Source: Ref 126.

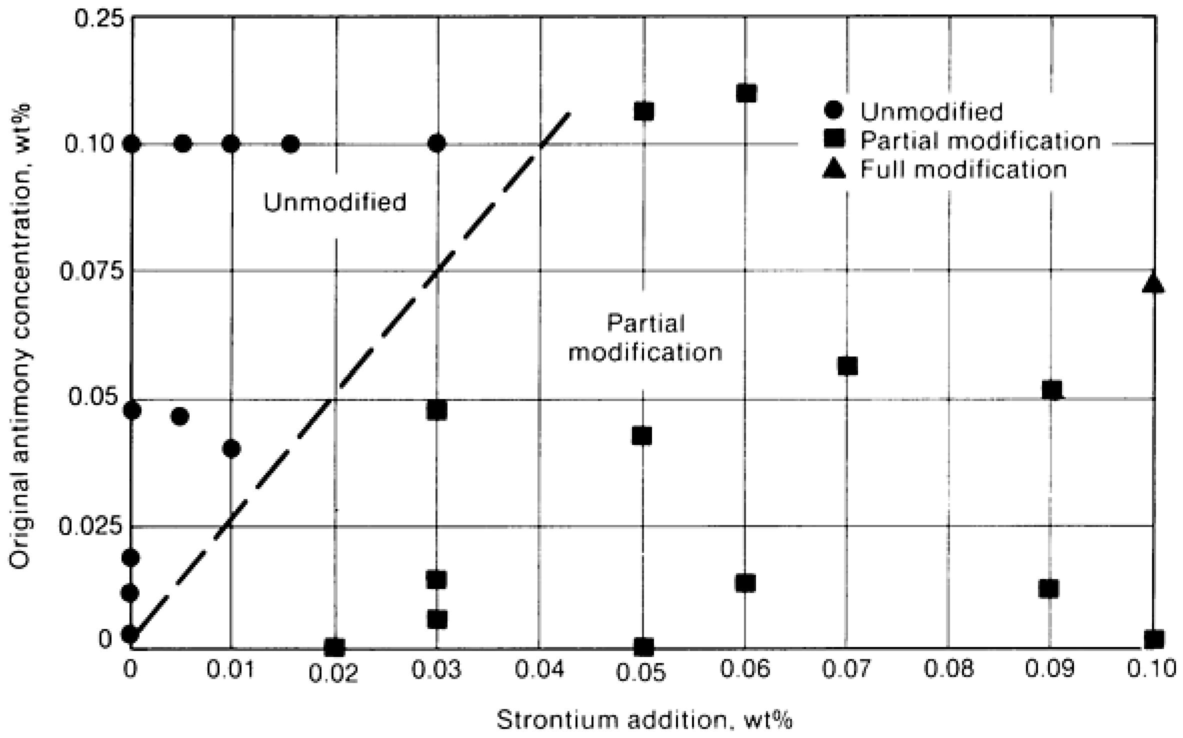

Fig. 78 Effect of antimony on strontium modification in A356 alloy. Source: Ref 126.

When all three modifiers are present, the ternary interactions behave as expected on the basis of the binary interactions. The antimony content decreases as either strontium or sodium is added, reflecting the intermetallic compound formation. Sodium content decreases rapidly at first, especially when elemental sodium is plunged. If the total modifier concentration is high enough, particularly strontium at 0.010 to 0.020%, the effects of antimony contamination can be overcome and modification maintained.

Phosphorus is chemically similar to antimony and has a similar deleterious effect on either sodium or strontium modification. For a given level of phosphorus (which could be present as an impurity arising from hypereutectic alloy scrap or phosphate-bonded refractory materials), a higher amount of either sodium or strontium is necessary to achieve full modification.

Hydrogen and Degassing. The effect of modification practice on hydrogen gas absorption and the subsequent response in degassing have been commonly observed and studied in some detail. Researchers (Ref 124) have noticed a tendency toward higher gas levels using either sodium or strontium (Fig. 79). The increase in gas content does not necessarily occur immediately, but increases with time. An increase in gas absorption when modifiers are present is especially noticeable at temperatures above 745 °C (1375 °F). Deliberately gassed strontium-modified melts show greater hydrogen uptake and less natural outgassing than unmodified melts. The influence of antimony on gas levels has not been discussed in the literature as frequently, but antimony modification appears less gas prone than strontium modification (Ref 127), with much higher densities (less porosity) reported for a given gas content (Fig. 80).

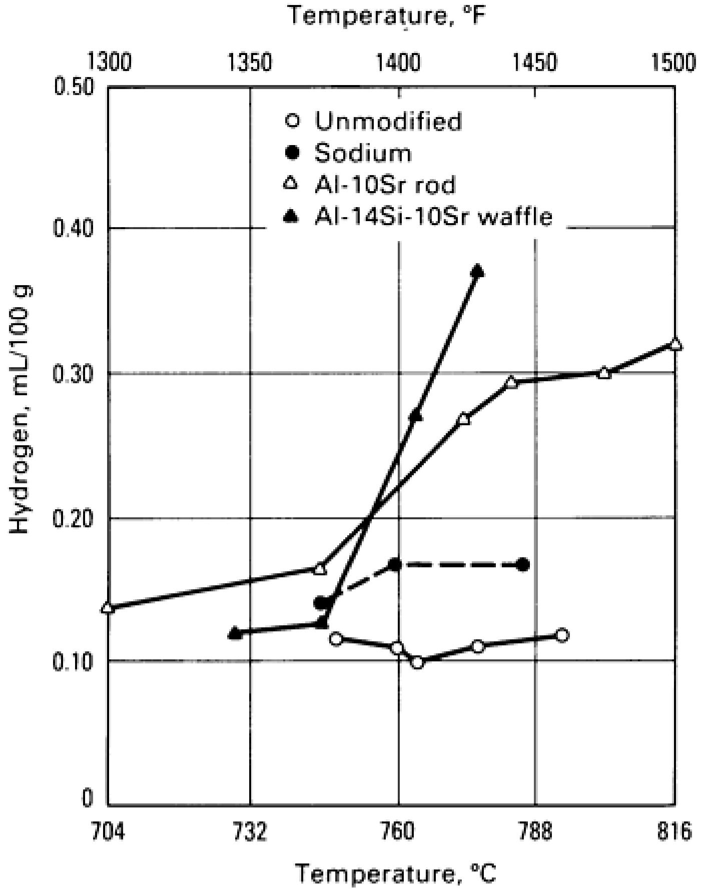

Fig. 79 Hydrogen content as a function of holding temperature for aluminum alloy 356 melts with various modifiers. Source: Ref 124.

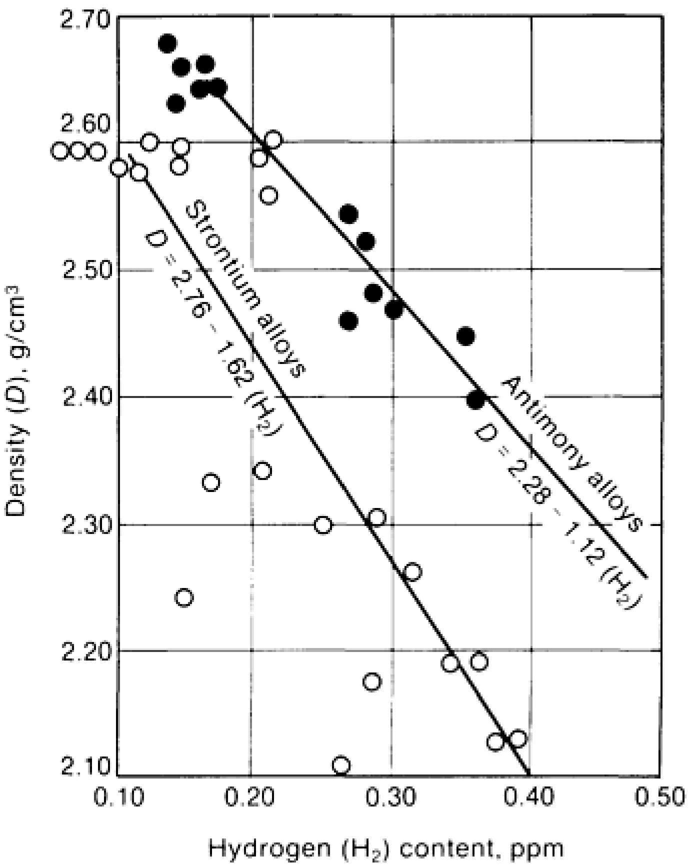

Fig. 80 Effect of modifier used on the density of an aluminum-silicon alloy for a given hydrogen content. Source: Ref 127.

On the other hand, there is a recent body of work indicating that strontium modification does not necessarily increase the propensity for an A356 alloy melt to absorb hydrogen (Ref 121, 125, 128). Binary master alloy additions may be better than ternary alloy modifier additions; this suggests that the silicon in the latter may be harmful (Ref 121). In another study (Ref 126), there was no evidence to suggest that hydrogen is carried into the melt from any such occlusion in the strontium itself (Fig. 81), nor was there any noticeable difference in regassing behavior with either a clean strontium surface or a corroded strontium hydroxide surface layer. A subsequent study confirmed that there was no significant difference in the rates of regassing for a strontium modification versus an unmodified melt (Ref 128). Stirring, however, increases the rate of regassing for both strontium-modified and unmodified melts.

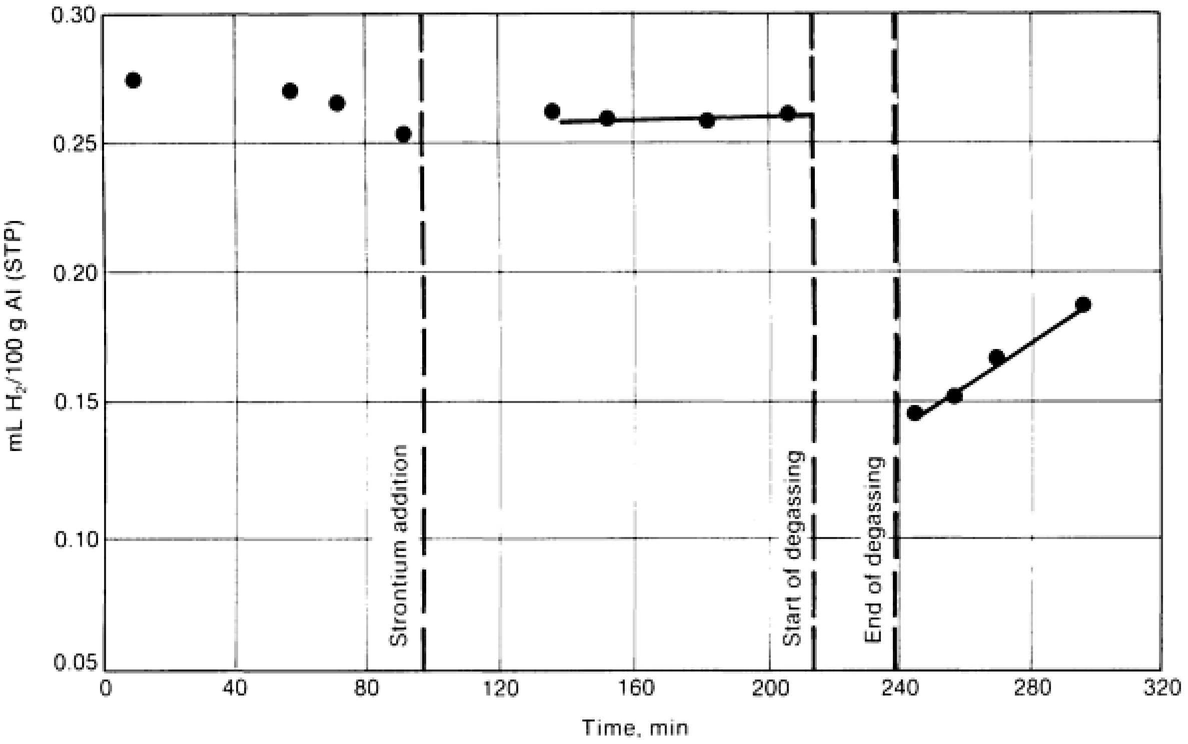

Fig. 81 Effect of 0.03% Sr addition (90% Sr master alloy) on hydrogen level in A356 alloy. Source: Ref 126.

The degassing of modified melts does illustrate significant differences between sodium and strontium modifiers. In the case of sodium, degassing with either inert gases (argon, nitrogen) or reactive gases (chlorine, freon) removes sodium and depletes modification. Consequently, melts to be sodium modified should always be degassed before modification. On the other hand, strontium-modified melts exhibit markedly different behavior (Ref 125, 128). Argon is effective in degassing a strontium-modified melt, and the rate of degassing is not affected by the presence or absence of strontium. Argon shows no detrimental effect on strontium content. Therefore, in contrast to sodium-modified melts, strontium-modified melts may be, and should be, degassed after the modification treatment. The fade rate during degassing is almost negligible.

Nitrogen-freon mixtures have been found to be ineffective degassers when strontium is present and in fact may actually remove strontium through the possible formation of strontium chloride. It has been postulated that such a compound may retard degassing by blocking hydrogen transport into the purging gas bubble (Ref 125).

Molten Metal Pumping Systems

Molten nonferrous metals have traditionally been transferred from the melting vessel to a mold or casting unit by tapout or lip pouring (essentially gravity flow systems) or by using an intermediate ladle. Mechanical transfer pumps are now commonly used with aluminum, magnesium, zinc, and lead alloys (Ref 25, 26, 129, 130). A mechanical pumping system has several advantages. Pressurized flows permit larger volumes of metal to be transferred per unit time, with resultant productivity gains. The ability to move greater volumes of metal in shorter times also means that less superheat must be put into the metal to accommodate temperature losses during transfer. Thus, shorter overall furnace melting cycles are possible. Because most metal transfer pumping systems have submerged intakes, dross entrainment from the surface is avoided, providing better metal quality. Transfer pumping *per se* does not produce additional oxidation or dross losses, because molten nonferrous metals are always subjected to turbulent flows (high Reynolds numbers) even with gravity flow tapout systems.

Transfer pumps can often be used with closed piping systems to provide transfers surmounting physical obstacles (over other equipment, for example) or overcoming head and height limitations when gravity flow is limited or not possible. Melting and casting facilities can therefore be mixed and matched and need not be directly in line with one another.

Transfer pumps are now commonly used in many segments of the aluminum casting industry to move molten metal from melting furnace to holding furnace, to feed or empty auxiliary refining vessels (used for alloying, degassing, and filtration), to empty and fill transfer ladles, to directly pour castings and fill molds, or to feed casting machines in the wrought industry. In the magnesium, zinc, and lead metal casting industries, mechanical pumps transfer metal between furnaces, fill ingot and pig molds, feed die casting machines, cast electrogalvanizing anodes, and empty galvanizing kettles when repairs or desludging is required. In an unusual application, one foundry has successfully poured a 9000 kg (20,000 lb) casting using hot metal delivery, an intermediate vessel, and a transfer pump (Ref 131). In this way, a much larger casting was produced than the foundry had actual melting capacity for.

Molten copper alloys have previously been transferred only by small pressure pump systems, but a centrifugal pump system has recently been shown to be successful in pumping 72,600 kg (160,000 lb) of molten copper continuously for 55 min (Ref 130).

Several kinds of mechanical pumping systems exist for nonferrous metals. The first is simply a positive-displacement pressure pump. This is often quite useful for small furnaces or small flows (<45 kg, or 100 lb). When actuated, external air pressure displaces the volume of air in the cylinder, which forces an equivalent volume of liquid metal through the delivery tube.

Another type of pump is the siphon pump. Both of these pumps are quite capable of filling small molds where the accuracy of fill demanded is moderate (several percent variation) and where pressure head requirements are minimal (0.3 to 0.6 m, or 1 to 2 ft, maximum).

When larger volumes of metal, more sustained flow, or higher head is required, a centrifugal pump can be used (Fig. 82). Flow is directed by an impeller up through a riser tube. Operated either by air or electric drive, these pumps are typically constructed of graphite and are easily operated in molten aluminum, magnesium, and zinc alloys. It is important to keep the riser tube open, using insulation and careful external heating if necessary, to prevent freezeups, especially if use is intermittent.

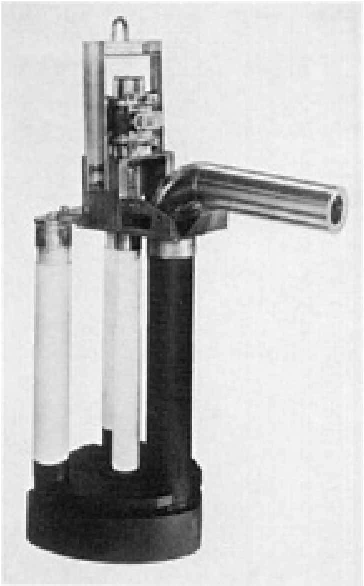

Fig. 82 Centrifugal transfer pump for molten aluminum and zinc. Courtesy of Metaullics Systems.

Another type of centrifugal mechanical pump often used with magnesium alloys is shown in Fig. 83. Pump construction is usually cast iron, low-carbon steel, or 400-series stainless steel. Nickel impurities in metal pump components should be specified to be below 0.20% to avoid the dissolution of nickel in the molten magnesium and the subsequent reduced corrosion resistance of magnesium castings.

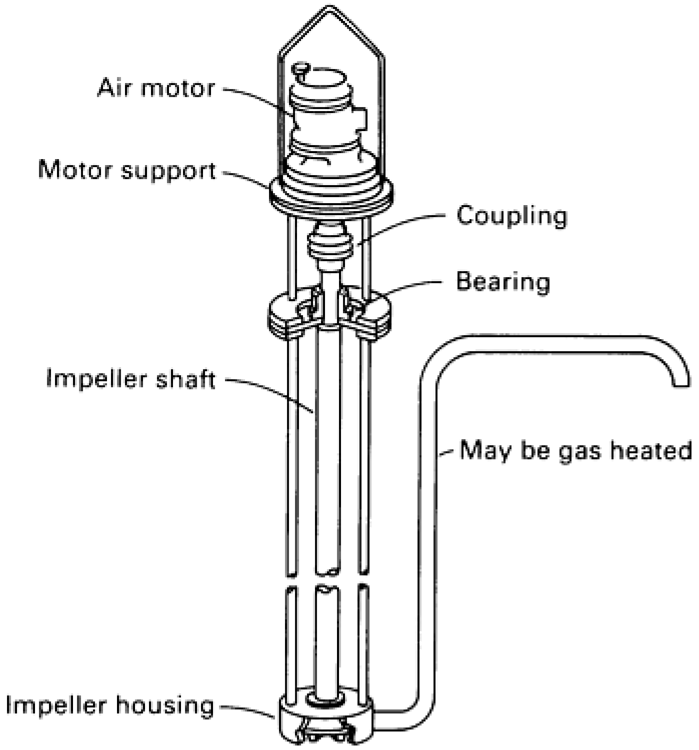

Fig. 83 Schematic of metallic centrifugal pump used to transfer magnesium. Source: Ref 124.

Electromagnetic pumps have recently been developed that offer promise for very controlled filling capabilities in such applications as permanent mold casting, large die casting, low-pressure die casting, and perhaps small ingot casting. This type of pump is constructed from ceramic materials and delivers metal through the left-hand rule of electromagnetic field theory, utilizing the molten metal as the secondary field in which the aluminum is caused to move upward. One specific advantage of this type of pump is that there are no moving parts. However, the molten metal channel opening must be kept very clean and free of oxide buildup or dross; otherwise, the field strength and resulting pumping capacity can be greatly reduced.

Centrifugal pumping systems for zinc are usually constructed of graphite, but metallic centrifugal pumps are often used as well. Pumping systems for lead are usually constructed with cast iron because little corrosion is experienced. Cast iron can also be used to pump zinc as long as the temperature is kept below 480 °C (900 °F), above which molten zinc begins to dissolve iron. Austenitic stainless steels can be used as pump materials with aluminum-containing zinc alloys 0.2 to 3.5% Al. Stainless steel must not be used, however, with pure zinc, because liquid-metal embrittlement and intergranular attack occur quite rapidly. With zinc-aluminum galvanizing alloys (40 to 60% Al), the high operating temperature (595 to 650 °C, or 1100 to 1200 °F) is in the region where austenitic stainless steels become sensitized to greater intergranular carbide precipitation and subsequent accelerated corrosion. Stainless steel pumps should therefore not be used for this application. A useful but expensive alternative for the latter two applications is an Mo-30W or Mo-40W pump shaft, which provides excellent corrosion resistance but is fairly brittle at high temperatures.

Molten Metal Filtration

The most significant modern development in nonferrous molten metal processing involves the application of filtration. Aluminum alloys, especially with their tendency toward oxidation, often contain impurities (nonmetallic inclusions) that are deleterious to physical, mechanical, electrical, and aesthetic properties. Filtration has become a primary means of removing such solid impurities. Zinc and copper alloy melts are filtered to a much lesser extent than aluminum, but use of filtration is increasing for these alloys also.

The filtration process consists of passing the molten metal through a porous device (a filter) in which the inclusions contained in the flowing metal are trapped or captured by one or more filtration mechanisms (see the section "Filtration Fundamentals" in this article). The filter material itself must have sufficient integrity (strength, refractoriness, thermal shock resistance, and corrosion resistance) so that it is not destroyed by the molten metal before its task is accomplished. Consequently, most filter media are ceramic materials in a variety of configurations.

Sources of Inclusions

Inclusions arise from many sources. Charge materials can contain nonmetallic inclusions from unfiltered primary or secondary ingot. Scrap materials may contain molding sand debris from back-charged gates and runners, metalworking lubricants, paint and coatings, plastics, or unsorted and unwanted heavy metal contaminant oxides (iron, manganese, chromium, and so on). Furnace tools, such as skimmers, puddlers, and rakes can also add solidified oxide skins back into the melt if they are not cleaned before use.

Excessive temperatures during melting accelerate the oxidation of aluminum and alloying elements. Where fluxes are used, incomplete skimming or separation of fluxing salts often results in contamination and salt-wetted oxide inclusions.

Grain-refiner additions can be a source of inclusions (see the earlier sections of this article on grain refining of aluminum alloys, magnesium alloys, and copper alloys).

Intermetallic compound precipitation may also contribute to inclusions. Iron, chromium, and manganese form intermetallics with aluminum and the formation of intermetallic sludge is a common problem in die casting alloys.

Refractory Inclusions. Finally, the erosion and wear of melting and holding vessels may add alumina, spinel, silica, and silicon carbide inclusions to nonferrous alloy melts.

Inclusions in Aluminum Alloys

There are several types of solid-phase inclusions in molten aluminum alloys:

- Oxides (Al_2O_3, MgO)
- Spinels (Mg_2AlO_4)
- Borides (TiB_2, VB_2, ZrB_2)
- Carbides (Al_3C_4, TiC)
- Intermetallics ($MnAl_3$, $FeAl_3$)
- Nitrides (AlN)
- Exogenous refractory inclusions (oxides and/or carbides of iron, silicon, aluminum, etc.)

These inclusions possess a series of complexes, true formulations, and densities ranging from lighter to heavier than the molten aluminum itself, as well as a range of sizes and shapes (Table 7). Gravity separation alone plus skimming is not always successful for adequate removal. In addition, there are different degrees of wettability of these inclusions with molten aluminum, thus allowing the use of fluxing salts to wet the inclusion properly and render separation possible by detaching the inclusion from the melt.

Table 7 Characteristics of inclusions commonly found in aluminum alloys

Inclusion type	**Chemical formula**	**Form**	**Density**		Size range	
			g/cm^3	**lb/in.^{3}**	**µm**	µin.
Oxides						
Alumina	Al_2O_3	Particles, skins	3.97	0.143	0.2-30 (particles) 10-5000 (skins)	**8-1200** **400-2 × 10^5**
Magnesia	MgO	Particles, skins	3.58	0.129	0.1-5 (particles) 10-5000 (skins)	**4-200** **400-2 × 10^5**
Spinel	$MgAl_2O_4$	Particles, skins	3.60	0.130	0.1-5 (particles) 10-5000 (skins)	**4-200** **400-2 × 10^5**
Silica	SiO_2	Particles	2.66	0.096	0.5-5	**20-200**
Salts						
Chlorides	Varies	Particles	1.98-2.16	0.072-0.078	0.1-5	**4-200**
Fluorides	Varies	Particles	1.98-2.16	0.072-0.078	0.1-5	**4-200**
Carbides						
Aluminum carbide	Al_4C_3	Particles	2.36	0.085	0.5-25	**20-1000**
Silicon carbide	SiC	Particles	3.22	0.116	0.5-25	**20-1000**
Nitrides						
Aluminum nitride	AlN	Particles, skins	3.26	0.117	10-50	**400-2000**
Borides						
Titanium boride	TiB_2	Agglomerated particles	4.50	0.163	1-30	**40-1200**
Aluminum boride	**AlB_2**	**Particles**	**3.19**	**0.115**	**0.1-3**	**4-120**

The size and shape of the inclusions vary from globular (oxides and borides) to stringerlike (oxides and spinels). The latter are particularly insidious in their effect on castability and the properties of the casting.

Liquid-phase inclusions can occur in molten aluminum alloys. The most prevalent is $MgCl_2$ arising from the chlorination of magnesium-containing melts. These inclusions are not generally removed to a great extent by conventional filtration techniques and therefore must be avoided. Preventing excessive and inefficient chlorination of the melts during degassing and thorough skimming at least help to avoid such inclusions. The nature of these and other inclusions in aluminum alloys is discussed in more detail in Ref 133, 134, 135, 136, and 137.

Inclusions in Magnesium Alloys

The inclusions found in magnesium melts are similar in many cases to those found in aluminum--oxides, spinels, furnace refractory particles, and so on. In addition, alloying elements (zirconium and the rare earths) lead to both oxides of these elements as well as intermetallic compound precipitates. If the fluxing process is used to clean magnesium, fluxing salt inclusions may also be present.

Inclusions in Copper Alloys

In addition to the usual inclusions arising from oxides, fluxing salts, and intermetallics, copper oxide inclusions and phosphorus pentoxide (from deoxidation) may be present in copper alloys if the melt is not allowed to settle or if it is inadequately skimmed before pouring and casting.

Inclusions in Zinc Alloys

In the zinc foundry and die casting alloys containing aluminum, nonmetallic oxide inclusions are usually less important than intermetallic inclusions (Ref 18, 138, 139). Iron-zinc and iron-aluminum intermetallic compounds may also be present, especially above 480 °C (900 °F) in melting in iron-base vessels. These particles may be small crystals less than 5 μm (200 μin.) in size or may agglomerate into millimeter-size aggregates.

Other heavy metals present, such as lead, cadmium, nickel, manganese, and chromium, can also lead to intermetallic compound precipitation (for example, Mn_2Al_5, Ni_2Al_3, and $CrAl_4$). These compounds (often called aluminides) can form when the concentration of impurity exceeds the liquid solubility level of the element, which is often quite low (<0.02% for manganese, silicon, chromium, and nickel in die casting alloys). The intermetallic particles can be lighter than the base alloy and therefore rise to the top dross. Fluxing salt inclusions and exogenous refractory particles can also be present, as with the other nonferrous alloy systems.

Oxide inclusions in zinc are somewhat limited because of the high positive vapor pressure of zinc. However, alloys containing aluminum can be subject to greater oxidation of the aluminum constituent. Oxide inclusions can also result during melting or casting when excessive turbulence is encountered; thus, mechanical stirring or molten metal pumping should be controlled. Other nonmetallic inclusions arise from refractory vessel erosion and include silica, alumina, and silicon carbide. There is an appreciable density difference between these oxides and the base melt, unlike in aluminum; for this reason, gravity separation and thorough removal are substantially easier.

Filtration Fundamentals

Two types of filtration modes occur when filtering particles from a flowing liquid stream: cake mode and depth mode.

In cake filtration, inclusion removal occurs by the mechanical entrapment of inclusions on the surface of the filter. Particles larger than 30 μm (1200 μin.) especially are captured by this method. These particles agglomerate to form a filter cake on the filter surface, which further aids filtering of inclusions during subsequent molten metal flow. Ceramic foam filters, one of the most prevalent kinds of filters, function largely in this manner.

Depth filtration is the filtering mode most prevalent in bed filtration. Depth filtration is capable of removing particles much smaller than 30 μm (1200 μin.) as they are carried in a molten metal flow stream through a very tortuous path in a deep bed filter (Fig. 84) that is commonly used in mill product casthouses. The tortuosity provides increasing probability for a two-step particle capture mechanism involving transport from the liquid metal flow and attachment to the filter surface itself. Particularly in filters possessing irregular surface characteristics, the fluid transport phenomena of inertia,

sedimentation, particle interception, and diffusion come into play (Fig. 85). Particles brought into contact with the walls of the filtering medium then may attach themselves or be retained by one or more mechanisms:

- Gravity, friction
- Physical entrapment
- Chemical bonds
- Van der Waals forces
- Electrostatic forces

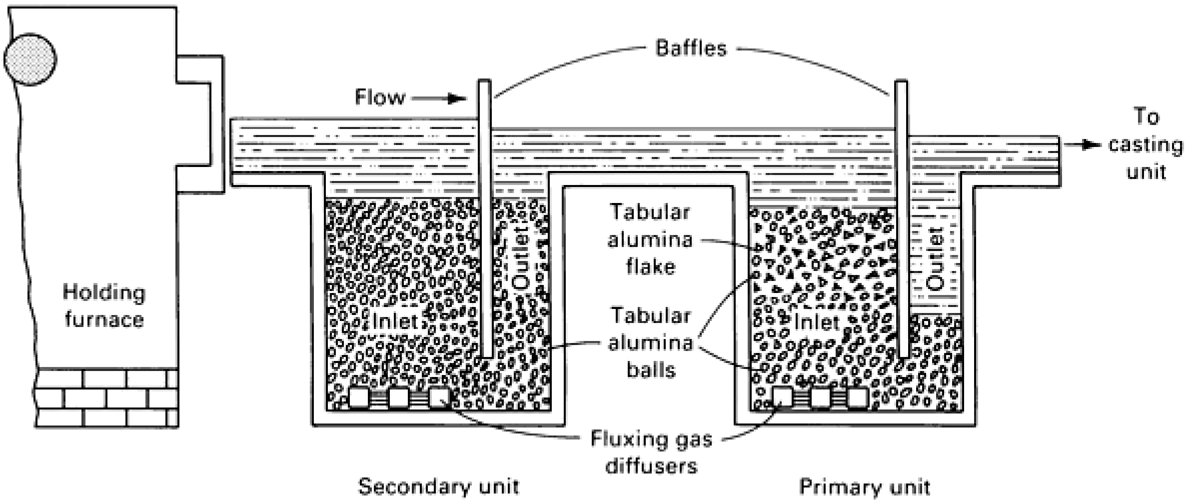

Fig. 84 Example of one type of bed filter used for in-line processing. Source: Ref 140.

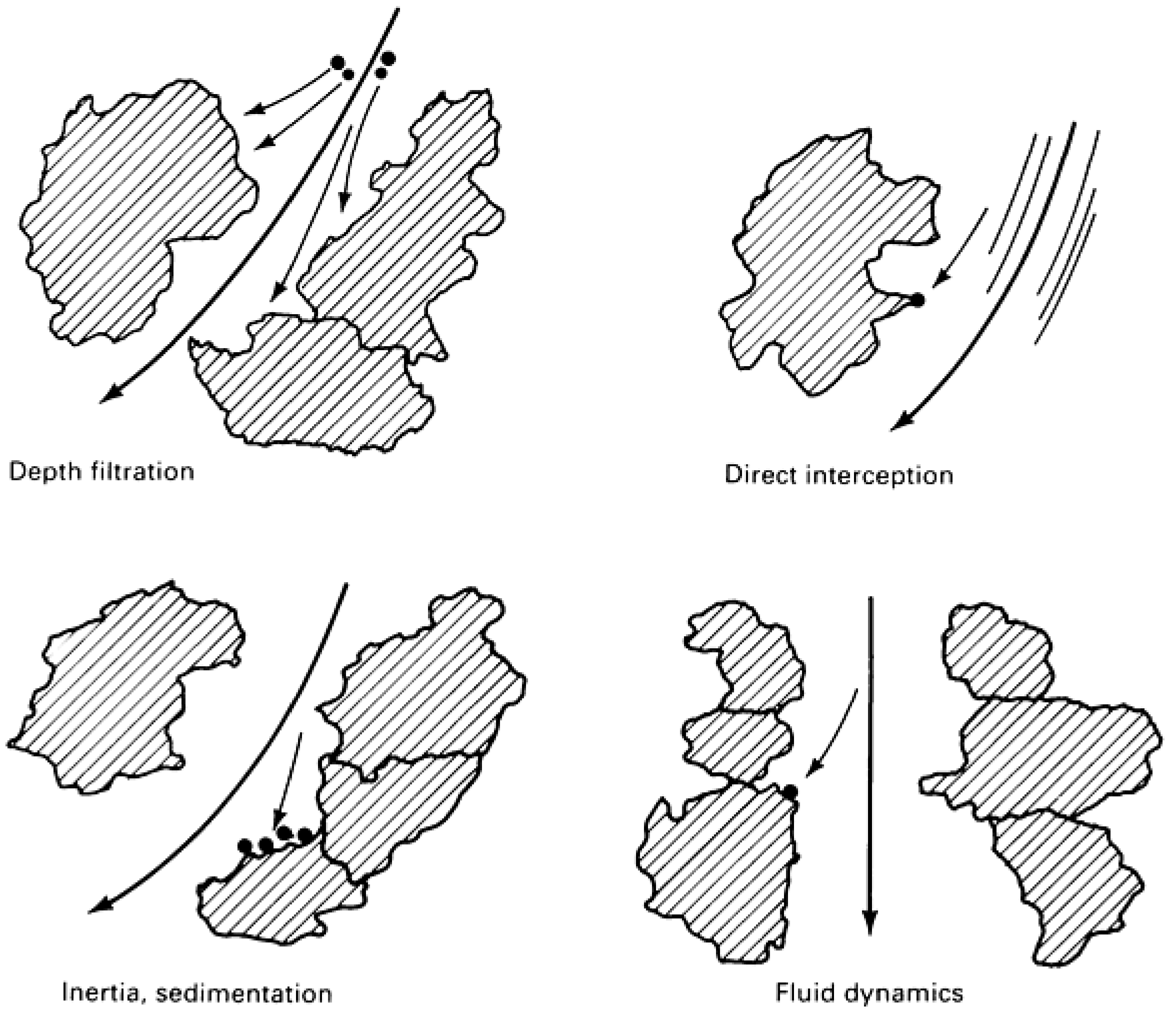

Fig. 85 Transport and capture mechanisms operating during depth filtration.

Researchers familiar with filtration theory are now concentrating more heavily on studying the nature of the chemical bonding mechanism. It appears that there are peculiar interactions between different types of inclusions and specific ceramic surfaces that give rise to differing filtration capabilities and efficiencies.

Filtration efficiency is influenced by several factors. First, the nature of the molten metal itself must be considered--the amount of inclusions, their size, shape, and distribution. Second, the dynamic conditions encountered by the filter will have a pronounced effect:

- Lower molten metal flow rates generally result in greater filtration efficiency because of better capture probability in/by the filter
- Greater filter surface area increases filtration efficiency
- Filters that provide a stronger balance between cake and depth filtration provide higher filtration efficiency
- Greater length or depth of filter dimension permits greater probability of inclusion capture and therefore greater filtration efficiency

The efficiency of various filters is subject to considerable debate (Ref 132, 141, 142, 143, 144). Taking the above-mentioned factors into consideration, however, it can be said that those filters providing more depth plus cake filtration function more efficiently than those that rely more or only on cake mode filtration. Figure 86 compares the efficiencies of ceramic foam and bed filters over a range of metal flow rates.

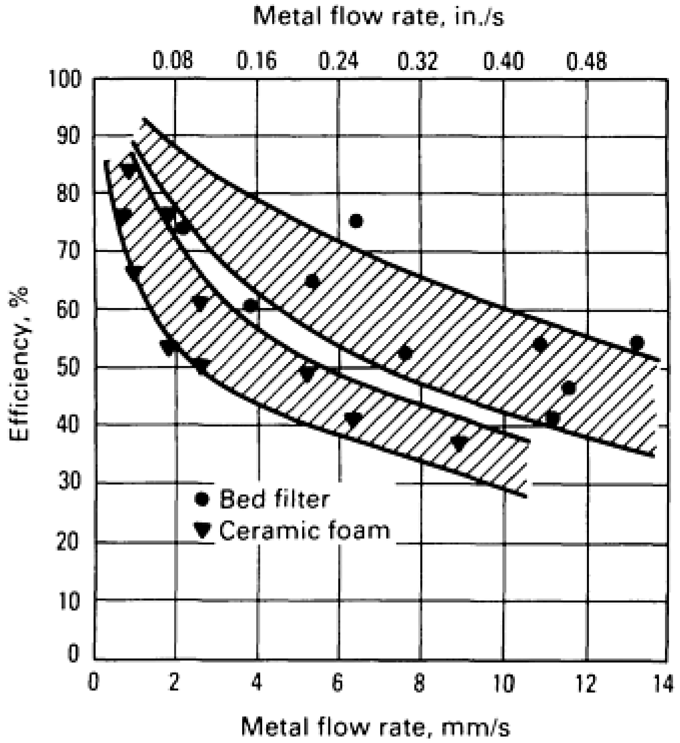

Fig. 86 Comparison of filtration efficiencies of a bed filter and a ceramic foam filter as a function of melt velocity. Source: Ref 144.

Types of Filters

The simplest filters are the strainer cores used in downsprues in conventional foundry sand casting. While serving to choke or control metal flow, they also trap some particulate by surface attachment and a degree of cake filtration.

Metal or Fiberglass Screens. Steel mesh screens and fiberglass cloth are also commonly used for aluminum, and molybdenum mesh is used for copper alloys. These materials act as planar filters. They provide moderate filtration, particularly of larger particles and inclusions exceeding 100 μm (0.004 in.) in size. The mesh screen, fiberglass cloth, and strainer cores are of course single-use filters.

Rotary degassing can also remove inclusions by flotation. It is usually effective in removing inclusions larger than 40 μm (1600 μin.) in size.

Bed filters composed of tabular Al_2O_3 are quite common in the casting of mill products, where up to 1800 Mg (2000 tons) of a single alloy might be filtered in-line between holding furnace and casting station before replacement is necessary. Bed filters provide the best source of fine particle filtration, but their size, expense, and single-alloy use preclude their economic use in multiple-alloy wrought casting (ingot) or foundry casting operations. Bed filters are capable of providing nearly the highest filtration efficiency attainable, but because the bed is not rigid, movement and flow channeling can occur, which can dump inclusions.

Bonded particle filters are finding greater use in foundry and die casting operations (Ref 131, 145, 146). These filters consist of a refractory grain (either Al_2O_3 or SiC) bonded together to form a rigid structure (Fig. 87). Bonded particle filters provide a relatively tortuous path for metal flow through the filter (good depth filtration). These filters are often used vertically to separate melting or holding furnace hearth areas from the dip-out well (Fig. 88) and thus provide cleaner metal on the dip-out side. Silicon carbide vertical gate filters are quite durable and offer the potential of low thermal gradients between the hot face and cold face because of the relatively high thermal conductivity of silicon carbide compared to other materials, such as oxide ceramics. Temperature gradients of 22 to 42 °C (40 to 75 °F) have been reported for these filters, versus 33 to 72 °C (60 to 130 °F) for oxide ceramic foams, for example (Ref 145).

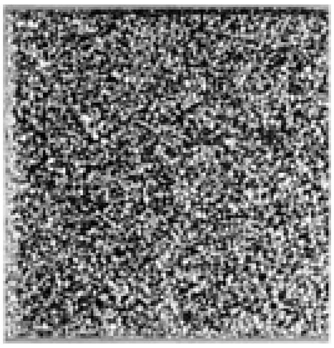

Fig. 87 Typical bonded particle filter.

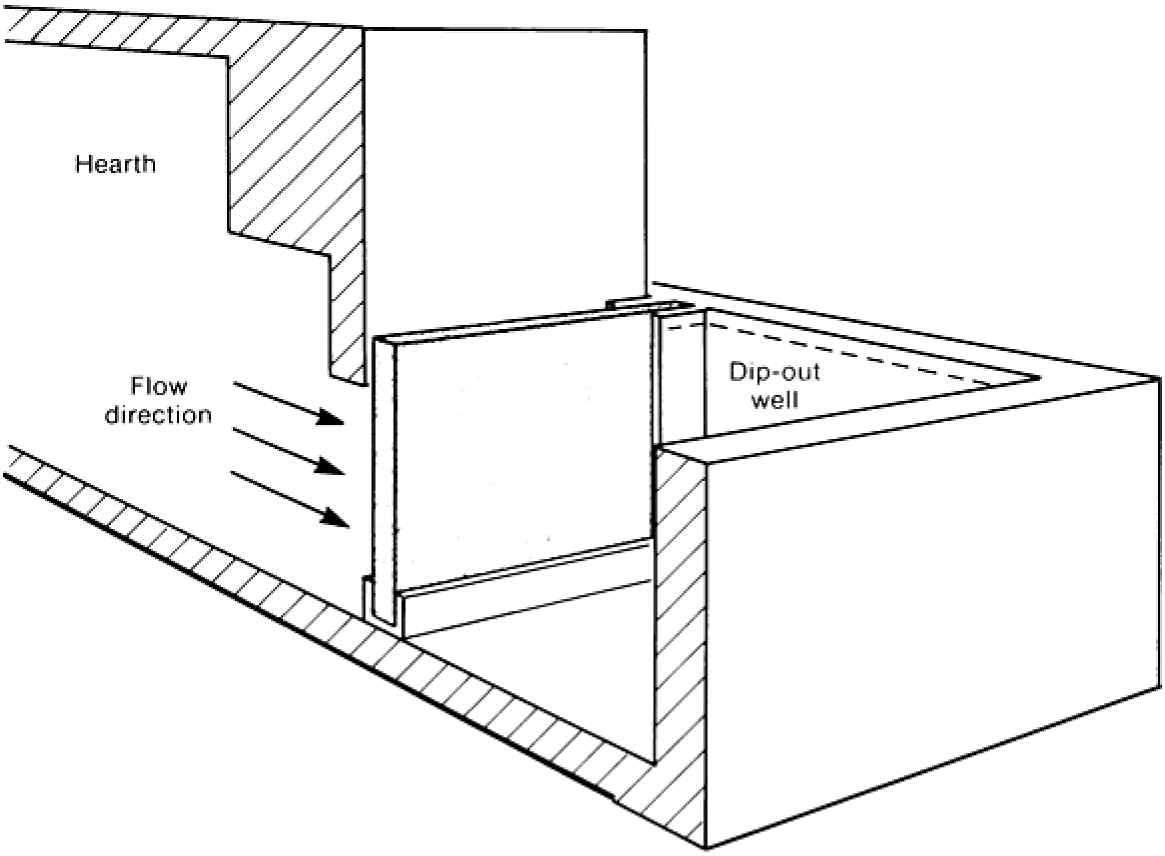

Fig. 88 Schematic of a vertical filter (bonded particle) used for holding furnace filtration for die casting operations.

One proprietary bonded particle filter system employs the bonded particle filter in a three-dimensional configuration (Fig. 89). This system has been successfully used in mill product, foundry, and die casting operations. The filter is housed in its own holding furnace, and it stays primed between casts or pours. The filter is rejuvenated between uses by backflushing to remove much of the accumulated filter cake, thus permitting continued metal flow capability. Up to 455 Mg (500 tons) of throughput has consistently been achieved before filter replacement is necessary, depending on initial metal cleanliness. In this sense, the filter is reusable (unlike a single-use ceramic foam) and offers the potential for substantial cost savings for filtration.

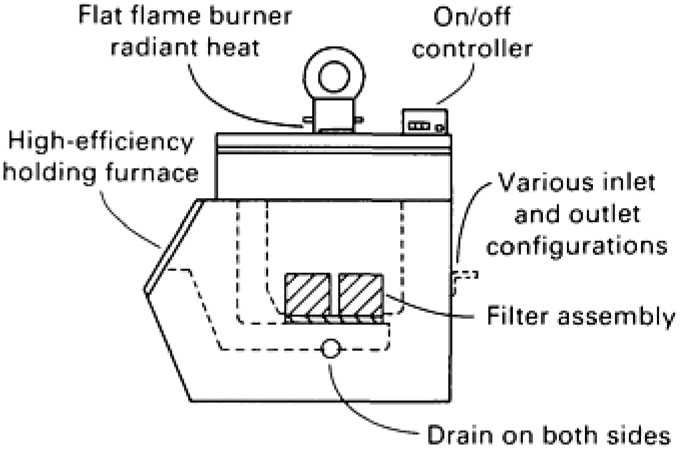

Fig. 89 Schematic of a proprietary bonded particle filter system. Source: Ref 146.

Cartridge Filters. One interesting application of the rigid filter concept is the cartridge filter (Fig. 90). This is simply a shell and tube type construction similar to a heat exchanger. This type of filter provides a great amount of surface area and usually has very fine pore size. Therefore, although substantial priming head (up to 0.3 in, or 1 ft) of metal may be required before flow through begins and although the flow rate is not very high, filtration efficiency is excellent. Cartridge filters are now receiving attention for such premium-quality applications as aircraft plate, computer disks, and foil. Efficiencies of 95% or better in removing particles less than 5 μm (200 μin.) in size have been reported.

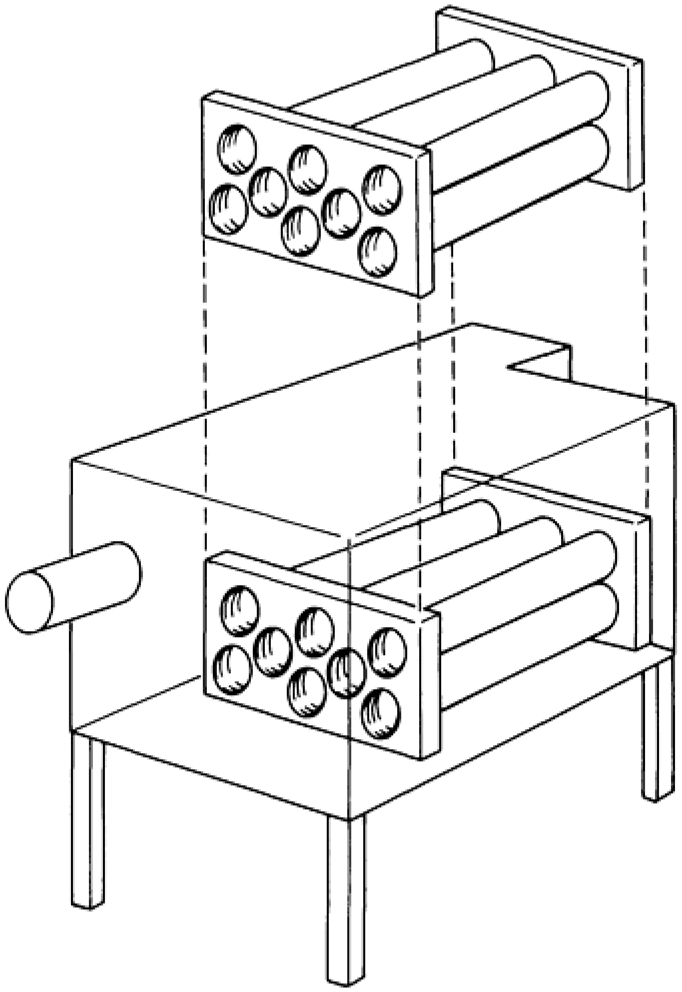

Fig. 90 Schematic of a cartridge bonded particle filter.

Ceramic foam filters are the most common types of filters currently used in nonferrous casting. They are produced by slurry coating a reticulated polyurethane cellular foam, followed by drying and firing to burn out the precursor foam. This results in a ceramic replica of the original organic foam structure (Fig. 91). Suitable ceramics for these filters are alumina, zirconia, and mullite. Some ceramic filters also employ chromic oxide. These filters are approximately 75% porous and are produced in a variety of pore sizes as measured by pores per lineal inch (ppi). Ceramic foam filters are used in flat, platelike form. In the primary aluminum industry, plate sizes vary from 305 × 305 mm (12 × 12 in.) to 585 × 585 mm (23 × 23 in.), depending on flow rate (up to 680 kg/min, or 1500 lb/min) and casting size (up to 34,000 kg, or 75,000 lb). Smaller filters are used in the die casting and foundry industries.

Dual-structure or multilayered ceramic foam filters are also employed. These use a finer pore size for greater inclusion capture capability, coupled with a coarser pore size to permit greater throughput before the filter becomes saturated or clogged.

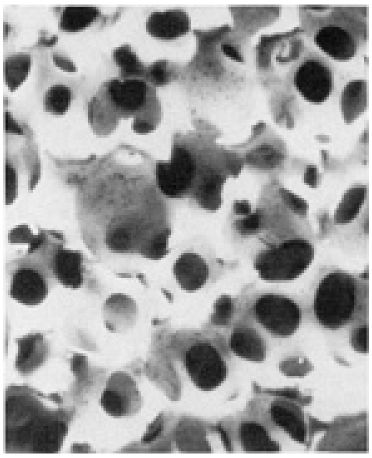

Fig. 91 Structure of a ceramic foam filter. Courtesy of Foseco Inc.

It is generally believed that ceramic foam filters function primarily through cake filtration, although undoubtedly some depth filtration also occurs. Bonded particle filters possess less porosity (38% versus 75% for a ceramic foam) and greater tortuosity; therefore, they function more as depth filters.

Choosing a Filter. Filter selection often depends on ease of use. Ceramic foams are lighter, easier to preheat, and provide easier flow capability than bonded particle filters, although the filtration efficiency of the latter is reported to be greater. For most foundry applications, however, a ceramic foam filter is most suitable. In the primary and mill products casting industry, filter selection will depend on economics, space constraints, auxiliary metal treatment capabilities, desired filtration efficiency, and end product application.

Ceramic foam filters and bonded particle filters have both been employed in filter baskets, baffled melting crucibles, and pouring ladles with some degree of success in many foundry operations (Fig. 92). Care must be taken to properly install, preheat, and maintain the filters used in these applications. In this way, such filters can be used through a number of repetitions.

Foundry Filters

The typical ceramic foam filter sections used in foundry gating systems are square, rectangular, or round sections up to 150 mm (6 in.) long and 19 to 25 mm (0.75 to 1.0 in.) thick. The filters are placed either tangentially or vertically to the metal flow path in a filter-sized print in the molding medium (sand, plaster, permanent mold). Typical placement schemes for gating or runner system filters are shown in Fig. 93. It is desirable to place filters as close to the actual mold cavity as possible to maximize effectiveness and to minimize turbulence. Bottom filling, when practical, is preferred.

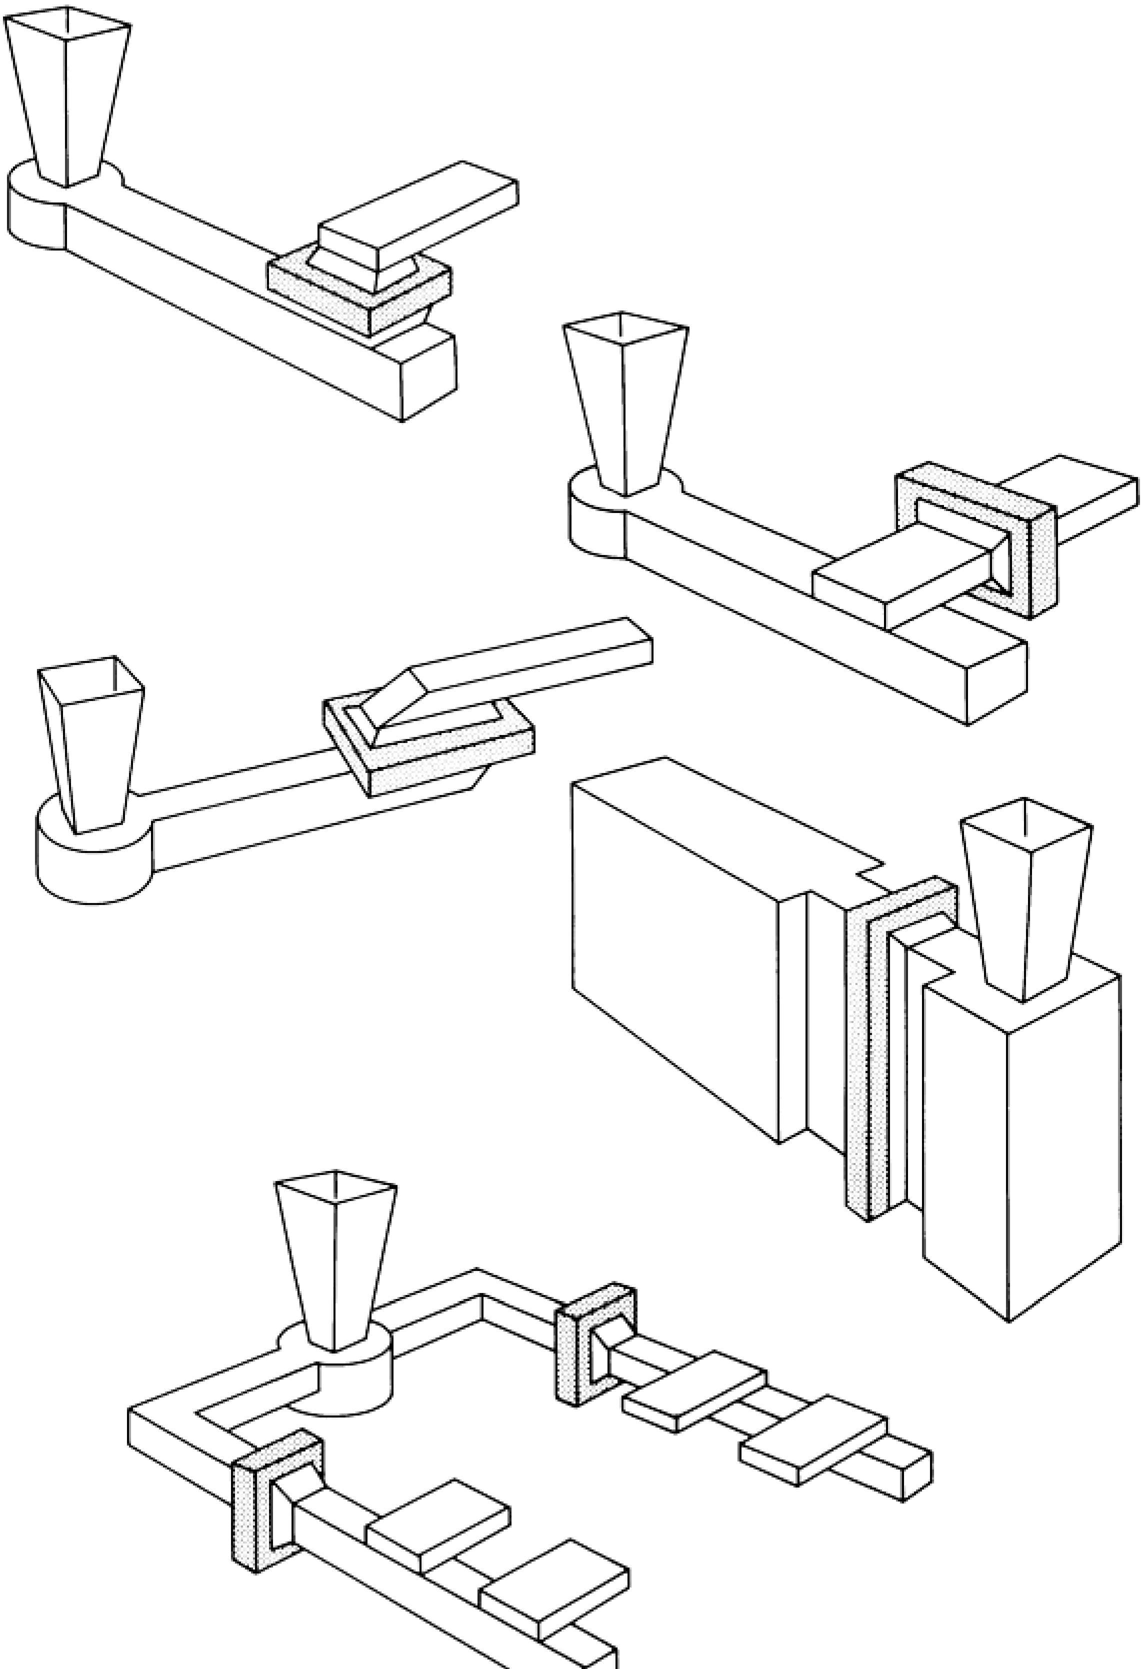

Fig. 93 Typical foundry filter placements (shaded). Courtesy of Selee Corporation.

Filter Size. Rules of sizing relate filter size to the flow rate and throughput capability desired. Sizing must also be tailored to the proper mold filling time necessary to achieve the desired solidified cast structure, because any filter produces a restriction to metal flow. Experience has shown that the following general rules apply when sizing gating system filters for nonferrous alloys, principally aluminum (Ref 149, 150):

- For a given required fill rate, enlargement of the gating system is necessary to accommodate the restriction created by the filter
- Total ratio of filter area to runner area must be at least 2:1. Often 5:1 to 10:1 is most desirable, particularly to maintain a desired fill rate for soundest cast structure
- To take full advantage of a vertical filter placement, the runner system should be flared (Fig. 92)
- Each square inch of filter area in a (typical) 20 ppi ceramic foam filter is capable of passing (roughly) 2 kg (5 lb) of total metal throughput. Consequently, a 45 kg (100 lb) casting fed with a single gate would require at least a 100 × 100 mm (4 × 4 in.) filter or possibly larger. Of course, multiple gates are often employed in larger castings. Each gate would have its own filter in the runner system ahead of each gate
- Some increase in metal temperature (between 6 and 28 °C, or 10 and 50 °F) is usually necessary to accommodate the temperature drop in the system caused by the filter absorbing heat energy and/or the drop associated with restricted flow
- Flow rate, and thus fill time, is also a function of the metallostatic head (sprue height). Sprue height can often be increased to offset the flow rate restriction caused by a filter

Benefits of Filtration

The presence of any dross, inclusions, or nonmetallic impurities, as well as insoluble intermetallic precipitates, detracts from the natural fluidity of any nonferrous alloy melt. As shown in Fig. 94, filtering of these impurities results in substantial improvement of fluidity (as much as 25%). Such fluidity is required to provide mold filling, especially in the casting of thin, intricate sections.

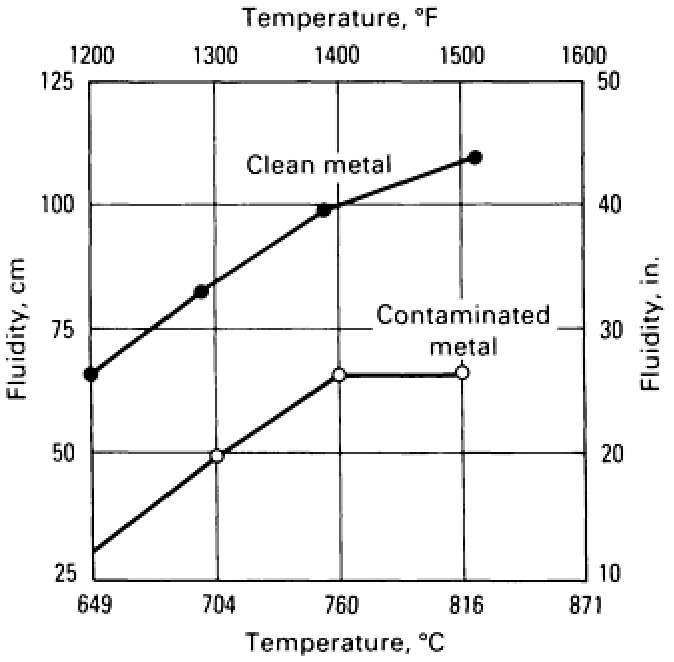

Fig. 94 Effect of metal cleanliness on fluidity of an aluminum die casting alloy. Source: Ref 151.

Removal of inclusions by filtration results in lower die wear, decreased tendency toward die soldering, and less scoring in permanent mold or die casting operations. Inclusions also cause hard spots in machining; therefore, filtration provides longer tool life and often permits faster metalworking.

For articles requiring smooth finish, superior corrosion resistance, and better appearance, filtration usually removes the vast majority of inclusions responsible for defects that detract from these characteristics. Inclusions can also nucleate hydrogen porosity, so their removal can result in reduced shrinkage, voids, and microporosity. As might be expected, the mechanical properties of filtered metal castings are usually superior to those of unfiltered metal castings, as detailed in Ref 151.

The greatest benefit of filtration to the operating foundry is the increase in production generated. Filtration reduces the number of defective castings that must be scrapped, and it reduces cleaning, rework, and repair. Reject rates on problem castings have been reduced substantially, virtually to zero in many cases (Ref 145, 151).

In the wrought aluminum casthouse and in subsequent shaping operations, filtration increases yields, reduces hot tears, reduces surface defects (inclusion lines, pinhole, and so on), and improves mechanical properties (Ref 152). Quality improvements and increased productivity are vital benefits achieved in the production of mill products.

Filtration of copper casting alloys is on the increase, using ceramic foam sections in the gating system. Oxide inclusions have been successfully removed from aluminum bronze alloys (Ref 153). Investment castings, both aluminum and copper base, can be successfully filtered using a filter section in the pouring cup or, in the case of larger castings, molded directly into the wax runner bars. Ceramic filters for copper alloys are usually alumina, mullite, or zirconia. Filtration of zinc alloys (foundry ingot, die casting alloys, and sand casting alloys) is not yet as prevalent as filtering of aluminum, but the use of filters has resulted in reduced concentration of intermetallic particles, improved impact resistance, and slightly improved mechanical properties (Ref 139).

Determining Melt Cleanliness

The determination of general melt cleanliness (that is, characterization of inclusion content) is attempted using various techniques. All of these methods have disadvantages, and no single technique has yet been established as the standard throughout the industry.

By far the most common, and certainly one of the most laborious, techniques is conventional metallography and optical microscopy. A polished section of a solidified sample from the melt is examined for inclusions in this manner. Inclusion particulate may be further characterized and identified, if not fully quantified, by x-ray or electron diffraction, microprobe, or other spectrographic analyses.

Analytical techniques such as dissolution and the Coulter Counter analysis of individual particles have been attempted in several instances and may be reasonably accurate with respect to particle size and particle size distribution. However, this method is very tedious, and the nonmetallic particles themselves often become dissolved along with the aluminum matrix, thus rendering the quantified particle and particle size distribution count inaccurate.

Ultrasonic methods have been used by several mill products producers to determine inclusion counts *in situ* in the melt during a casting run (Ref 154). The technique also permits the evaluation and comparison of various metal cleaning parameters, such as holding time, fluxing times, and filtration. The largely proprietary instrumentation for this technique is relatively sophisticated and expensive; therefore, this method is beyond the reach of all but the largest melting and casting installations.

Another technique used is the liquid inclusion sampler described in Ref 155. In this method, inclusions from the melt are concentrated by passing the liquid stream through a precisely controlled porous carbon or ceramic disk. The aluminum-impregnated disk is then solidified and prepared metallographically for examination using typical optical microscopy. The concentration of inclusions from the melt into this relatively small and fine porous disk provides easier analysis and permits quantifiable image analysis techniques to be used. Recently, back-scatter x-ray reflection has been successfully applied (Ref 156). Various samples can be compared and indexed from melt to melt, or differences in cleanliness can be identified as a function of degree of filtration or other metal cleaning processes employed.

Automatic Pouring Systems

Jack Thielke, ASEA Brown Boveri, Inc.

Introduction

AUTOMATIC POURING EQUIPMENT includes a wide range of mechanized pouring methods and specialized equipment designed for automatic pouring. Traditional metal transfer from the molten metal supply to the mold is done with open-top ladles ranging from hand held to multi-ton, crane-supported, mechanized tilt ladles. Underpouring from a ladle, either through the incorporation of a teapot spout or bottom stopper rod and nozzle, reduces slag inclusions in castings (Fig. 1). The first semiautomatic pouring units used controlled stopper rods in bottom-pour ladles mounted above indexing molding lines to pour into molds indexed into position beneath the ladles (Fig. 2).

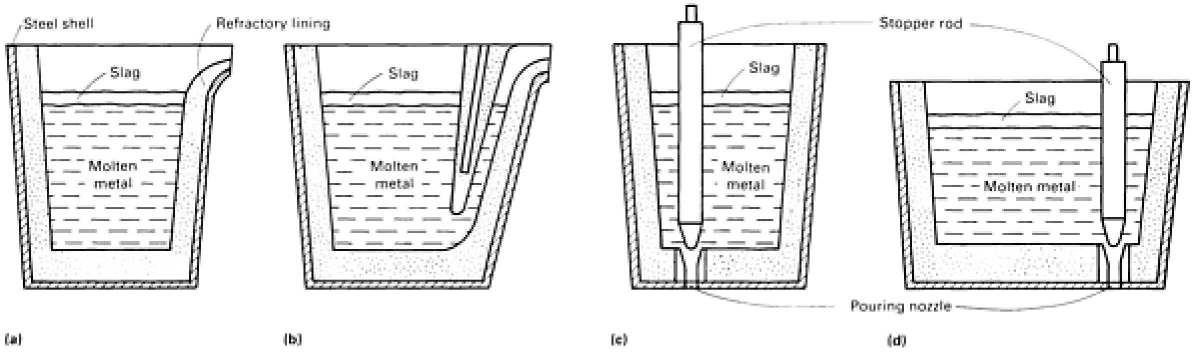

Fig. 1 Four types of pouring ladles. (a) Open lip-pour ladle. (b) Teapot ladle. (c) and (d) Bottom-pour ladles

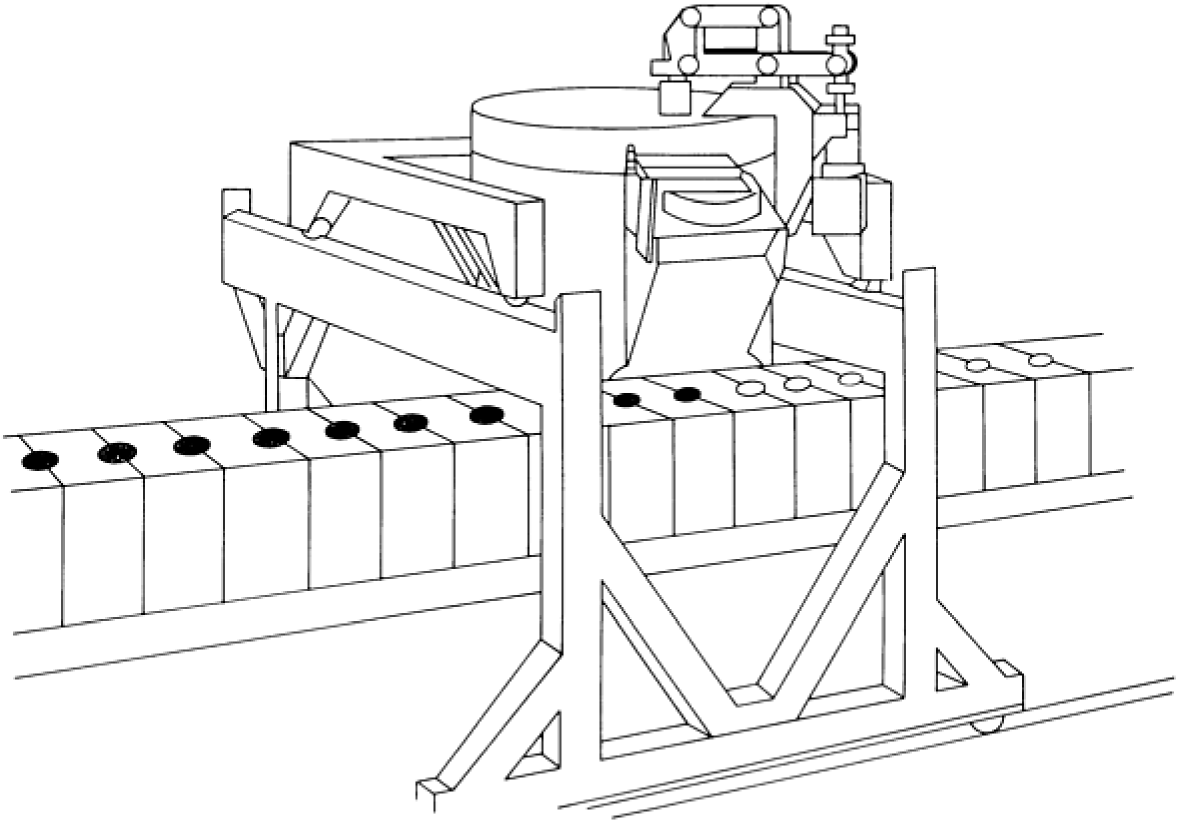

Fig. 2 Stopper rod pouring into flaskless molds on an indexing pouring line

Because the logical application of automatic pouring is in conjunction with automatic molding equipment in foundry applications, the synchronization of controls, interlocking, and safety devices must be considered in the control system. The *x*- and *y*-axis positioning of the pour stream with respect to the pouring basin must be adjustable to compensate for variations in mold production.

Benefits of Automatic Pouring Systems

The benefits of automatic pouring soon became evident and directed the development of the various equipment types currently available. The benefits fall into six categories:

- Increased productivity
- Increased yield
- Reduced scrap costs
- Improved quality control
- Improved process control
- Improved working conditions

Increased Productivity. Automated pouring systems do not necessarily reduce the manpower requirements in all applications, but they do increase the productivity of the personnel involved in the pouring operation. The productivity improvement is related to the consistency of pours from one mold to the next. Manual pouring is subject to inconsistent results due to variations in the workers' performance on repetitive tasks and the learning curves associated with changes in patterns. Modern automatic pouring systems pour faster and more efficiently than any manual system. The consistent control of pour rates and metal levels within the mold during automatic pouring allows operational and design savings that result in increased operational efficiency.

Increased Yield. The most significant benefit of automatic pouring is the increase in yield due to the elimination of nonproductive metal pouring. Nonproductive pouring naturally includes overpours and spills, but also includes the typically larger size of the pour basin and the resultant increase in sprue weight required for manual pouring. The pigging of manual pouring ladle heels is also eliminated. Consistent, controllable pour rates may allow for the design of less complex gating and riser systems as well as for simultaneous multiple-pour streams in the same mold.

Reduced Scrap Costs. The reduction of scrap and the associated costs directly related to the incorporation of automatic pouring include the reduction of slag inclusions in castings and the reduction of pouring failures. Pouring failures include underpours, interrupted pours, and casting defects due to irregular pour rates.

Improved Quality Control. Casting quality is improved in automated systems because of the previously mentioned benefits as well as the benefits of better temperature control within the pouring vessel and more consistent metallurgy. Both of these benefits are due in part to the buffer effect of the volume of the pouring ladle and in part to a more continuous pouring operation. Alloy and inoculant additions can be automatically fed into the pouring ladle or metal pour stream.

Improved Process Control. The improvements in process control include the benefits that occur before, during, and after the pouring process. Melt system pouring temperatures can sometimes be reduced when automatic pouring equipment is used because of the reduction in temperature losses before pouring. Even slight reductions in melt temperatures can result in significant energy and refractory cost savings. Frequent pattern changes are made more effective with automatic pouring systems. Microprocessor-based process control systems can provide both production and inventory information for defect identification and tracking, as well as statistical data on molten metal and casting production.

Improved Working Conditions. Benefits relating to improved working conditions fall into three areas: health and safety, environmental, and operational. The health and safety benefits include the isolation of the operator and the metal pouring. This protects the operator from the effects of metal spatter, gases, and smoke. Such protection is particularly

important when pouring lead-bearing alloys. Environmental benefits include those mentioned above as well as the natural concentration of areas requiring fume collection. Operational benefits include more variability in worker tasks as well as isolation from the pouring area.

Methods of Automatic Pouring

There are two basic methods of automatic pouring: mechanized ladle pouring and direct pouring. Automated mechanized ladles are used to transfer measured amounts of metal from a storage vessel or a controlled pouring unit to the mold. Automated dip and pour mechanized ladles and robotic ladles are used for aluminum and other nonferrous pouring. Mechanized ladles and pouring robots are programmed to duplicate pouring sequences. The use of a mechanized ladle allows for in-ladle alloying and inoculation before pouring. Dripping of molten metal onto the mold is eliminated when a mechanized ladle is used in combination with a stopper rod and nozzle pouring unit. This is very important when pouring lost foam molds. Ladle tilting about an axis in line with the pouring lip can reduce molten metal stream travel during pouring. Mechanized ladles generally have capacities matched to single mold requirements and include load cell weighing systems and controlled tilt rates (Fig. 3).

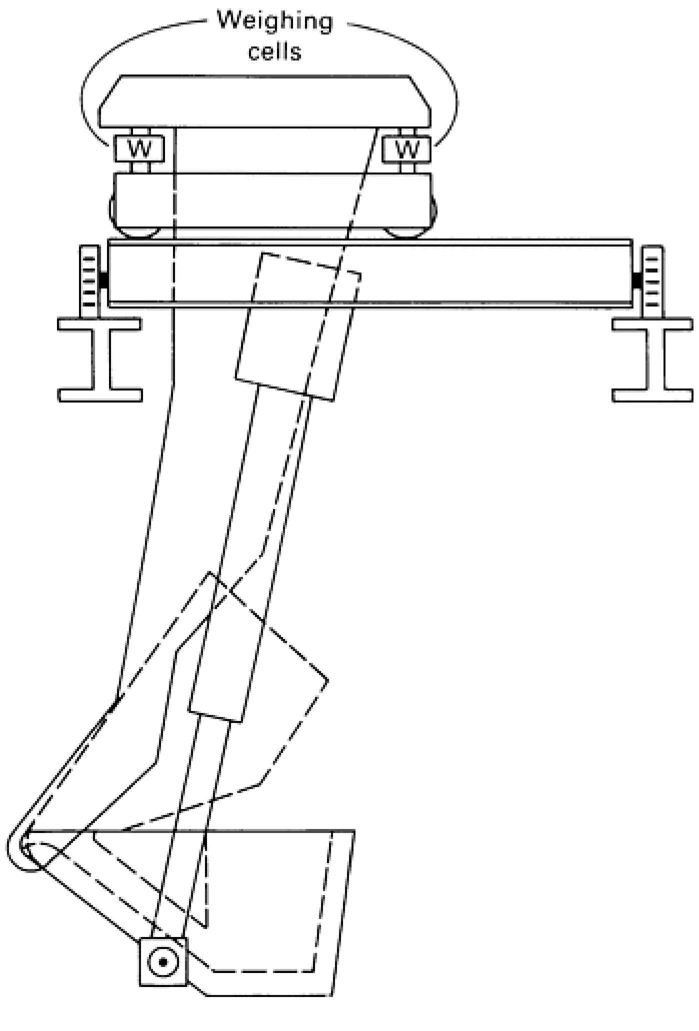

Fig. 3 Schematic showing the operation of a mechanized pouring ladle

In the case of direct pouring, metal is metered directly into the mold from the pouring vessel with the appropriate controls to ensure the desired results. The capacities of mechanized pouring ladles are based on anticipated metal requirements. The dispensing of a metal stream from a ladle at a specific point requires that the nozzle or pouring lip not move, relative to the mold, during pouring (Fig. 4).

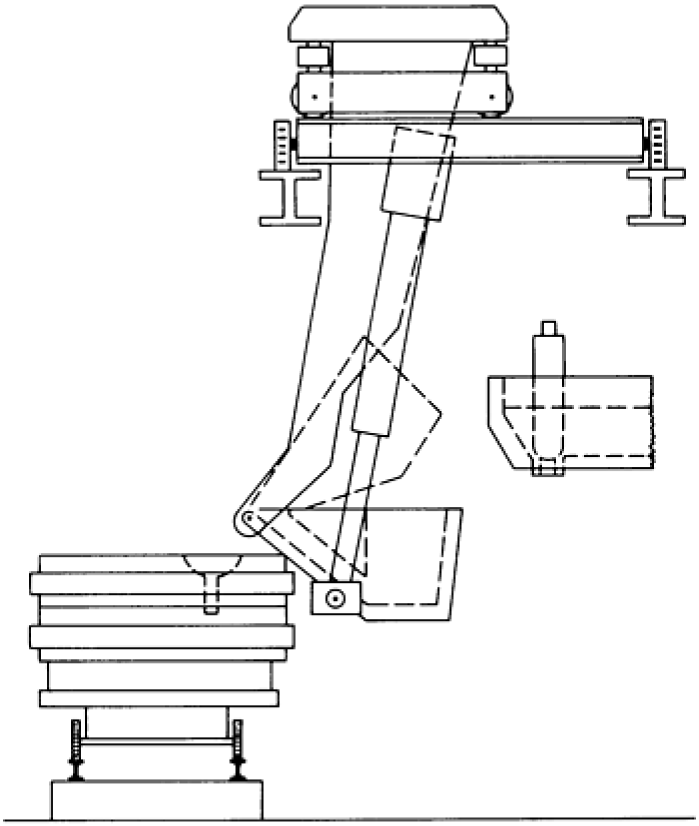

Fig. 4 Schematic of automatic mechanized pouring system

One method of synchronized pouring on a continuously moving mold line may require the use of a pouring vessel to measure predetermined weights of metal and either one or two (depending on line speed) mechanized pouring ladles. Each of the mechanized pouring ladles must be capable of *x*- and *y*-axis travel and synchronization with the pouring line (Fig. 5).

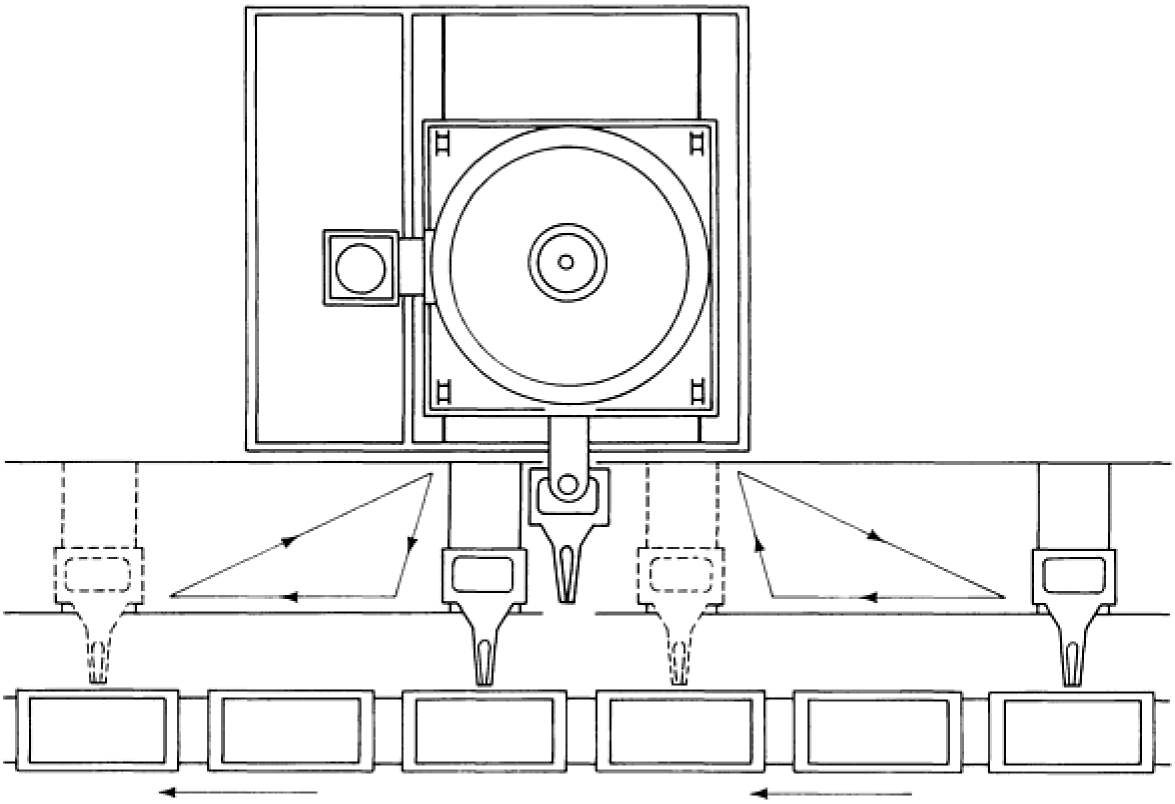

Fig. 5 Synchronized pouring on a continuously moving line

Direct bottom-pour ladles use either slide gates or stopper rods and nozzles to control and stop the flow of metal to the mold. Slide gates and nozzles are most commonly used to control flow rates on bottom-pour ladles for continuous and semicontinuous strand casting operations (see the article "Continuous Casting" in this Volume). Slide gates offer more reliable shutoff than stopper rod valves (Fig. 6); however, service life of the slide gate can be shorter than that of the stopper rod. Stopper rods and nozzles offer more control of pour rates than slide gate valves and are less expensive. For these reasons, bottom-mounted stopper rods and nozzles are more common in foundry pouring operations.

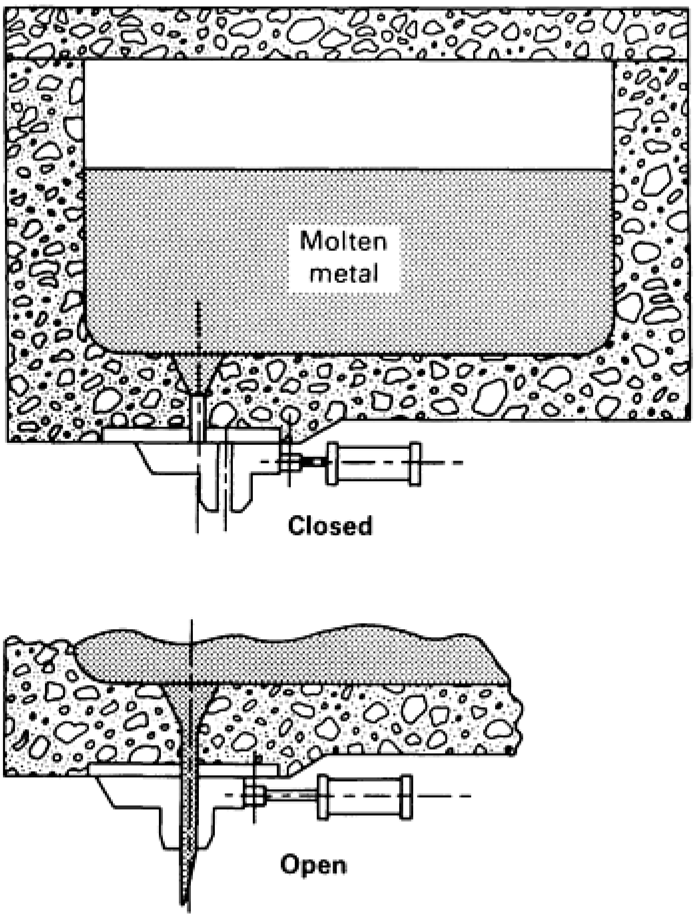

Fig. 6 Schematic of a slide gate pouring system

Electric Heating of Pouring Vessels

The metal temperature can be controlled, the heat losses of a pouring vessel replaced and the capacity of the vessel increased with the addition of electric heating devices. The holding of molten metal during extended pouring interruptions is possible because of the replacement of heat losses that would reduce the metal temperature. Metal chemistry is more consistent in large capacity pouring vessels, and other improvements in melting and pouring process control are obtained. Electric heating methods will be discussed below.

Electric Resistance Heating. Heat is produced by passing an electric current through a resistance heating element. The heating element may be in the form of a coil surrounding a crucible or in the form of a radiating element or glow bar positioned over the molten metal. In either case, the heat produced replaces heat loss within the vessel, thus maintaining molten metal temperature.

Electric Induction Heating. Heat is produced through the generation of electric currents within the molten metal. Magnetic induction generates electric currents directly into the molten metal, and these induced currents produce heat by passing through the resistance of the molten metal. There are two methods of applying this principle: channel induction and coreless induction.

Channel Induction. A channel or loop of molten metal is passed through a magnetic core that is very similar to a transformer core. The induction coil acts as the transformer primary, and the molten metal acts as the transformer secondary. Magnetic forces acting on the metal in the channel cause molten metal circulation through the loop.

Coreless Induction. An induction coil surrounds the crucible containing the molten metal and induces circulatory currents into the molten bath. Magnetic forces acting on the metal in the crucible cause metal circulation within the

crucible. The electric induction heating of a pouring vessel provides metal stirring to reduce alloy segregation and the capability of superheating the metal to a temperature higher than the initial charging temperature before pouring.

Electrically Heated Pouring Furnaces

Radiant element, electric resistance heated pouring furnaces are used in both nonferrous and ferrous pouring applications (see the articles in the Sections "Ferrous Casting Alloys" and "Nonferrous Casting Alloys" in this Volume). For nonferrous, low-temperature applications, metal or silicon carbide heating elements are used. For ferrous high-temperature applications, graphite rod heating elements are used (Fig. 7). Radiant-heated furnaces are typically bottom-pour units with stopper rods and nozzles mounted in the furnace bottom or in a detachable pour box. The furnace can be tilted to drain the pour box and to contain the molten metal beneath the radiant heat source.

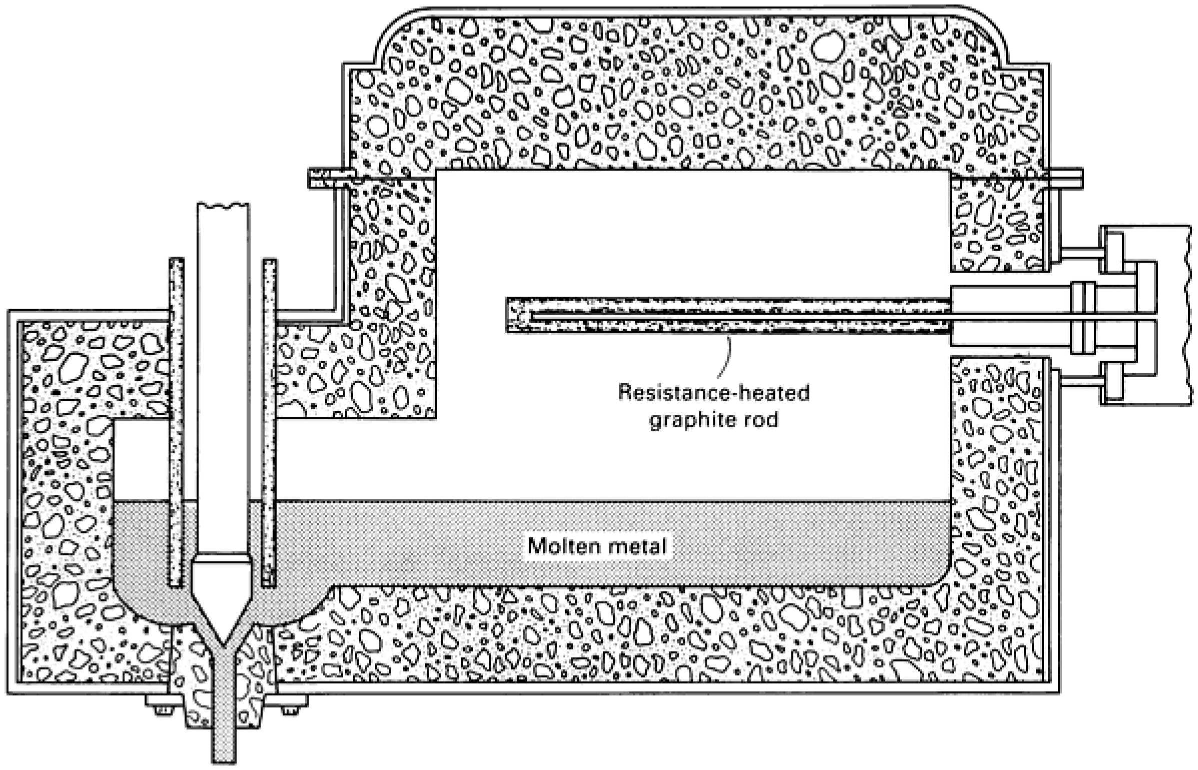

Fig. 7 Pouring furnace heated by resistance-heated graphite rods

Crucible-type electric resistance heated and coreless induction-heated furnaces are most commonly used in nonferrous pouring applications. These applications vary from the simple dip and pour mechanized ladle systems to the underpour stream discharge, axial-pour, and trunion-pour furnaces (Fig. 8). Underpour stream discharge in aluminum pouring for continuous and semicontinuous casting processes uses the oxide skin on the metal surface to protect the metal stream from further oxidation while transferring metal from the melting furnace to the automatic pouring ladle.

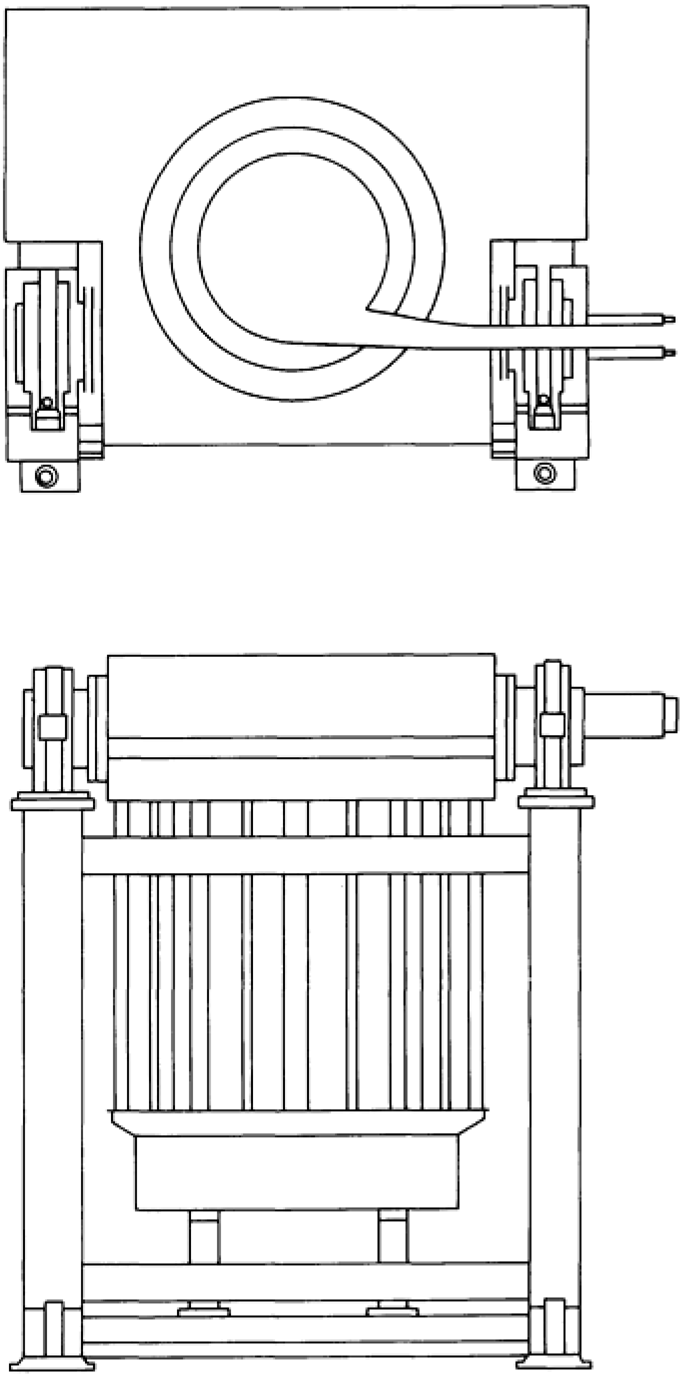

Fig. 8 Schematic of a trunion pouring furnace

Channel-type electric induction heated pouring furnaces are sealed and designed to use gas pressure to discharge metal from the furnace vessel. Pouring can be accomplished over the lip of a pour spout or through a nozzle, with or without a stopper rod, in a pour box mounted on the furnace vessel. Vessel gas pressure can be varied to control the rate of pouring or to control the level of metal over the pouring nozzle (Fig. 9). Control of the level of metal in the pour box establishes a constant static head pressure above the nozzle and ensures consistent pour rates. Venting of the pressure in the vessel causes the metal in the pour box to drain back into the furnace. Inert gas can be used as the pressure medium in applications where the metal is particularly susceptible to oxidation.

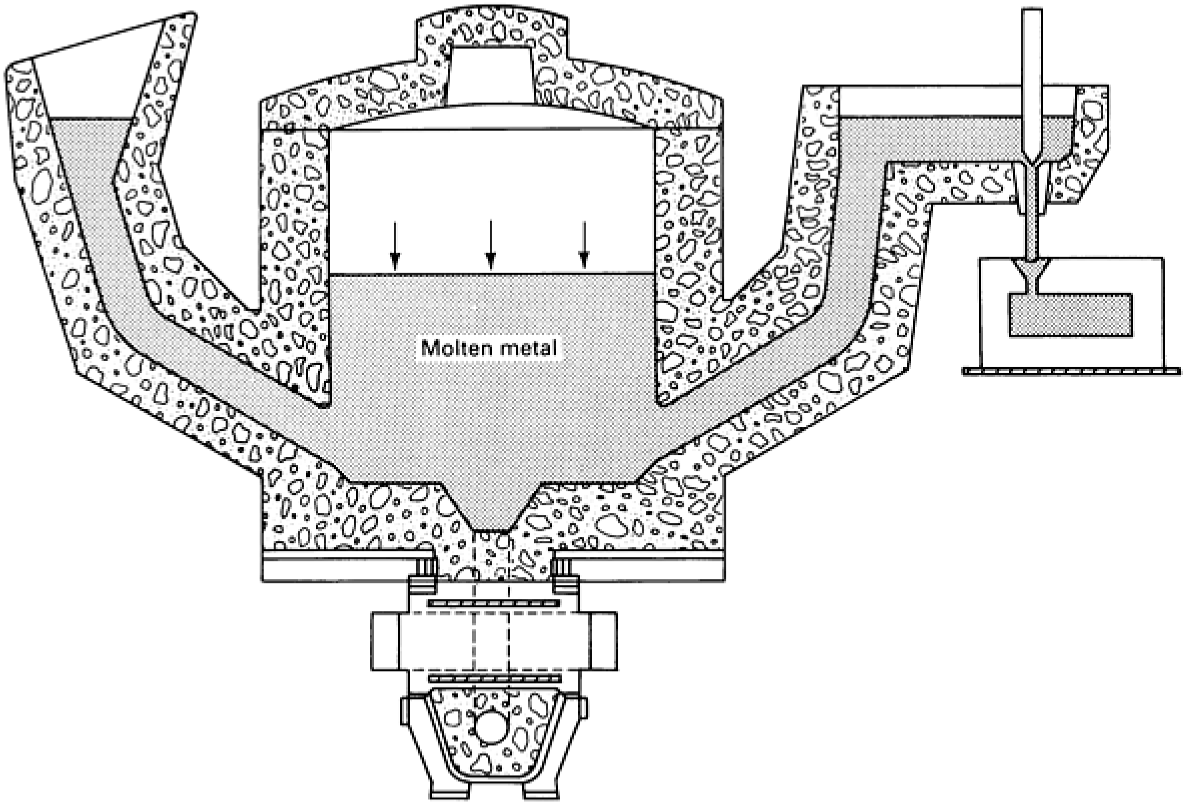

Fig. 9 Schematic of pressurized pouring furnace

Pouring Control Parameters

In the final analysis, there are only two variables in pouring: rate and duration. The optimum pour rate is the maximum rate at which a mold will accept metal, and the optimum duration is the time from the start of the pour until the mold will no longer accept metal. Other important considerations in automatic pouring systems include the relative positioning of the mold and pour spout or nozzle and the sequencing of the pour.

In manual pouring, the worker compensates for variables in the mold, ladle, and metal while pouring to produce the best results for each pour. Duplication of this effort is the challenge of automatic pouring.

Control Schemes

Satisfactory pouring results can be obtained in some automatic pouring applications without complex electronic control systems. Some requirements can be met by establishing a flow rate and simply timing the pour. A slightly more complex system includes dual pour rates and pour times. Simple infrared photosensors designed to detect the presence of molten metal can be used to end the pour cycle.

If the exact weight of metal required for a mold is known and a mechanized ladle is weighed while filling, at least one variable is under control. If the movements of the operator controlling the pouring of a mechanized ladle are measured and then stored in a programmable controller, these movements and the results can be duplicated under automatic control. The programming of a controller by duplication of remote control is referred to as a teach-in system. The program is referred to as the pouring profile.

Weighing of a bottom-pour ladle and pouring by weight can also be effective in some cases, although the relatively small capacity of the ladle results in substantial variations in metal head pressure above the stopper and subsequent variations in pour rate. Increasing the capacity of the pouring vessel, facilitated by electric heating, reduces the variation in head pressure. The incorporation of a process control system to compensate for reduced head pressure through stopper positioning by feedback of weight, anticipated weight, or actual bath height is effective in some cases.

If the rate of metal flow through a nozzle is constant for a constant head pressure, the repeated variations in the position of a stopper rod above the nozzle will yield repeatable and controlled pouring rates. A teach-in system is used to program the pouring profile.

If slag buildup on the nozzle and variations in metal head pressure cause flow variations, the system pouring profile program must be corrected by a process control feedback loop. Feedback can be provided by a timing and metal presence sensing system that checks the rate of mold fill or by a more sophisticated control system for mold level measurement.

Mold level measurement and control systems fall into two categories: laser systems and vision systems. Both of these electronic process control systems monitor the level of metal in the pour cup and control the position of the stopper rod to maintain a nearly constant level throughout the pour. This type of feedback system most closely duplicates the efforts of a skilled operator.

The laser reflection angular detection system (Fig. 10) determines the position of a low-power laser beam reflected from the surface of the molten metal in the pouring basin. The laser beam is directed at the pouring basin from an angle. The distance to the molten metal level will affect the incident and reflected angle and therefore the position of the beam on a sensing unit. The comparative value of the beam position on the sensor is used to control the position of the stopper rod; thus, the level of the metal in the pouring basin is controlled.

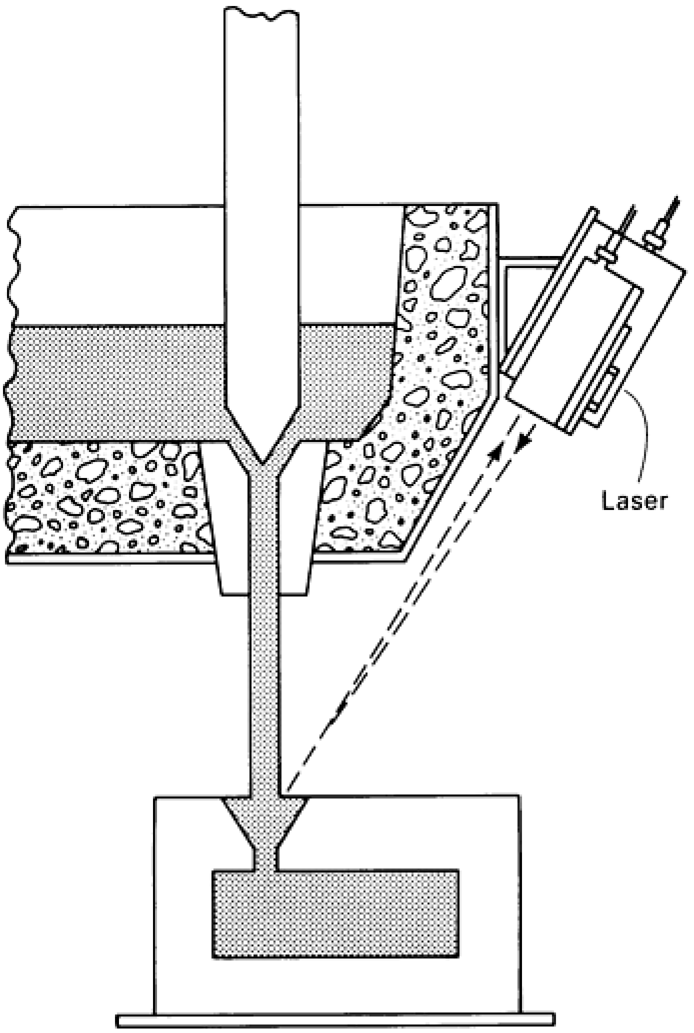

Fig. 10 Schematic showing laser pouring control. See text for details.

A vision system uses a video camera to observe the pouring process (Fig. 11). The video signal is displayed on a monitor for the operator and processed electronically in a manner that separates the brightness levels of the molten metal from the other portions of the picture. The molten metal stream is electronically blanked from the composite picture of the metal in

the pouring basin and the area of metal fill compared to the actual area of the pouring basin. The comparative value is used to control the position of the stopper rod, and the level of the metal in the pouring basin is controlled.

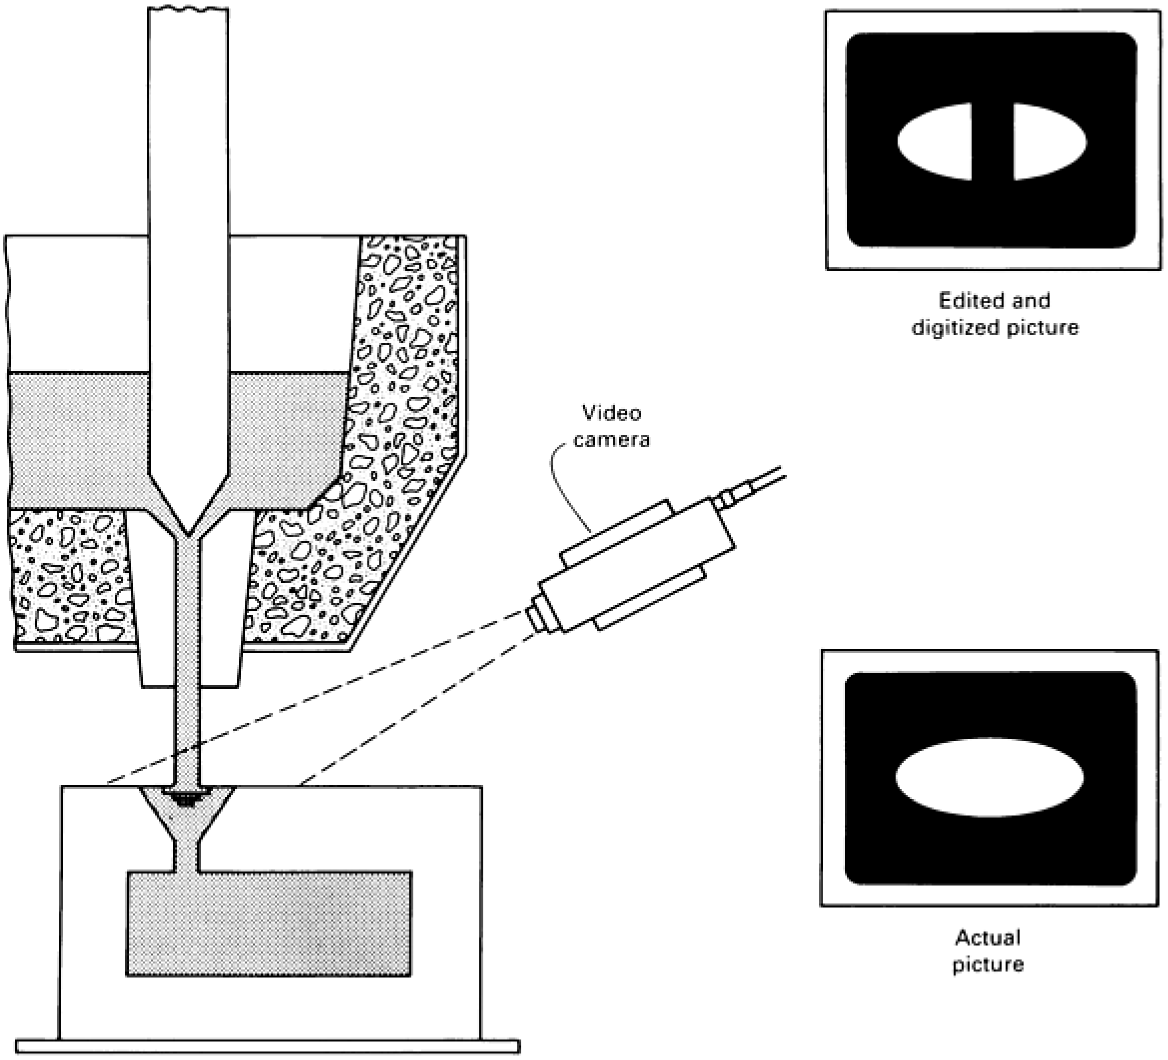

Fig. 11 Schematic of vision-controlled pouring. See text for details.

The most sophisticated pouring systems may incorporate more than one set of controls. The use of integrated control schemes allows the system backup, improved safety, and increased flexibility that are required for pouring a variety of castings. For example, the benefits of mold level measurement and control are enhanced when used in combination with a teach-in duplicated pouring profile in some pouring applications.

Shakeout and Core Knockout

Gene J. Maurer, Jr., United States Industries

Introduction

THE SHAKEOUT OPERATION, that is, the separation of the casting from the mold and core sand, is the first step to finishing a casting after it has solidified and cooled in the mold. Figure 1 shows the position the shakeout operation holds in a typical foundry flow chart. A considerable amount of energy is required to remove the adhering layer of sand and

oxide (that formed under the effect of heat from the metal which was poured into the mold) and also to separate the casting from lumps of sand still strong bonded together.

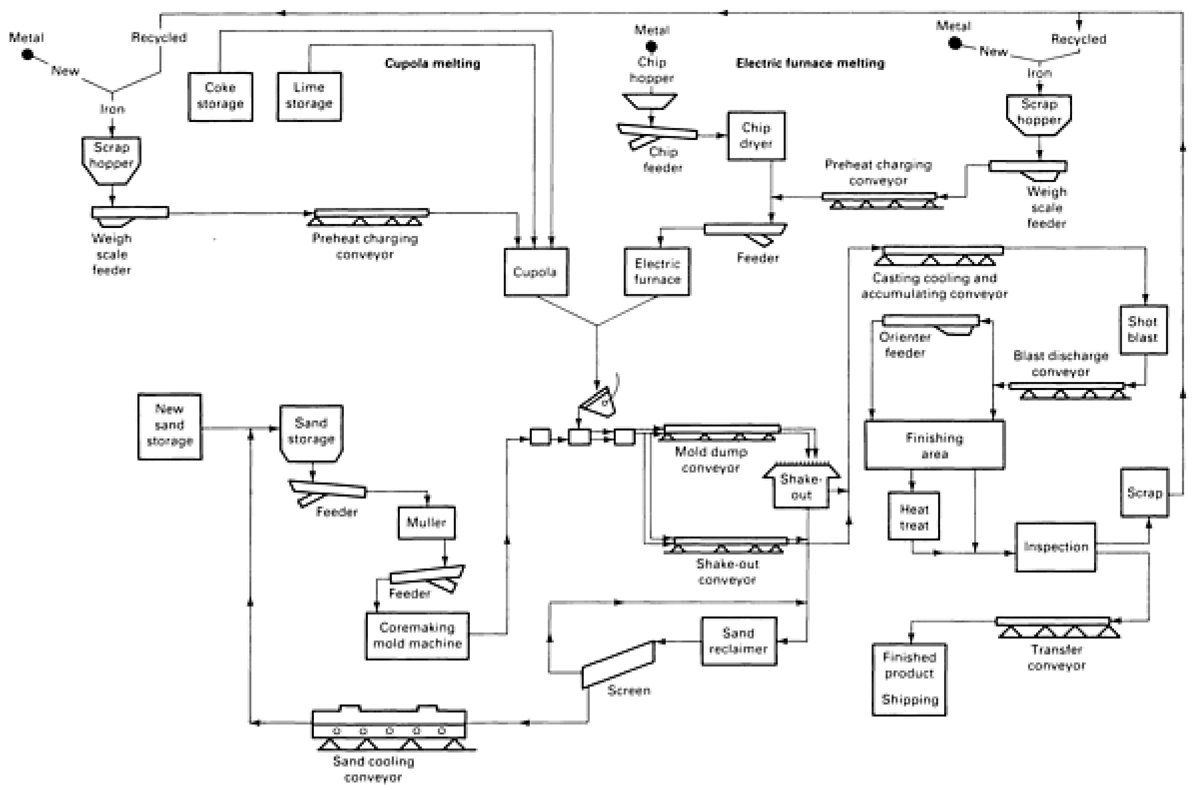

Fig. 1 Typical foundry flow chart

Regardless of the metal poured, castings must solidify before shakeout can begin. Some castings will crack if shaken out too soon. Others require a controlled cooling rate to attain a specific microstructure. In establishing the time for shakeout, consideration must be given to the metal, pouring temperature, casting size and design, coring, and sand mixture used.

The energy needed to separate the casting from the mold may be supplied by a shaker pan conveyor, vibrating deck or grate, or any other type of vibratory, oscillating, or rotational mechanical action (Fig. 2). For small castings, the vibratory shakeout action may be combined with a means of conveying the casting to the location at which the next operation is performed.

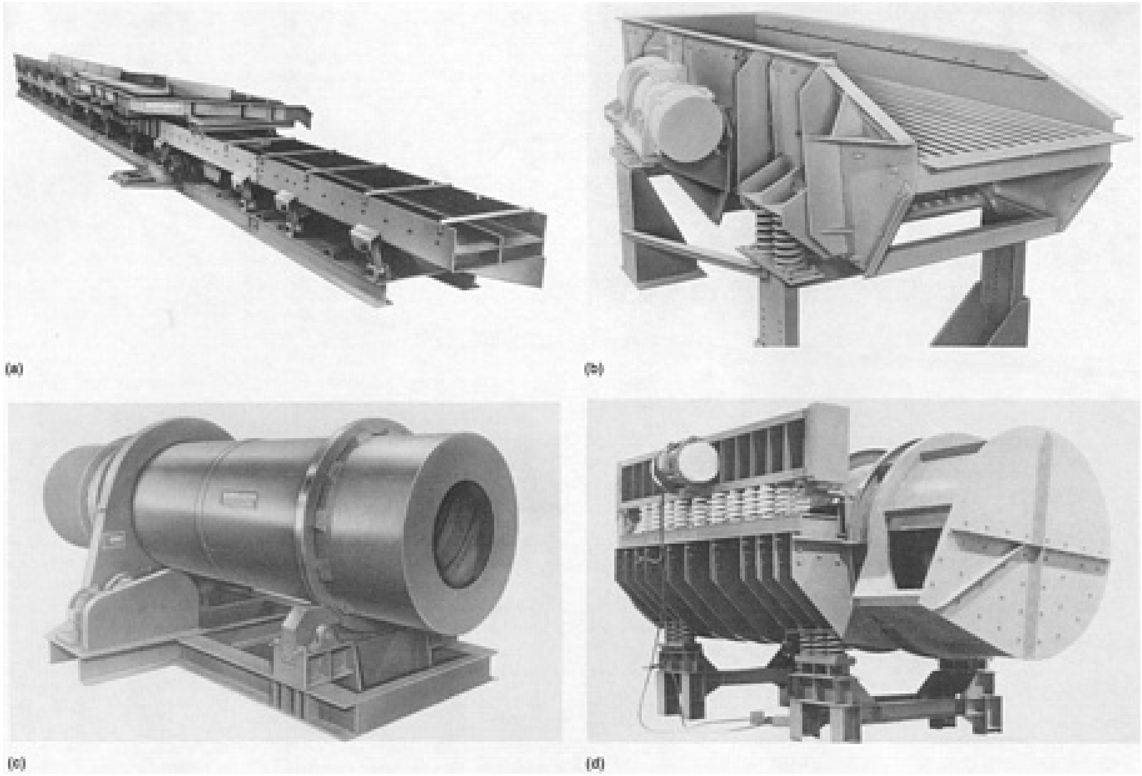

Fig. 2 Examples of various types of shakeout equipment. (a) Vibrating conveyor. (b) High-frequency shakeout table. (c) Rotary shakeout device. (d) Vibrating drum. Photographs (a), (b), and (c) courtesy of Simplicity Engineering, Inc. Photograph (d) courtesy of General Kinematics Corporation

Vibrating conveyors all use some periodic motion of a trough to produce conveying action. Their use has grown for shakeouts and feeders, and even in scrap preheating systems.

In general, the conveyor consists of a pan or trough driven by a vibrating force. The motion of the pan can be linear, circular, elliptical, or helical. The stroke, frequency, and motion pattern are selected to meet specific requirements, from the high-intensity near-vertical action of a shakeout conveyor to the shuffle action of a transfer-type feeder conveyor.

Direction of flow can be horizontal, up an incline, down a decline, around right-angle turns, or in a complete circle. Vibrating equipment is either a single vibrating mass or multiple vibrating masses, with either brute-force or natural-frequency drives. In a brute force driven system, vibrations are generated continuously and directly by the drive, which is usually electric-motor powered. Outboard rotating weights attached to a concentric shaft produce out-of-balance centrifugal forces required to vibrate the shakeout or conveyor.

Natural- or resonant-frequency systems use springs to amplify a relatively small drive force to create vibrations of large, heavy masses. The force-amplifying spring system can distribute vibrations along great conveyor lengths. The electric-motor power sources are relatively small compared to those of brute-force systems.

For feeder applications, vibrating conveyors that move with a straight-line quick-return motion are available. Castings can be transported without bouncing, and sand can be moved without dusting. More detailed information on the types of shakeout equipment available and their applicability can be found in the article "Sand Processing" in this Volume (see the discussion on shakeout). Information on shakeout practice for specific metals and alloys can be found in the Sections "Ferrous Casting Alloys" and "Nonferrous Casting Alloys" in this Volume.

With the exception of those castings poured from low melting point metals (aluminum or magnesium), the heat of the metal burns out the resin bond in the sand sufficiently for the mechanical action of the shakeout device to cause almost all of the sand to fall away from the casting. Sand remaining on the surfaces of the castings can be removed by abrasive blast cleaning, which is described in the following article, "Blast Cleaning of Castings," in this Volume.

Core Knockout

Core knockout, or decoring, is the process of removing internal resin-bonded sand cores from castings. Ferrous metal castings are poured at much higher temperatures (~1650 °C, or 3000 °F) than nonferrous castings. Consequently, more energy is required to remove core sand from aluminum castings than from gray iron castings. In gray iron, relatively low energy shaking, vibrating, tumbling, and/or shot blasting is used to force loose core sand out through the casting openings. Core sand in ferrous castings has much less strength because the ambient heat of the metal, as it solidifies in the mold, burns the resin-bonding agents out of the sand. When the resin is burned out, the grains of sand cannot attach to one another, making high-production cleaning of ferrous castings less complex.

The major focus of this section will be the cleaning of aluminum castings, which are molded in a temperature range of 705 to 815 °C (1300 to 1500 °F), approximately one-half the temperature required to cast ferrous metals. This comparatively low molding temperature does not allow sufficient heat to transfer from the casting walls to the resin-bonded core sand. Only the cored passageway closest to the metal will show heat penetration and breakdown.

Types of Core Knockout Equipment

Casting complexity, type of resin, type of sand, wall thickness, type of core (solid or hollow), metal to sand ratio, and gating/risering all affect the amount of energy required to remove the sand core from the casting. The most common method used to clean core sand from aluminum castings is mechanical vibration, which is best described as an air tool driving a piston that impacts a chisel. The chisel transmits energy into the risering or gating of the casting. The shock waves move through the metal, creating a momentum that causes the resin-bonded sand to break down. In most instances, the core sand has less inherent strength than does the metal; therefore it breaks down prior to metal fatigue or fracture.

Many foundries use hand-held, vertical, A-frame, or fixtured air tools that operate in the 1000-to-3000-blows-per-minute range. Each type of casting and each core sand is unique. For optimal cleaning, the proper type of vibration and/or blows per minute must be suited for each application. This is not easily determined, however, and because foundrymen normally operate with only one or two settings for all their castings, cracked castings or excessive air tool component failure may result.

The hand-held air tool method of decoring castings involves an operator placing a casting on the floor or on a table and locating the chisel of the air tool on the risering. When the operator pulls the trigger on the tool to allow air to pass through and create vibration, the casting shakes, and core sand breaks down.

The advantages of hand-held air tools include:

- Low cost
- Flexibility (can be used on many different castings)
- Effectiveness for low-volume cleaning applications

The disadvantages are:

- Noise (100 to 120 dB); hearing protection required for personnel
- Vibration, which affects operator's hand, arm, and body
- Required maintenance of air tool
- At times, insufficient energy to clean casting
- Operator required to hold air tool
- Creation of silica dust, which affects operator
- Insufficient speed for high production

The vertical core knockout machine (Fig. 3) involves the use of a specially made air tool that strokes down to clamp the casting for holding and simultaneously vibrates the casting to break down the core sand. When the operator sees that the internal passages are cleared, the foot switch is depressed to stop the vibration and the air tool is retracted from the casting. These tools are commonly referred to as C-frame models because the supporting structure resembles the

letter C. This cleaning method uses the vibration-under-compression theory, which is generally applicable for all castings, yet is somewhat slow.

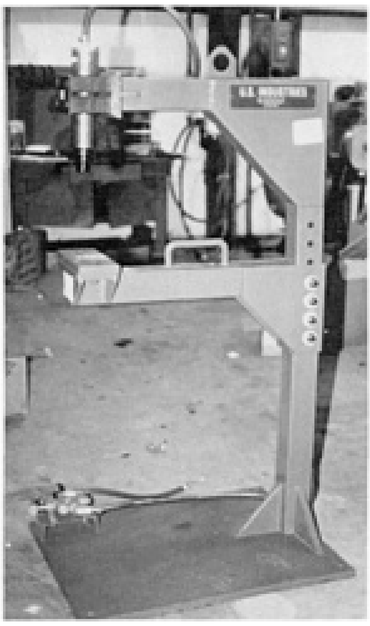

Fig. 3 Vertical core knockout machine. Courtesy of United States Industries

The advantages of vertical core knockout tools include:

- Low cost
- Flexibility (can be effectively used on castings from 2 to 15 kg, or 5 to 35 lb)
- No adverse effect on operator's hands, arms, or body
- Several machines can be run by one operator
- Applicability to low-volume production
- Relatively small amount of floor space required
- Portability
- Easily adjustable frequency and amplitude

The disadvantages are:

- Noise (100 to 120 dB)
- Required maintenance of air tool parts
- Lower effectiveness on larger castings
- Insufficient speed for high production
- At times, inappropriate for a cleaning method
- Creation of silica dust

The A-frame core knockout machine involves the use of a cast iron clamp/vibrating head and cast iron clamping head mounted on a common shaft and A-frame leg stands and controls (Fig. 4). The cast iron heads are supported by the common mounting shaft and face one another. The left side contains a clamping and vibrating tool, and the right side contains a bumper or an air cushion device to soften the vibration and energy transmission.

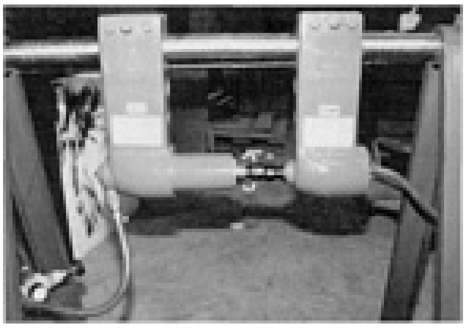

Fig. 4 A-frame core knockout machine. See also Fig. 6(b). Courtesy of United States Industries

To operate the A-frame core knockout machine, an operator positions the casting between the clamp heads and depresses a foot switch to simultaneously hold and vibrate the casting to break down the core sand. This method allows the operator to rotate and probe the casting to reduce cleaning cycle time. When the core sand has been removed, the operator depresses the foot switch to stop vibration and unclamp the casting. The A-frame machines use vibration under compression, which is generally suitable for all types of castings. On this machine, both the clamping pressure and the vibrating pressure are independently adjustable so the vibration can be adapted to suit the casting.

The advantages of A-frame machines include:

- Moderate price
- Flexibility (can be used on both large and small castings, that is, from 2 to 45 kg, or 5 to 100 lb)
- No harmful effect on operator's body
- Several machines can be run by one operator
- Applicability to low- and high-volume production
- Rugged construction to withstand abusive foundry practices
- About 2.5 m^2 (25 ft^2) of floor space required

The disadvantages are:

- Noise (100 to 120 dB)
- Multiple-unit facilities generate sound waves that can have harmful effects on internal organs
- In medium- to high-production plants, excessive maintenance is required
- High replacement part inventory is necessary
- Castings must be transported to and from special acoustical rooms
- Insufficient speed for high production
- Ineffectiveness on thin-walled heavily cored castings
- Creation of silica dust

The multiple-station air tool fixture involves the use of air tools mounted on a supporting structure with holding and locating blocks to position castings. These fixtures are dedicated to the core knockout of a specific casting. These devices either operate by means of vibration under compression, whereby the casting is clamped and vibrated, or they have a 6 to 10 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) gap surrounding the casting, which undergoes vibration. As the casting is impacted, it moves violently within this tight space. This allows more energy to penetrate the casting from many different directions. The major problem with this method is that loading and unloading of the casting can be difficult because of the varying sizes of risers.

The retractable tools employing vibration under compression allow easy loading/unloading and maintenance, yet can reduce cleaning effectiveness. With dedicated fixtures, multiple air tools can be used on a single casting, thus inducing greater amounts of energy to those areas that require it most. Multiple-station fixtures are normally built to clean two (Fig. 5a), three (Fig. 5b), or four castings (Fig. 5c) simultaneously. These core knockout fixtures must be isolated from their support structures by vibration-proof mounts.

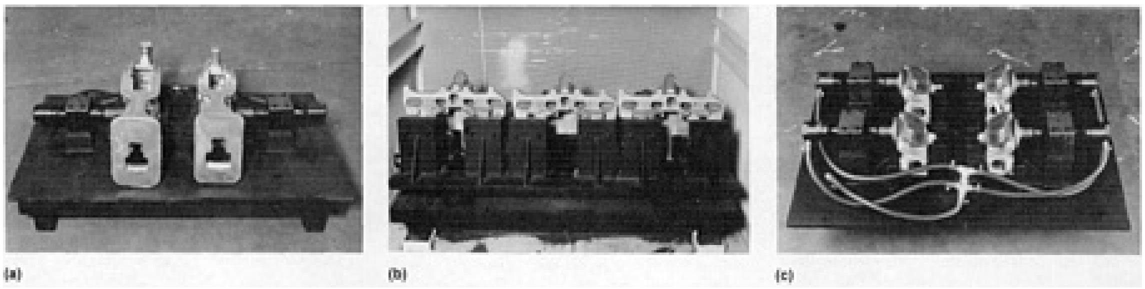

Fig. 5 Multiple-section air tool fixtures. (a) Two-station. (b) Three-station. (c) Four-station. Courtesy of United States Industries

Dedicated fixtures are most commonly used on high volume production applications, although certain low to medium production run castings may require dedicated tooling because of the complexity of the casting. These units generate extremely high noise levels; therefore, they are often housed in acoustical-control cabinets that are designed to be portable with interchangeable fixtures (Fig. 6).

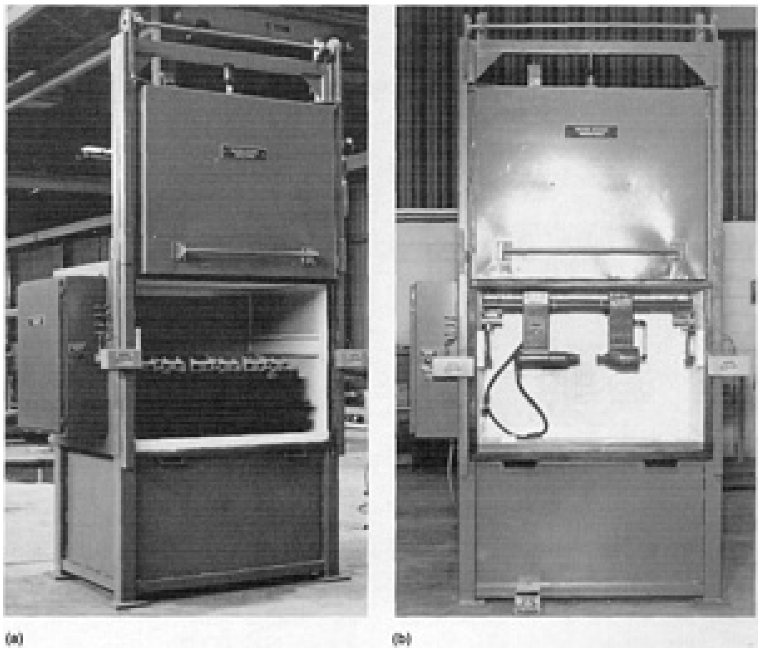

Fig. 6 Acoustical-control cabinets. (a) With three-station dedicated fixture. (b) With A-frame tooling. Courtesy of United States Industries

The advantages of acoustically enclosed, dedicated fixture units include:

- Low noise levels
- High production and lower per-casting cleaning cost
- Easier cleaning

- Timed cycle
- Interchangeable fixtures
- Sand containment
- Improved safety
- Portability
- Location possible near production line

The disadvantages are as follows:

- High initial capital expenditure
- Acoustical enclosures are a nonincome-producing expense
- Maintenance required for air tool components
- Few available suppliers
- Fixturing dedicated to specific castings (not universal)

New Developments in Core Knockout

Methods that are in the development stage for cleaning both ferrous and nonferrous castings are described below.

A high-frequency drive machine involves the use of two motors spinning weights in opposite directions to develop a rapid push-pull movement of a load table. The casting is hydraulically retained on the mounting table. The rapid back and forth movement causes a floating piston to move and contact a strike plate that transmits energy to the casting. This high-frequency drive device is said to develop between 5 and 32 *g* (~50 and 315 $m \cdot s^{-2}$, or 160 and 1030 $ft \cdot s^{-2}$) of force. The motors operate at between 2900 and 3600 rpm. The optimal amplitude or stroke is between 5 and 10 mm ($\frac{3}{16}$ and $\frac{3}{8}$ in.). These units have proved to be effective in cleaning some of the most difficult castings. However, they are very loud, and the hydraulic clamping devices have failed in production settings.

The advantages of high-frequency drive machines include:

- Speed
- Adjustability
- Interchangeable fixtures
- Timed cycle

The disadvantages are:

- High cost
- Self-destruction
- Dedicated construction
- Noise (110 to 130 dB)

The high-pressure water blast device incorporates the use of a gimbal-mounted spray gun positioned in a stainless steel enclosure with a high pressure pumping system. The successful operating pressures lie within a 17 to 105 MPa (2.5 to 15 ksi) range. A casting is located on a rotating, tiltable table, and the water is directed at the core material through the spray gun. The operator moves the casting to blast the water at the cored passageways. This system is effective in cleaning ceramic material from investment castings and complex sand-cored castings, and is also effective for removing burnt-in core sand from internal passages.

The advantages of a high-pressure water blast system include:

- Adjustable water pressure
- Water can be focused directly at core
- Safety
- Quiet operation
- Dedicated fixturing can be used

The disadvantages are:

- High cost
- Contaminated water disposal
- Low operating speed
- Maintenance required for nozzle and pump
- Unreliable water recirculation
- Expensive spare parts
- Possible inability to direct water at blind or oblique passageways

In the shot blast cleaning method, castings are hung on a tree and placed in an enclosure. Shot is spun off a wheel at the casting. This method is not very effective for cleaning aluminum castings because the energy is not sufficient to break down the cores and the cycle time is longer than with other methods. Also, mixing sand with spent shot can cause excessive wear to the reclamation system. Nevertheless, some foundrymen do use this process because of the availability of a shot blast machine and/or because the casting requires shot blasting.

With the core bake-out method, castings are loaded into baskets and placed into the ovens. The castings are heated to the temperature that will completely burn out the resin binders without affecting the metallurgical structure of the casting. Eventually the sand becomes loose enough to flow out of the castings when moved. This method is normally used when all other processes fail, but it is expensive and time consuming, and requires heat energy. The castings still hold the loose sand. Either the loose sand that does fall out has to be cleaned from the ovens or a sand reclamation unit must be added to the system.

A vibrating-media-type system involves submerging the castings in a media that is vibrated at a high frequency. These machines are expensive and slow and leave media in the casting. Such systems must also be fine tuned for each casting.

Blast Cleaning of Castings

James H. Carpenter, Pangborn Corporation

Introduction

Blast cleaning of castings is a process in which abrasive particles, usually steel shot or grit, are propelled at high velocity to impact the casting surface and thereby forcefully remove surface contaminants. The contaminants are usually adhering mold sand, burned-in sand, heat treat scale, and the like. For aluminum castings, the process is often used to provide a uniform cosmetic finish in addition to merely cleaning the workpiece. This is especially true of engine components such as heads and manifolds that are highly visible. In the case of cast aluminum wheels, die cast transmission cases, and so on, the process prevents leakage by healing surface porosity. Additionally, in some cases deburring and a pleasing cosmetic surface are obtained.

The usual methods of imparting high velocity to abrasive particles are by the use of either centrifugal wheels or compressed air nozzles. The performance characteristics of each of these components will be discussed later.

Centrifugal wheels are the most widely used method because of their ability to propel large volumes of abrasive efficiently. For example, a 56 kW (75 hp) centrifugal wheel can accelerate steel shot to 73 m/s (240 ft/s) at 55.8 Mg/h

(123,000 lb/h) flow. To do the same with 13 mm ($\frac{1}{2}$ in.) direct pressure venturi nozzles at 45 kg (100 lb)/min per nozzle would require approximately 20 nozzles and an air flow of 0.120 m^3/s/nozzle (260 ft^3/min/nozzle) × 20, or a total of 2.45 m^3/s (5200 ft^3/min) at 550 kPa (80 psi). Approximately 700 kW (940 hp) at the air compressor would be required to supply this amount of air, which gives a 700 kW/56 kW = 12.5 to 1 (940 hp/75 hp = 12.5 to 1) efficiency advantage for the centrifugal wheel.

Even though the nozzle blast is not as efficient overall as the wheel blast, in some applications it may be more efficient because the blast stream can be more efficiently applied, when, for example, blasting into small holes to clean the interior areas of a casting. Other reasons for using nozzle blast are requirements for:

- Low production
- Portability
- Suitability for very hard abrasives, such as aluminum oxide

Choosing Blast Cleaning Equipment

In general, the choice of the equipment is based on the following criteria:

- Production requirements, such as high production of a single or similar parts
- Complexity of the parts
- Ability of the parts to be tumbled
- Size, shape, and mix of the parts

All of these factors must be evaluated in order to select the most cost-effective blasting equipment.

Batch-Tumbling Barrel Type. When the production requirement is low to moderate and the parts are of a size and shape that can be tumbled, the machine type most often used is a batch tumbling barrel (Fig. 1(a) and 1(b)). This type of machine is probably the most widely used machine for cleaning castings and is available from many vendors in sizes ranging from 0.028 to 2.2 m^3 (1 to 76 ft^3) capacity. Standard-size barrels from 0.028 to 0.34 m^3 (1 to 12 ft^3) can handle parts weighing from approximately 11 to 45 kg/piece (25 to 100 lb/piece). Heavy-duty barrels will handle parts weighing from 230 to 1100 kg/piece (500 to 2500 lb/piece). These machines consist of a continuous rubber belt or steel slat conveyor that continuously tumbles the parts while they are being blasted. By reversing the conveyor, the parts can be unloaded into a tote box or a takeaway conveyor. Sometimes, to increase productivity, several of these machines are positioned side by side, and automatic loading and unloading systems are used to move castings to and from the machine. One advantage of this type of machine is that the blast time can be set to allow sufficient time for every casting to be cleaned.

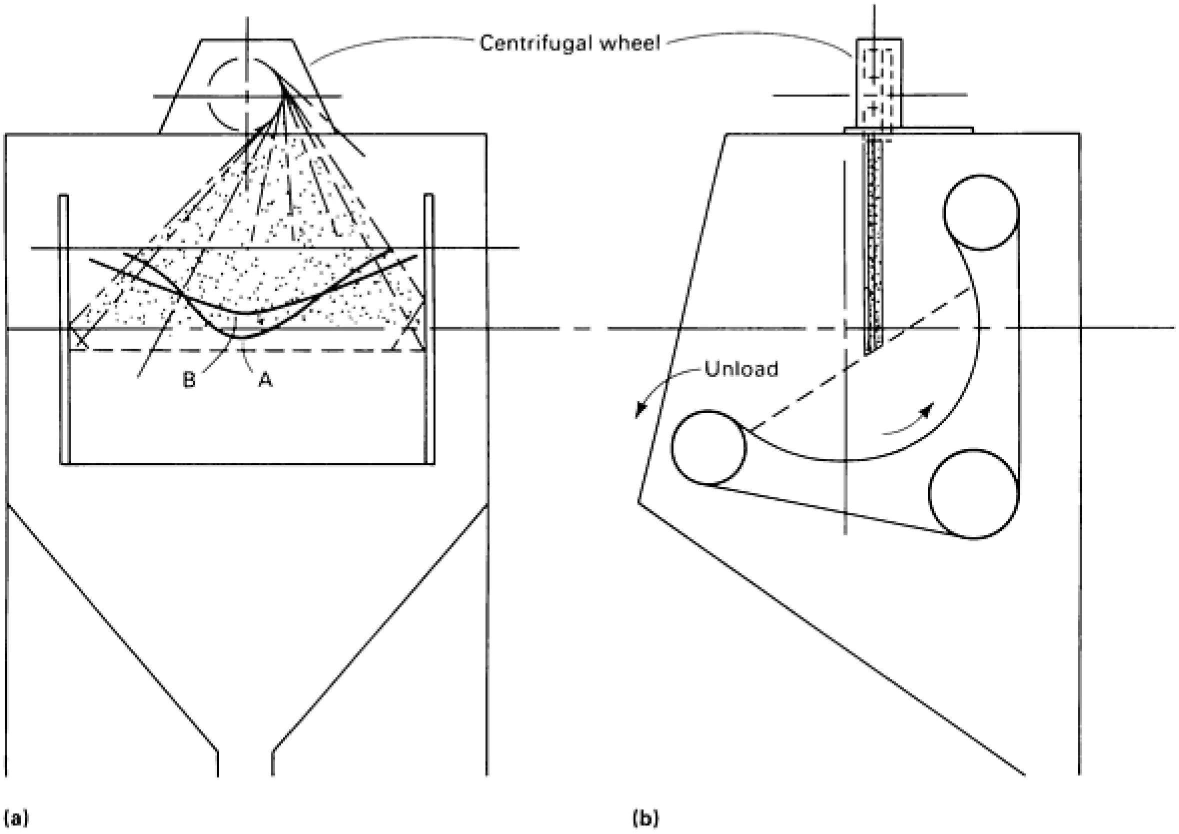

Fig. 1(b) Blast pattern produced by a batch tumbling barrel type abrasive blasting machine. The extent of the pattern is illustrated in (a) the front and (b) side views of the blast pattern. Also illustrated in (a) are two distinct abrasive distribution patterns of the centrifugal wheel; A, short pattern; B, long pattern.

Continuous Tumbling Barrel Type. When production requirements are high and the parts are of a size and shape that can be tumbled and an in-line continuous flow of parts is desired, the continuous tumbling barrel is used. There are three types of these barrels (Fig. 2). Figure 2(a) shows the type that has been in use since the 1950s and consists of an in-feed drum with screw flights to feed the parts to the tumbling blast section, which is constructed like the previously described batch tumbling barrel. The parts then enter a discharge drum for unloading. These machines have served satisfactorily for years; however, a serious shortcoming is that fragile parts are often broken because of the bed depth required to cause the parts to flow. A further disadvantage of the bed depth is that some parts slip through without being completely blasted. Perhaps the most serious drawback of these machines is that they have many individual parts that are exposed to the blast; therefore, maintenance and downtime can be significant.

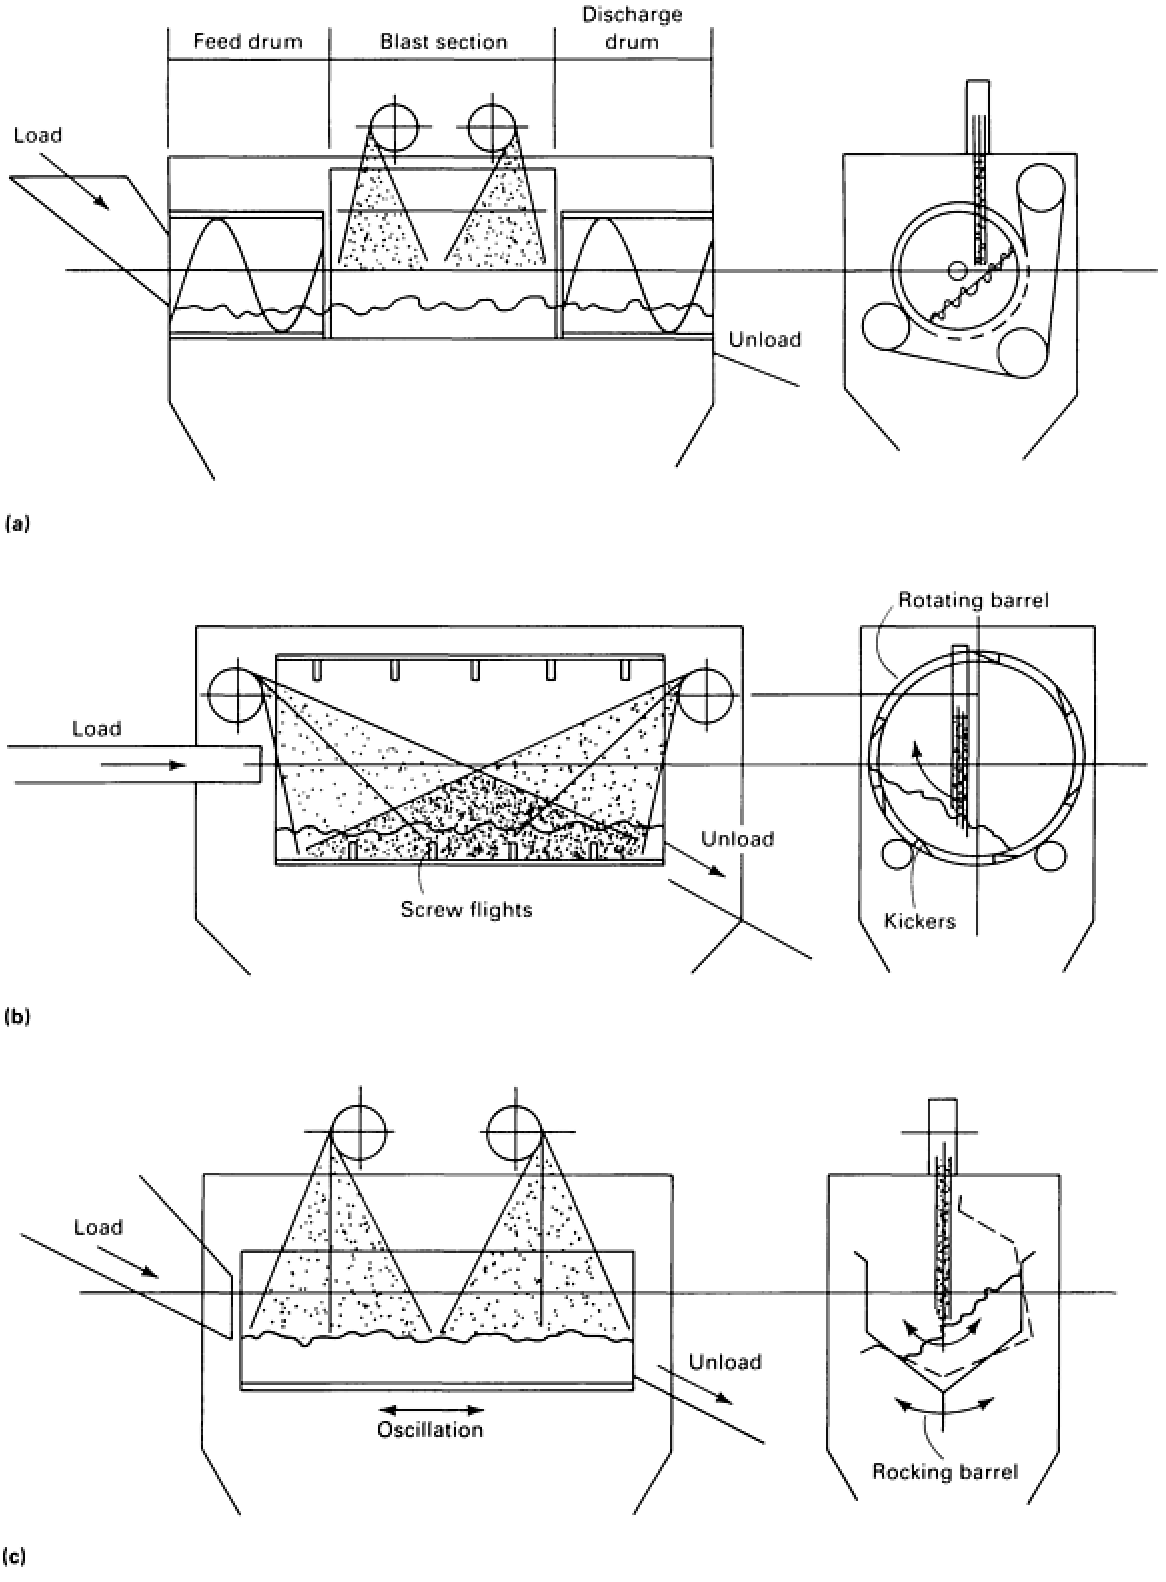

Fig. 2 Three variations of a continuous tumbling barrel type blast cleaning machine, each shown in front and side views. (a) Infeed drum type that uses screw flights to feed each workpiece. (b) Simple perforated-drum type incorporating internal screw flights to move each workpiece and kickers to cause parts to tumble. (c) Rocker type incorporating trough-shape perforated barrel that is rocked back and forth around its transverse axis and moves the parts along the longitudinal axis either by sloping the barrel or by oscillating the barrel longitudinally.

A more recent type of equipment consists of a simple, perforated drum with internal screw flights to move the parts and kickers, causing the parts to tumble (Fig. 2b). The centrifugal wheels are mounted at each end of the drum. This type allows for a low bed depth for parts and has fewer parts to wear out. The main disadvantage is that the blast lacks efficiency because the wheels are outside of the drum rather than directly over the work. These drums are 2.1 to 2.7 m (7.0 to 9.0 ft) in diameter. Breakage of fragile parts is still a problem because some parts ride up the side of the drum above the drum centerline before they tumble.

The most recent continuous barrel design is the rocker-type barrel (Fig. 2c). In this piece of equipment, the barrel is a trough-shape perforated barrel that rocks back and forth about its longitudinal axis. The wheels are directly over the work, and the tumbling action is gentle. The parts are moved axially either by sloping the barrel or by a recently introduced system that oscillates the barrel longitudinally to convey the parts while the barrel rocks back and forth simultaneously. The advantage of the oscillating system is that the throughput can be accurately controlled so that the conveying action can be slowed for hard-to-clean parts while the tumbling rate remains unchanged. For easy-to-clean parts, the conveying speed can be increased. This barrel concept also allows batch processing of parts because it can empty itself of parts.

For the most part, the three types of continuous machines described are for high production (9 to 36 Mg/h, or 10 to 40 tons/h). Machines of Fig. 2(b) and Fig. 2(c) configurations are currently being developed for low production (1.8 to 5.4 Mg/h, or 2 to 6 tons/h).

Rotating Hanger Type. For parts that are of moderate size but are too fragile or are of a size and shape that cannot be tumbled, the machine type most often used is the rotating-hanger-type machine. Basically, all of this type have one or many rotating hangers and a hook to hold one or more castings (Fig. 3). The hanger and hook are moved horizontally to a position opposite the centrifugal wheels, where the castings are blasted while rotating about a vertical axis.

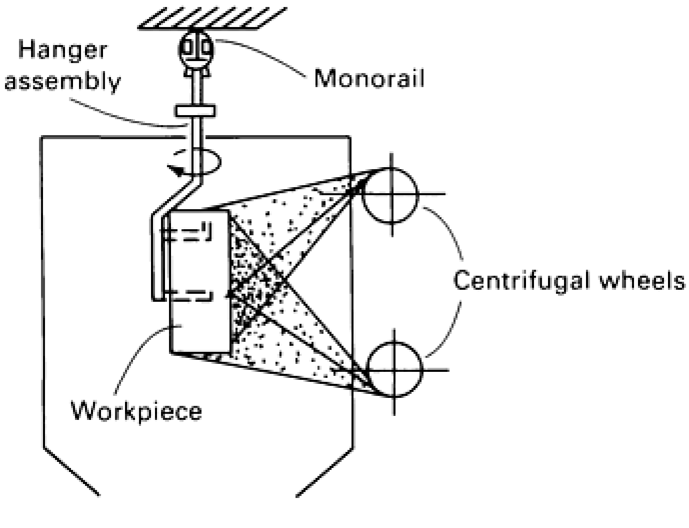

Fig. 3 Front view of a typical rotating hanger assembly. The workpiece is rotated 360° as it is held in position on the monorail track to provide full coverage by the blast pattern produced by the centrifugal wheels.

These machines come in a number of configurations (Fig. 4). For low-production requirements (20 to 30 hooks/h) and a maximum hook capacity of approximately 2700 kg (6000 lb), the hanger machine may be a simple in-and-out type, as shown in Fig. 4(a). In this machine, one of two hooks is loaded or unloaded at points A or B. After loading, the hanger and hook are moved either manually or with power-operated carriers into the machine to the blast area. Usually, while the part is being blasted, the hanger is indexed a short distance to give three horizontal blast positions for good cleaning coverage. While the part or parts are being blasted, the second hook is being loaded to be ready to enter the machine.

Fig. 4 Top views of three machine configurations that use hanger and hook assemblies for blast cleaning operations. (a) In-and-out type used in low-production operations. (b) Low-production setup with hanger assemblies mounted on two separate doors to allow loading and unloading of one workpiece while another workpiece is being cleaned. (c) Turnstile type, which indexes each hanger assembly into the blast station, allowing higher production rates than is possible with either of the two previously mentioned configurations.

Figure 4(b) shows another low production inexpensive hanger machine. In this machine, hanger and rotating mechanisms are located on two separate doors. When one door is closed, the part attached to the hanger and hook is being blasted. Simultaneously, the hook containing a finished blast-cleaned workpiece on the open door is being unloaded, and another workpiece is being loaded and readied to enter the machine. Because it is not easy to provide three blast positions with this arrangement, the wheels are oscillated to give better blast coverage.

Turnstile Hanger Type. When higher production rates are required, a turnstile-type hanger machine is sometimes used (Fig. 4c). With this machine, the load-and-unload operator station is never exposed to the blast because each turnstile index hooks into the blast station. The only time blast is not impacting the work is during the short index time. Production rates are governed by the blast time needed and the time required to load and unload the hook. Production rates are usually about 40 to 60 hooks/h with a hook capacity of 910 kg (2000 lb).

Powered Carrier Hanger Type. Another hanger machine that is popular and very versatile is the powered carrier or power-and-free carrier concept (Fig. 5). Production rates can be up to 120 hooks/h or more with a hook capacity to 18 Mg (20 tons). These machines may be a simple cabinet with doors at each end and two or three self-powered carriers (Fig. 6a) or a multi-blast station machine with many carriers (Fig. 6b). These carriers move the work to other functions such as through a cooling tunnel and then to a preselected grind station and onto a load station where the carrier rotates to position the hook for loading by a robot. At this point, the operator or robot can program the carrier, depending on the part being loaded, to select the blast hp to be applied, the number of wheels to blast the part, the blast positions, the grind station stop, and so on.

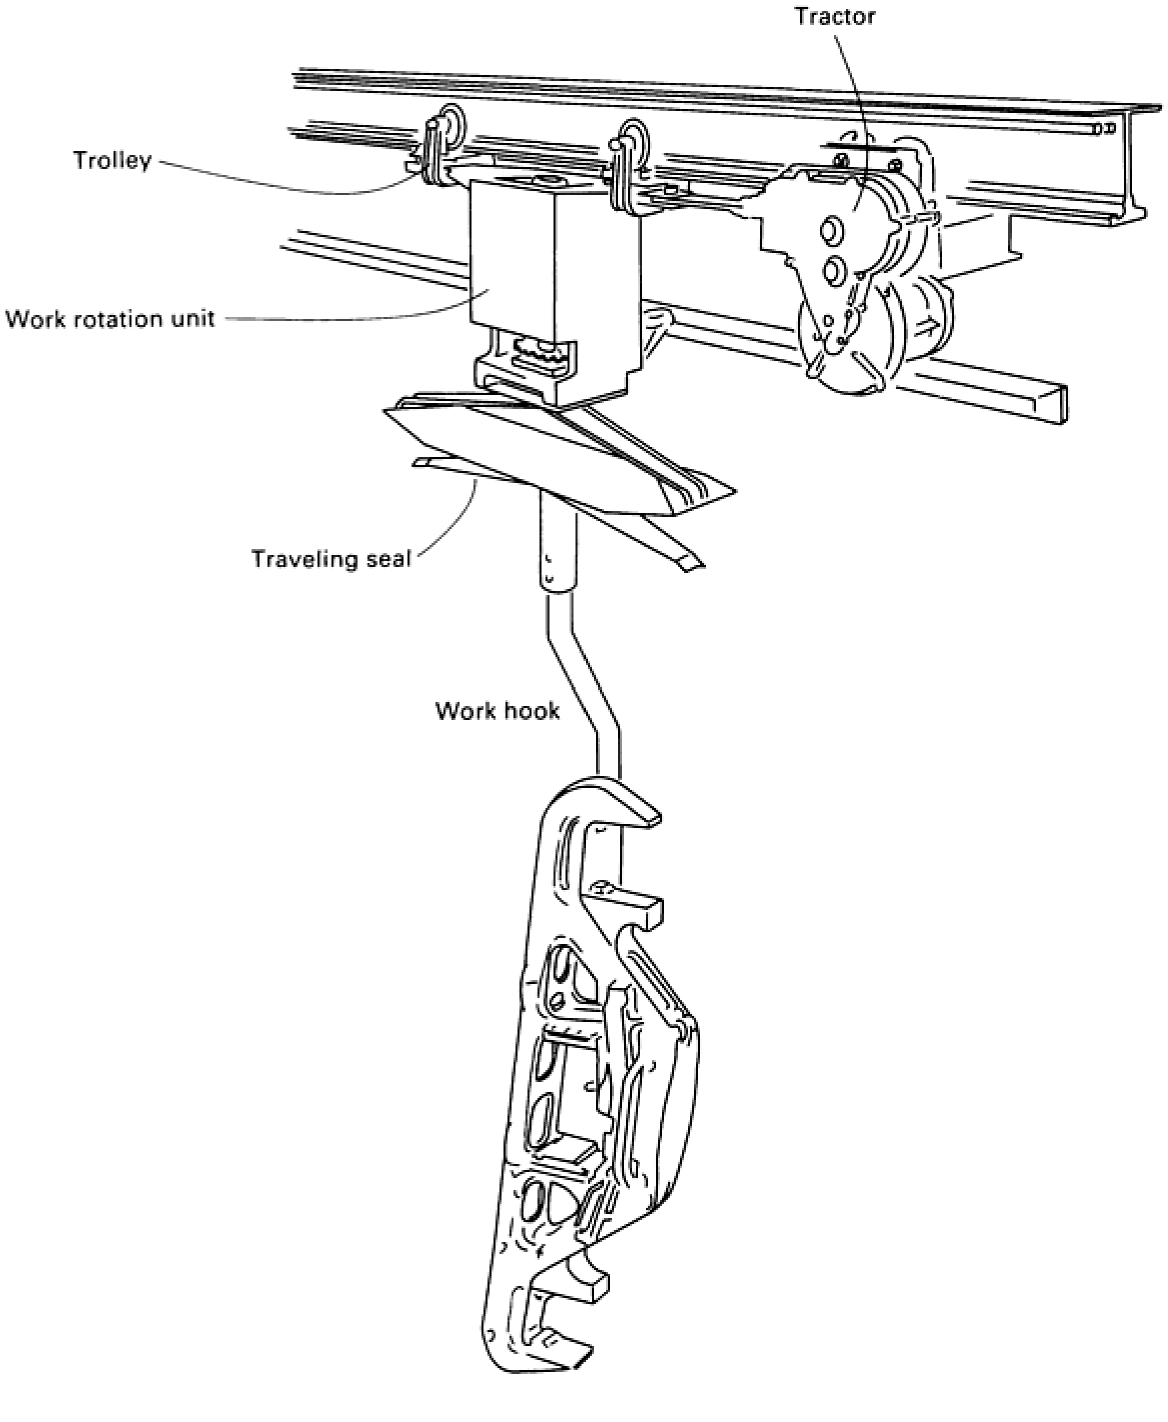

Fig. 5 Powered carrier type hanger capable of producing 120 pieces/h with a capacity to hold workpieces weighing up to 18 Mg (20 tons). Hanger is moved on rail using a 1.1 kW (1.5 hp) friction-drive motor. Work rotation unit is free turning when drive sprocket is disengaged, and it can incorporate optional ac motor drive.

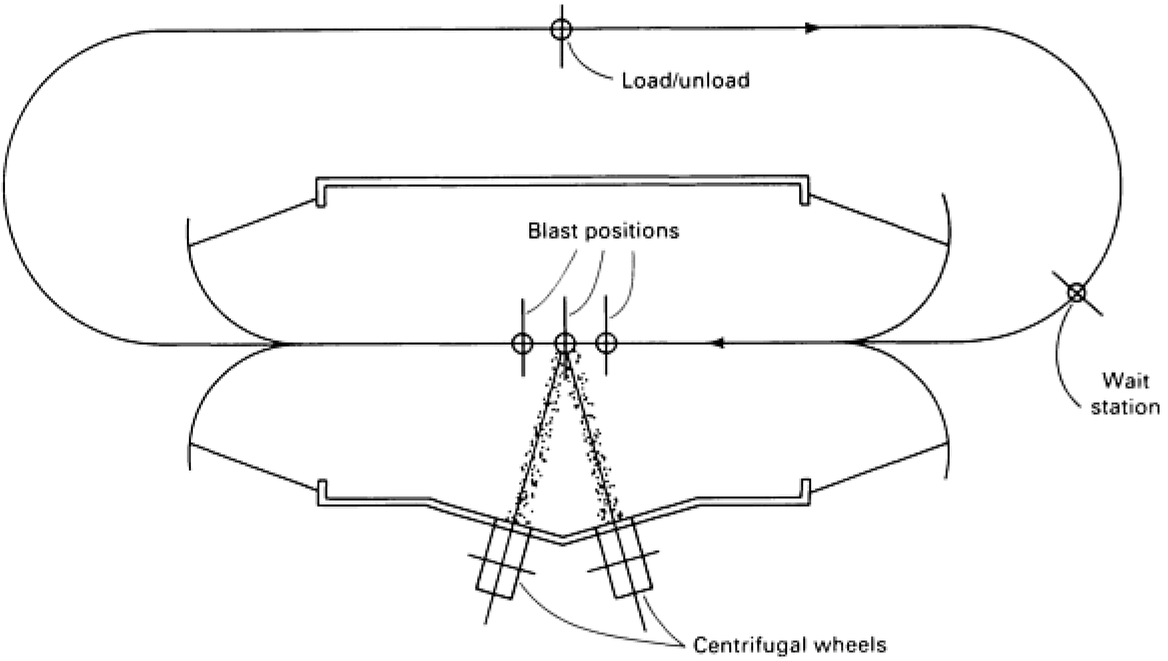
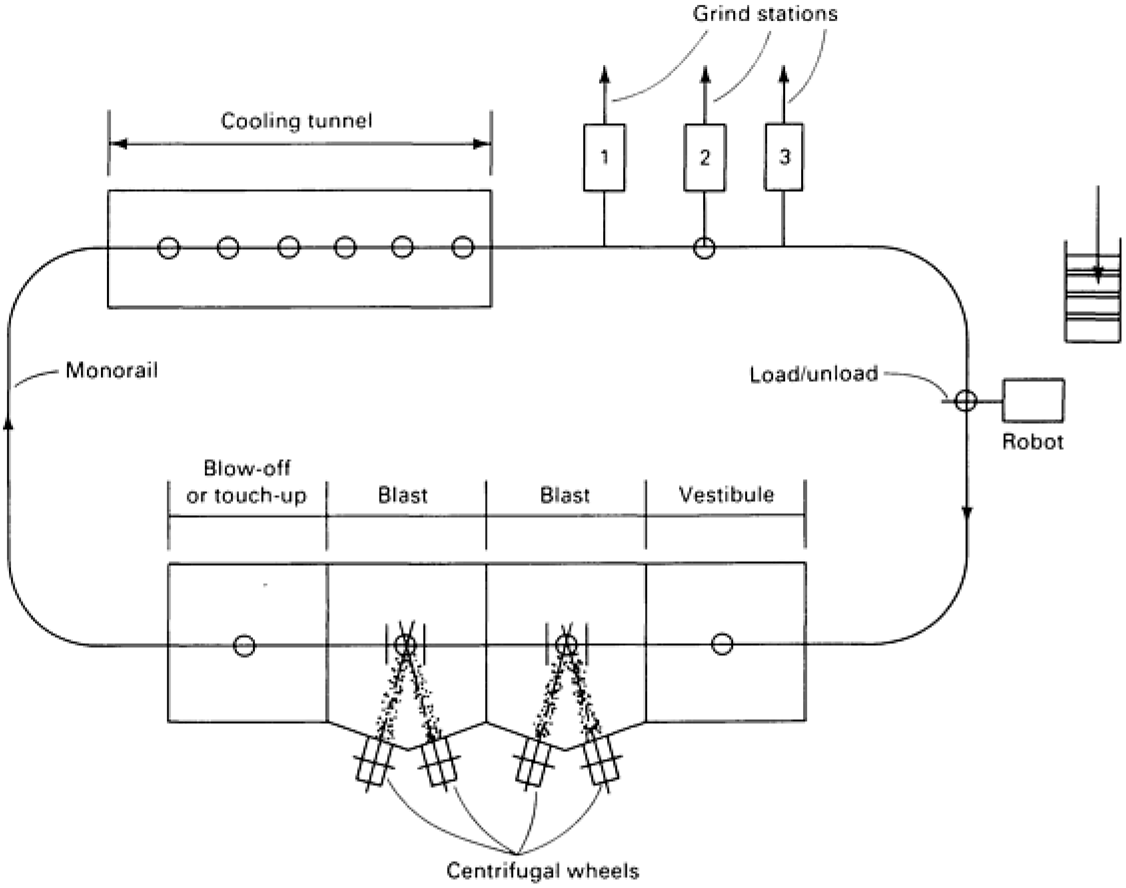


(a)



(b)

Fig. 6 Top views of two power carrier type configurations. (a) Single blast station with two to three self-powered carriers. (b) Multiblast station with numerous self-powered carriers.

Continuous-Monorail Hanger Type. When production requirements are very high, a continuous monorail (Fig. 7) is sometimes used. These machines can run up to 750 or more hooks per hour at a maximum hook capacity of 1.8 Mg (4000 lb). The conveyor may run at a continuous speed or at a fast speed between blast stations and then at a slow speed for a short distance at the blast station. These machines are hard to automate because the conveyor is always moving and there is no easy way to position the rotator for automatic loading and unloading. These machines have, for the most part, been used by high-production foundries such as automobile foundries. Today, these foundries favor automated, in-line machines.

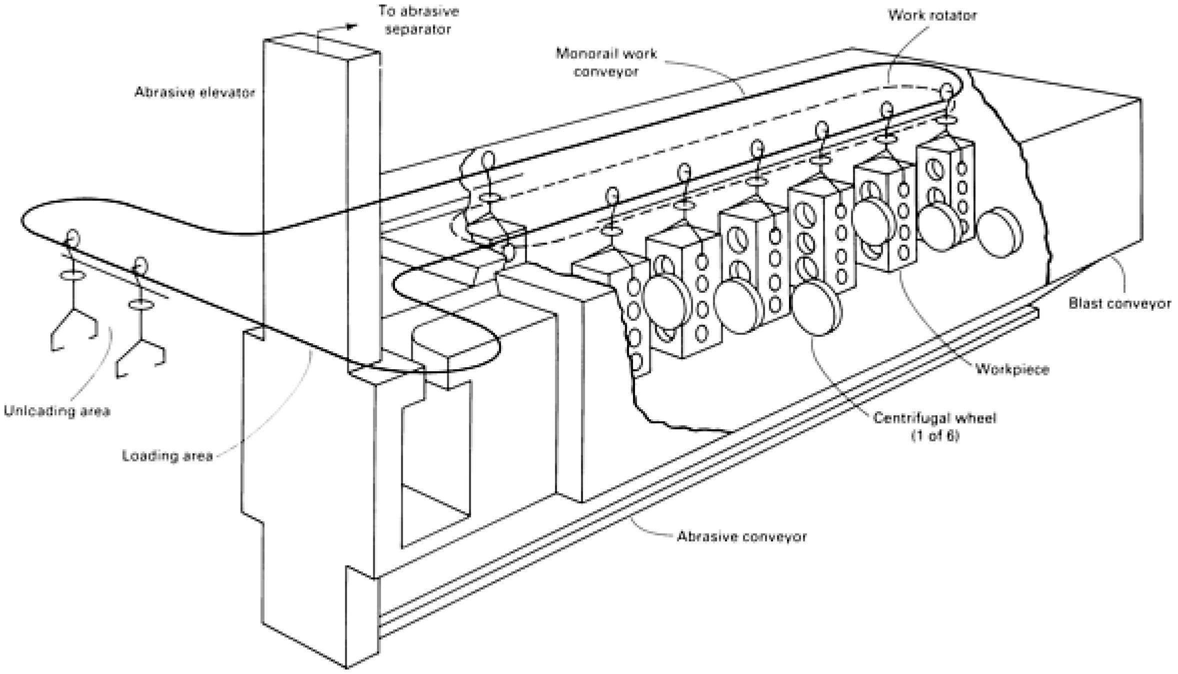


Fig. 7 Continuous monorail hanger type machine used in high-production foundry operations. Hook capacity is 1.8 Mg (4000 lb) with rail capable of transporting 750 hooks/h.

When parts are too large to either tumble or hang on a hook, or when production requirements are low, the machine types most often used are either a table-type machine or a room-type machine.

Table-type machines (Fig. 8) are furnished in sizes from 0.91 to 3.7 m (3.0 to 12.0 ft) in diameter. The smaller table machines are used to handle smaller castings that cannot be tumbled. They are also used when size, shape, or low production requirements rule out a hanger machine. A large table machine (2.4 to 3.7 m, or 8.0 to 12.0 ft in diameter) can handle castings weighing from 4.5 to 18 Mg (5 to 20 tons). The part or parts are placed on the table by a power lift device, and, after the doors are closed, the parts are blasted by one to three centrifugal wheels. A disadvantage of this type of machine is that usually the parts must be turned over or repositioned and the blast cycle must be repeated to effect complete cleaning.

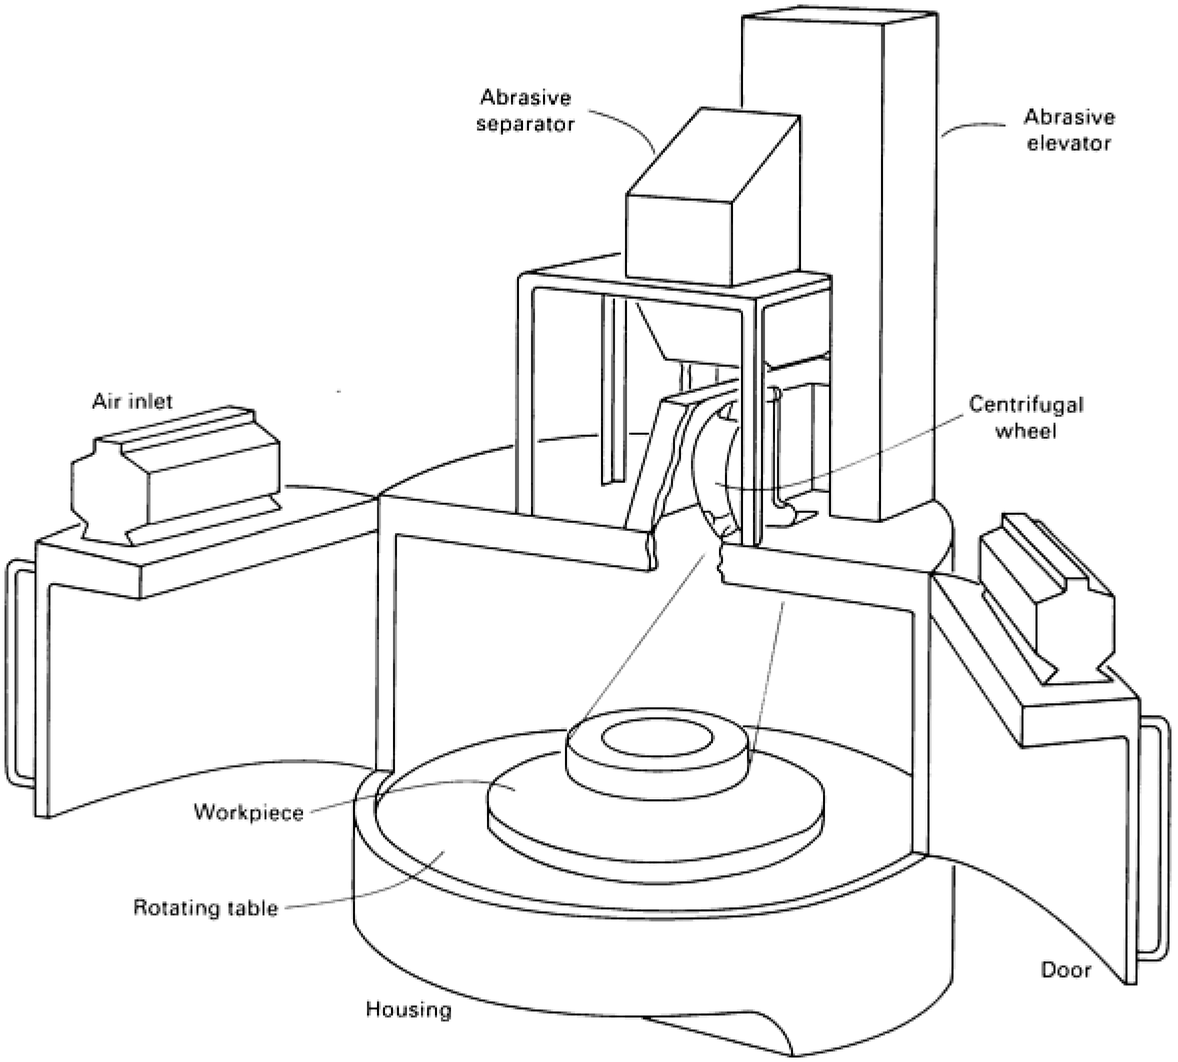

Fig. 8 Components of a typical table-type blast cleaning machine.

Room-type machines are used when the requirement is low production on a variety of medium-size to very large parts. These machines usually consist of a room with power-operated entrance doors. A self-powered car with a rotating table carries the work to be blasted into the room to the blast position. Mounted on the room are two or more centrifugal wheels. While the rotating part is being blasted, either the car moves to three blast positions, or, in some cases, the wheels are oscillated for better blast coverage. As with a table machine, the part or parts may need to be turned over or repositioned for complete coverage. Car and tables have been built with a capacity of 230 Mg (250 tons). For very low production of large castings, this type of machine may be furnished with a manual air nozzle blast system. If this is the case, the rotating table is not absolutely necessary, because the operator can walk around the part, which is supported on a work car.

In order to facilitate the blast cleaning of extremely large castings, some room-type machines incorporate slots in the roof of the room to allow the lowering of the casting into the work area using either an overhead crane or a gantry crane.

Axial-Flow Machine. There are times when the production requirements are so high that special machines must be developed for parts or a family of parts that cannot be successfully tumbled. This is especially true for some parts cast in foundries serving the transportation industry. For example, motor blocks are processed at up to 650 blocks/h, heads at 1000/h, disk brake rotors and brake drums at 1600/h, and so on.

One example of this type of machine is an axial-flow machine for cleaning motor heads (Fig. 9). This machine consists of a skeletal barrel through which parts are rammed one against the other while the barrel is simultaneously rotating. This

machine is very efficient because the entire blast stream impacts the parts. Additionally, the interior water passages are effectively cleaned because of the continual draining of the internal passages during the rotation of the part.

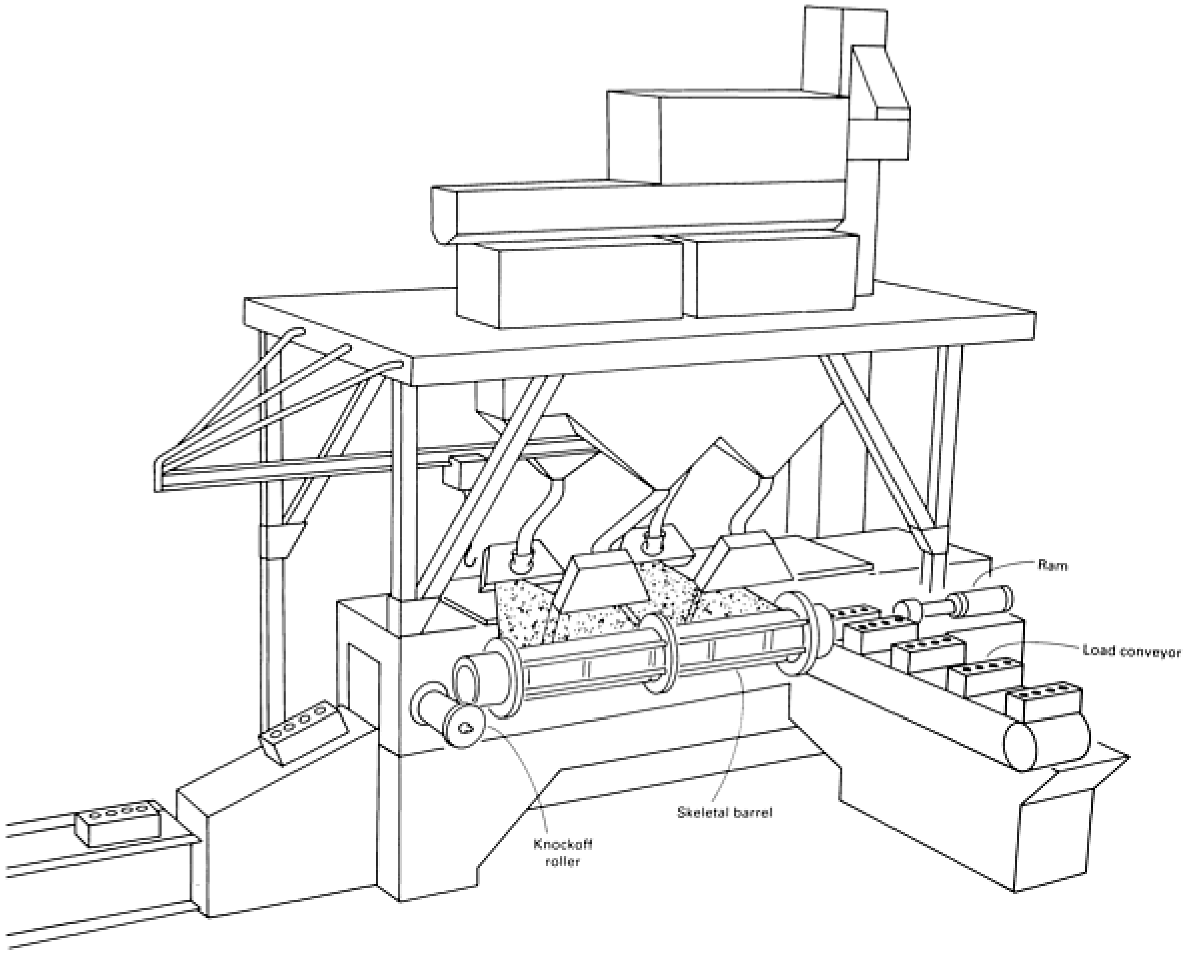

Fig. 9 Axial-flow machine capable of processing 7000 engine heads per hour. Sequence proceeds from load conveyor via ram and skeletal barrel to exit initiated by knockoff roller.

These machines are completely automated and give an in-line flow of parts. The main disadvantage of this concept is that the ends of large square-end parts such as motor blocks cannot be effectively cleaned. A recent innovation on the axial flow machine concept (Fig. 10) allows cleaning at the ends by traversing the parts through the skeletal barrel by oscillating the barrel through use of a flat-stroke drive mechanism instead of ramming the parts through an axially stationary barrel.

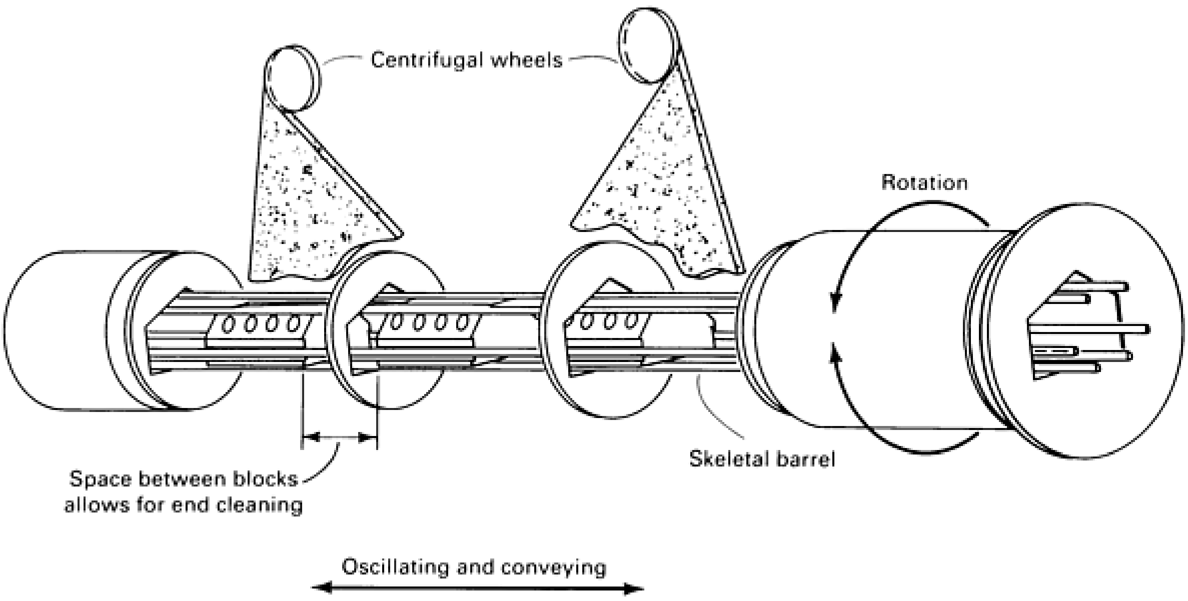

Fig. 10 Oscillating axial-flow machine for blast cleaning of large square-end surfaces of engine block castings, which are difficult if not impossible to clean using an axial flow machine as shown in Fig. 9.

Special Machines. Because of the demand for quality castings, sometimes called world class castings, there is a trend to preblast castings before grinding and then finish blast them to complete the cleaning. With this technique, motor blocks, for example, are conveyed by an oscillating conveyor system without rotation through a preblast machine. The blast wheels are mounted on the side of the machine and partially clean the castings, with most of the cleaning being done on the sides that require grinding. The castings then move to a shakeout and turnover station to remove loose sand and shot in the casting. Next, they move to a grind station where flash is removed and finally into an oscillating conveyor axial-flow machine where up to ten centrifugal wheels polish clean the castings. This example gives some idea of the special machines that are available. Other dedicated machines clean transmission cases, cam shafts, and so on.

Robotic Holding and Transferring Devices. Robots and similar manipulative devices have recently been incorporated into blast-cleaning operations. These devices travel on tracks and are programmed to stop at a designated centrifugal wheel blasting station as the casting is automatically transported from one workstation to another. When the workpiece is positioned within the abrasive pattern, the holder rotates the casting through a programmed cycle of movements. This motion includes oscillating the casting at varying speeds while it is within the abrasive pattern in order to concentrate the pattern on difficult-to-clean surfaces of the workpiece. For detailed information on the application of automation in foundry operations, see the article "Foundry Automation" in this Volume.

Abrasives

Usually abrasive manufacturers suggest asking the following questions in order to choose the correct abrasive size and type:

- What will clean the work rapidly and effectively?
- Will it subject machine parts to relatively gentle wear?
- Will it last a reasonably long time before breaking up?

In the past, chilled iron grit and malleable abrasives were used. Today, however, practically all the shot and grit used is high-carbon cast steel that is heat treated and drawn to give a desired tempered martensite microstructure and hardness. The hardness range of the most commonly used shot and grit is HRC 40 to 50. Harder shot and grit are also produced, with a range of HRC 55 to 65. For faster cleaning or special surface finish requirements, hard abrasive is not often used; but when it is, the wear on machine parts is high, and the abrasive breakdown rate is more rapid. This is especially true of hard grit. Table 1 lists commercially available shot and grit sizes.

Making a choice between shot and grit depends on the surface contaminants or the surface texture required. Grit is used when a chiselling action is required, for example, when removing rust, or perhaps to help remove burned-in sand or provide a good bonding surface for painting, plating, or enameling. Hard grit is used to clean the surface of bathtubs prior to enameling, where a definite tooth is required on the casting surface to provide for better adhesion of the enamel. In cleaning castings, steel shot is typically used; sometimes a shot and grit mixture is used.

The usual rule to follow when choosing the size of shot or grit is to use the smallest-size abrasive that will effectively clean the part. The reason for this is that the smaller sizes give better coverage and longer abrasive life at the same time. This can be illustrated by considering that if blasting were done with S-170 instead of S-460, an increase of $(0.046/0.017)^3$ or approximately 19.8 times the number of particles striking the work would be obtained. However, because the S-460 makes bigger and fewer indentations, the coverage increase with S-170 would be approximately $19.8 \times (0.017/0.046)^2$ or 2.7 times greater than the area coverage with S-460. The photos in Fig. 11 show steel scale blasted at approximately the same abrasive velocity and at the same pounds per square inch coverage. The surface blasted with the finer abrasive, S-170, has much more contamination removed when compared to the surface blasted with S-460.

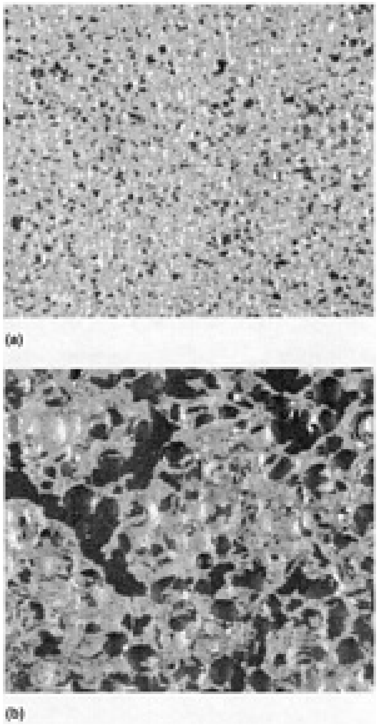

Fig. 11 Comparison of surface finish obtained using (a) finer S-170 abrasive versus (b) coarser S-460 abrasive. In both cases, abrasive velocity was 73 m/s (240 ft/s), and coverage was 97 kg/m^2 (20 lb/ft^2).

Another factor that needs to be considered in casting cleaning is that because of the sand in the abrasive mix that results from blasting sand cast parts, the abrasive used can be too small for the abrasive separator to separate the sand from the abrasive. Abrasive sizes smaller than approximately S-330 make it difficult to remove large percentages of sand efficiently without also removing an excessive amount of good abrasive. Usually, parts having large amounts of adhering sand are blasted with abrasives ranging in size from S-330 to S-550.

Another factor that needs to be understood in abrasive size selection is that it is inherent in the process that after a specific abrasive size is added to a machine, the abrasive soon breaks down to a size distribution called an operating mix. For example, an S-460 abrasive as purchased is usually a mix, approximately 85% of which is contained on two screen sizes. The size distribution would be approximately as follows:

Size	**New S-460, %**	Particles/lb
0.07	2	**397**
0.06	46	**14,526**
0.05	45	**24,555**
0.04	4	**4,263**

0.03	3	**7,578**
Total 51,319		

After this mix is in use for a period of time, it will break down to an operating mix. This mix can vary considerably depending on the blast application, separator setting, replenishing frequency, and so on. Typically, the mix would be:

Size	**S-460 operating mix, %**	Particles/lb
0.07	. . .	**. . .**
0.06	24	**7,578**
0.05	25	**13,641**
0.04	24	**25,578**
0.03	15	**37,893**
0.02	12	**102,313**
Total 187,003		

It can be seen that the operating mix has approximately 3.6 times more particles per pound so that there are a sufficient number of large particles to break up the surface contaminants and many small particles to remove the residue. Trial and error plus experience usually determine the best operating mix. Once determined, it can be maintained by carefully monitoring the separator performance and making small regular abrasive additions to compensate for losses.

Types of Centrifugal Wheels

In recent years, there has been a proliferation of centrifugal wheel types and sizes. These include the old, standard wheels (usually 495 mm, or 19 $\frac{1}{2}$ in. in diameter), belt driven, run at 2250 rpm, that give an abrasive velocity of 73 m/s (240 ft/s) and approximately 1035 kg/h/kW (1700 lb/h/hp) flow at hp_{net}, where $hp_{\text{net}} = hp_{\text{motor}} - hp_{\text{idle}}$. A standard centrifugal wheel having this dimension and these performance characteristics is shown in Fig. 12. The abrasive velocity was obtained as follows:

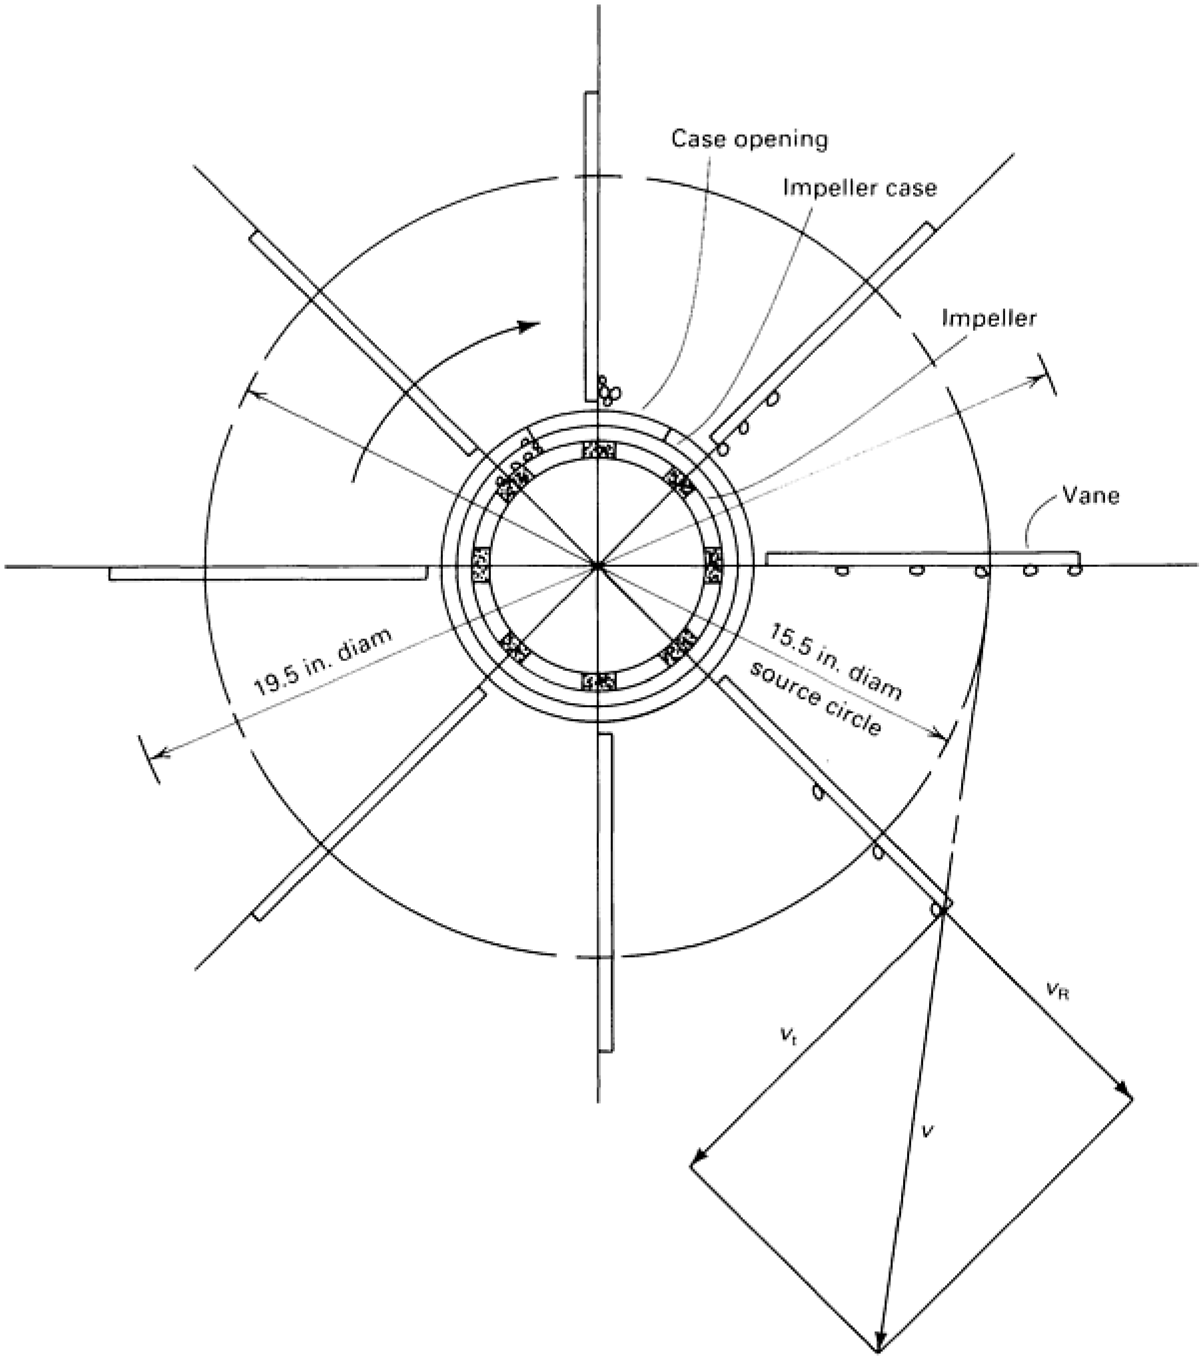

Fig. 12 Cross section of a standard (495 mm, or 19 $\frac{1}{2}$ in. diam) centrifugal wheel with straight vanes showing radial and tangential components of abrasive velocity. See text for discussion.

The tangential or vane tip velocity (ν_t) of the wheel is calculated using the equation:

$$v_t = 2p\,RN = 2p\left[\frac{9.75}{12}\right]\left[\frac{2250}{60}\right] = 191.4 \qquad \textbf{(Eq 1)}$$

where R is the wheel radius and N is the angular velocity of the wheel. The radial velocity of the wheel, ν_R, is given by:

$$\nu_R = \nu_t\ (0.76) \qquad \textbf{(Eq 2)}$$

= 145.5 ft/s

where 0.76 is an empirical factor derived from velocity tests. The resultant abrasive velocity, ν, is obtained from ν_t and ν_R:

$$v = \sqrt{v_t^2 + v_R^2} = \sqrt{(191.4)^2 + (145.5)^2} = 240\, ft/s \qquad \textbf{(Eq 3)}$$

The abrasive flow rate (in pounds per hour) at hp_{net} is given by:

$$\text{Flow rate}_{abrasive} = 1700\ (hp_{motor} - hp_{idle}) \qquad \textbf{(Eq 4)}$$

In addition to standard wheels, other wheel configurations are increasingly being used: curved-vane, canted-vane, and direct-drive wheels.

Curved-vane wheels were developed in order to reduce the noise source in the centrifugal wheel. In Fig, 12 and 13, it can be seen that a standard 495 mm (19 $\frac{1}{2}$ in.) diam wheel has a vane tip velocity of 57.9 m/s (191 ft/s) to give an abrasive velocity of 73 m/s (240 ft/s), whereas a 457 mm (18 in.) diam curved vane has a tip velocity of 50.2 m/s (165 ft/s) to obtain the same 73 m/s (240 ft/s) abrasive velocity. The abrasive velocity and flow rate for the curved vane wheel in Fig. 13 are obtained as follows:

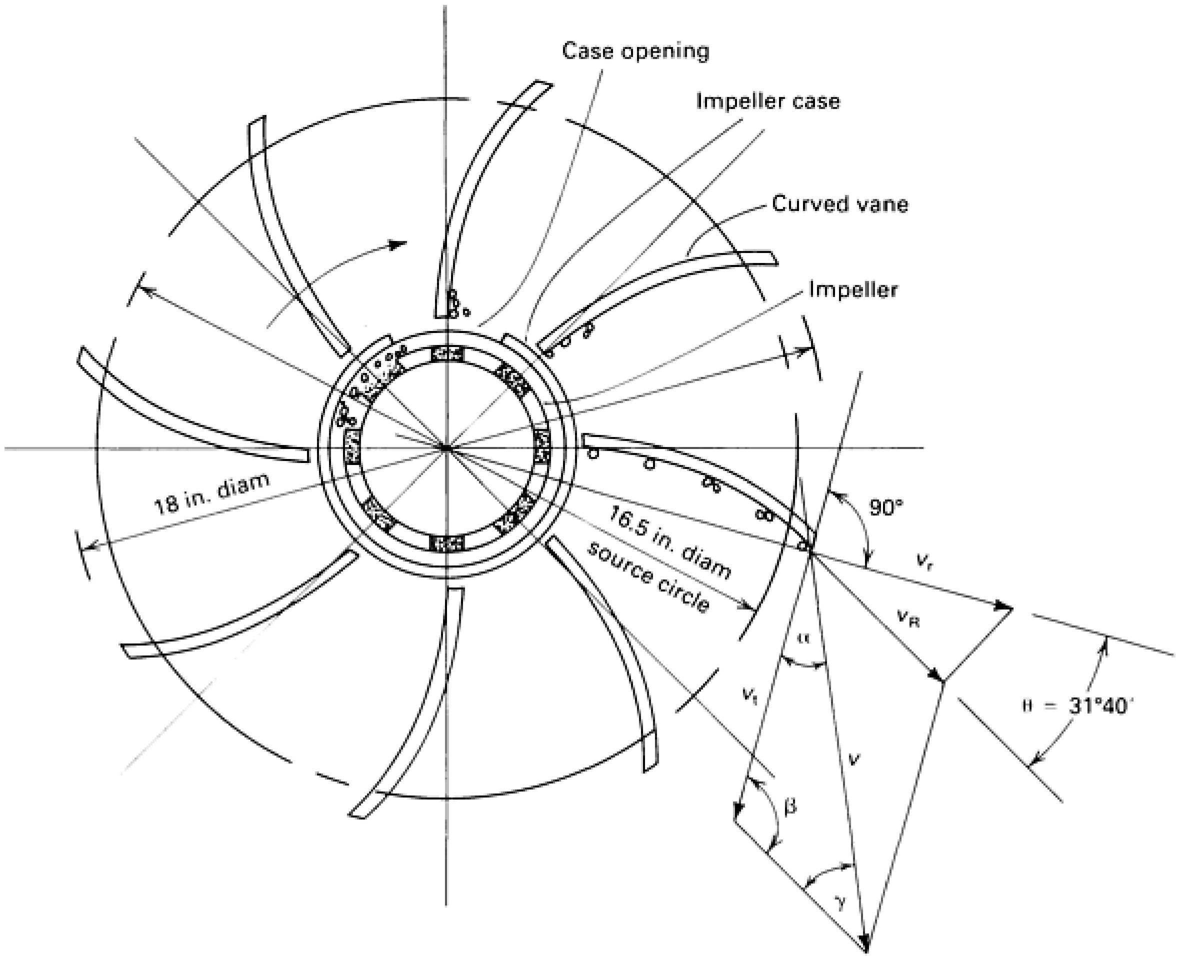

Fig. 13 Cross section of a 457 mm (18 in.) diam curved-vane centrifugal wheel showing radial and tangential components of abrasive velocity. See text for discussion.

Using Eq 1, the vane tip velocity is calculated as:

$$v_t = 2p\,RN = 2p\left[\frac{9.75}{12}\right]\left[\frac{2100}{60}\right] = 165$$

The radial component of velocity is obtained using:

$$\begin{aligned} v_r &= v_t\,(0.765) \\ &= (165)(0.765) \\ &= 126.23 \end{aligned}$$

where v_r is perpendicular to v_t and 0.765 is an empirical factor derived from velocity tests. Because v_t and v_R are not at a right angle:

$$\begin{aligned} v_R &= v_r \cos\theta \\ &= 126.23(\cos 31°40') \\ &= 107.43 \end{aligned} \qquad \textbf{(Eq 5)}$$

The resultant abrasive velocity is calculated as:

$$v = \sqrt{(165)^2 + (107.43)^2 - (2)(165)(107.43)(\cos 121°40')} = 239.54\,ft/s \qquad \textbf{(Eq 6)}$$

where β= 90° + θ, or, with θ= 31° 40', β= 121° 40', and the flow rate (in pounds per hour) is:

$$\text{Flow rate}_{abrasive} = 1700\,[hp_{motor} - hp_{idle}]$$

This reduction in rpm and tip speed gives approximately a 7 dB sound power reduction.

The most common curved-vane wheels are:

- 330 mm (13 in.) diam, 3450 rpm, direct drive or 2900 rpm, V-belt driven
- 457 mm (18 in.) diam, 2100 rpm, V-belt driven
- 559 mm (22 in.) diam, 1750 rpm, direct drive

Another advantage of the curved-vane wheel is that, for a given abrasive velocity, the hp_{idle} is less due to the fact that the wheel rpm is less (2100 versus 2250) and the wheel diameter is smaller (457 versus 495 mm, or 18 versus 19.5 in.). For a 102 mm (4 in.) wide vane, 457 mm (18 in.) diam curved vane, hp_{idle} is 1.9 versus 3.6 kW (2.6 versus 4.5 hp) for a 102 mm (4 in.) wide vane 495 mm (19 $\frac{1}{2}$ in.) diam straight-vane wheel. Laboratory testing and field experience have shown that the wear rate of the curved vane is as good and in some cases better than, an equivalent-width 495 mm (19 $\frac{1}{2}$ in.) straight vane, provided that the separation system is properly adjusted to remove most of the sand. The curved vane should not be used when using hard grit abrasive (55 to 65 HRC).

Canted-vane wheels consist of a centrifugal wheel in which the eight vanes are alternately canted forward and backward approximately 3 to 6°. This is done to project the abrasive at a slight angle from the wheel in an alternating fashion so that, from a single wheel, two side-by-side patterns are produced at the impact surface (Ref 1). These wheels were originally developed for high-horsepower steel descaling to reduce abrasive interference. However, recent use for casting cleaning has resulted in significant improvement in cleaning efficiency. It can be seen in Fig. 14 that the wider pattern improves the ability of the wheel to clean the sides of cavities, and so on, in a hanger-type machine by enabling

the abrasive to cover a wider surface area. In some cases, batch and continuous barrels also can realize better cleaning because of the wider pattern. These wheels are available in straight-vane and curved-vane versions.

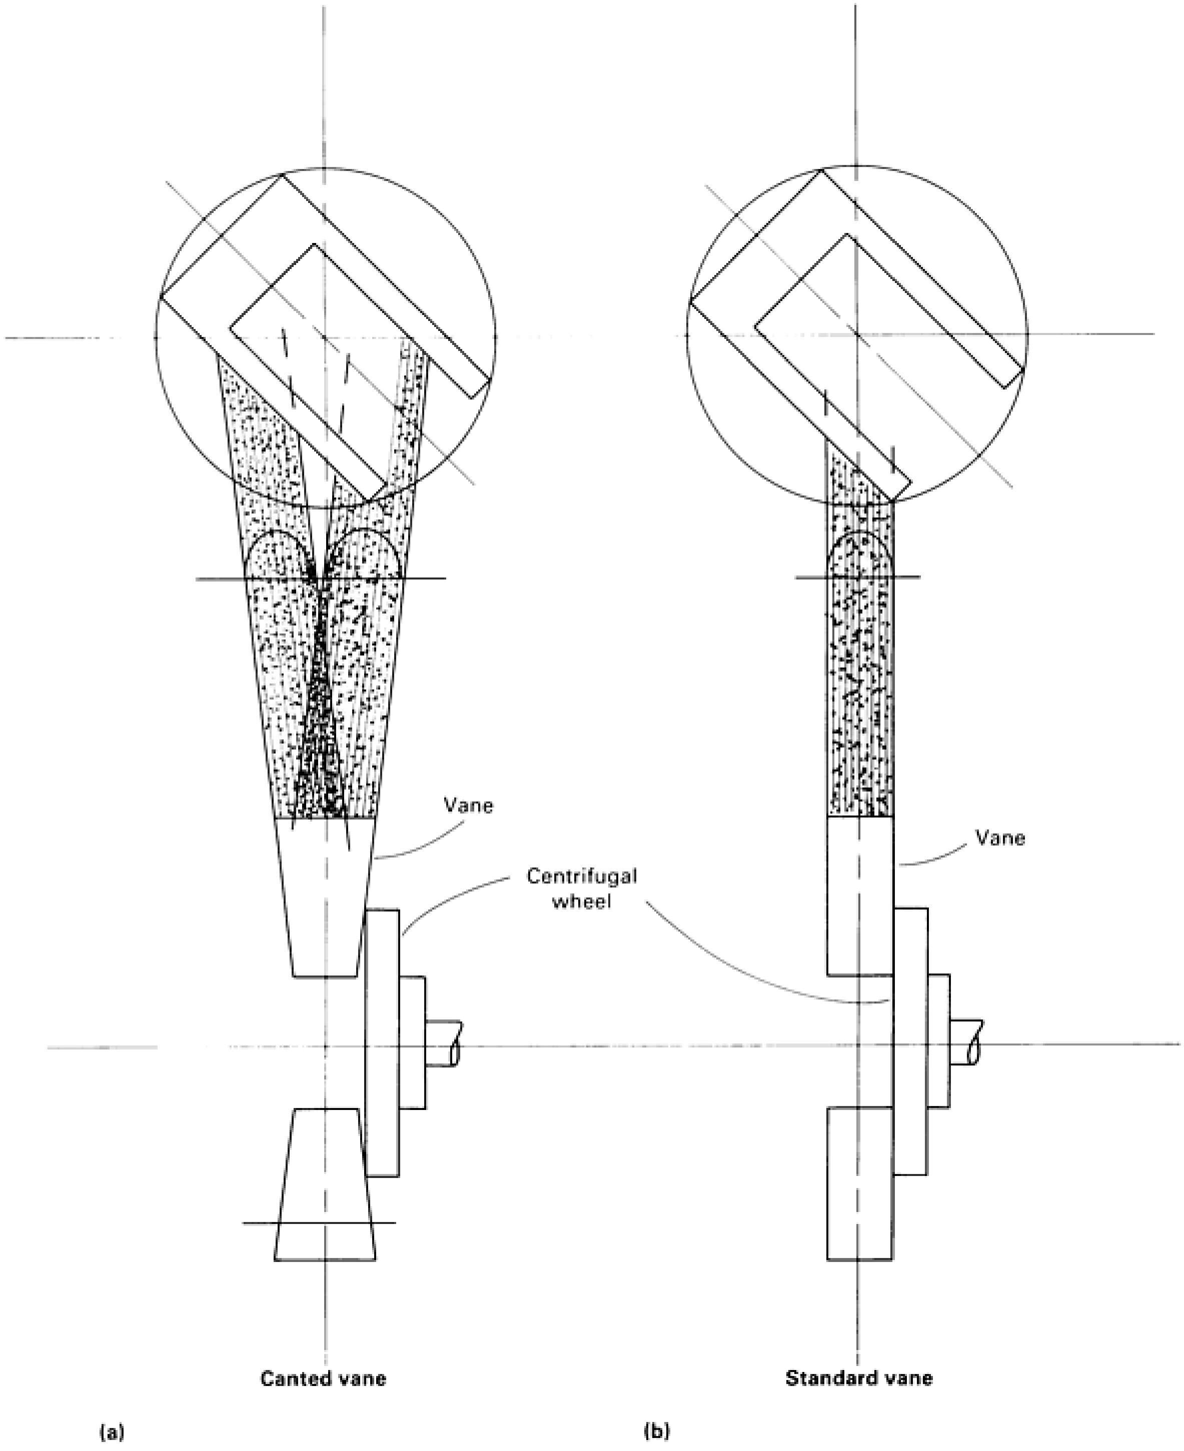

Fig. 14 Comparison of the blast pattern produced by (a) a canted vane centrifugal wheel versus that produced by (b) a standard centrifugal wheel.

Direct-drive wheels have been available for 15 to 20 years. Because of economic pressures to develop less expensive machines, direct-drive wheels are being furnished on new equipment more often. A direct-drive wheel is one in which the centrifugal wheel is mounted directly onto a motor shaft. This design eliminates the standard bearing spindle, V-belts, guards, and belt take-up device.

For the most part, industry experts agree that for high-production rigorous-use machines, the V-belt driven wheel is the most rugged and reliable centrifugal throwing device. There are, however, many applications for which the direct-drive wheel may be a satisfactory choice. This is especially true of wheels mounted on an 1800 rpm motor. These wheels are quieter because of less vibration and lower rpm. Because they are 558 to 610 mm (22 to 24 in.) in diameter in order to give sufficient abrasive velocity, the vane life is increased due to the lower abrasive accelerating forces on the increased area of long vanes running at lower rpm.

Some direct-drive wheels are mounted on 3600 rpm motors. These wheels are usually 330 to 381 mm (13 to 15 in.) in diameter. Because of their higher speed, vibration can be a problem, as can be seen by comparing the vane centrifugal force for the two wheels. The centrifugal force for a 381 mm (15 in.) wheel vane at 1.10 kg/vane (2.42 lb/vane) is 2000 kg (4420 lb) versus only 1420 kg (3130 lb) for a 2.2 kg/vane (4.8 lb/vane) on a 610 mm (24 in.) diam, 1750 rpm wheel. From this it can be seen that if the unbalanced weight is the same on a 381 mm (15 in.) wheel as it is on a 610 mm (24 in.) wheel, the unbalanced load on the motor bearings will be higher on the first wheel. The noise level will also be higher due to more vibration and higher vane tip speed. For a given horsepower, the vane wear will also be higher due primarily to the friction energy acting over a smaller surface area and to higher abrasive accelerating forces on the vane. However, for low-cost, low-horsepower machines, the 3600 rpm direct drive wheel may be the best choice due to space and economic considerations.

The main disadvantages of the direct-drive wheels are:

- The abrasive impact velocity is fixed and cannot be changed without changing the wheel diameter, changing to curved vanes, or running the motor from an expensive variable-frequency drive
- Motor bearings are not nearly as rugged as standard spindle bearings, and consequently bearing failure can be a problem

Technical Aspects of Blast Cleaning

Centrifugal Wheel Performance. With the proliferation of centrifugal wheels and the recent trend to run wheels at higher and higher speeds or, in other cases, at lower than traditional speed, there is some confusion about the performance characteristics of the different diameter wheels and the effect of both high and low speeds on flow rates and cleaning efficiency.

There are five factors that affect cleaning rates by centrifugal wheels:

- Abrasive velocity
- Abrasive flow rate
- Abrasive distribution in the wheel pattern
- Direction of the angle of impact of the abrasive
- Size, shape, and hardness of the abrasive

Figure 15 shows a cross section of a typical modern V-belt driven centrifugal wheel. All centrifugal wheels used today (except for some air-fed and batter wheels) have basically the same components shown in this photo. The components that affect the performance of a wheel, whether V-belt driven or direct drive are: the feed spout that feeds abrasive into the center of the impeller; and the rotating impeller blades that carry the abrasive around to the fixed impeller case opening, where the abrasive is discharged through the opening to the heel of the rotating vanes, which accelerate the abrasive to a useful velocity.

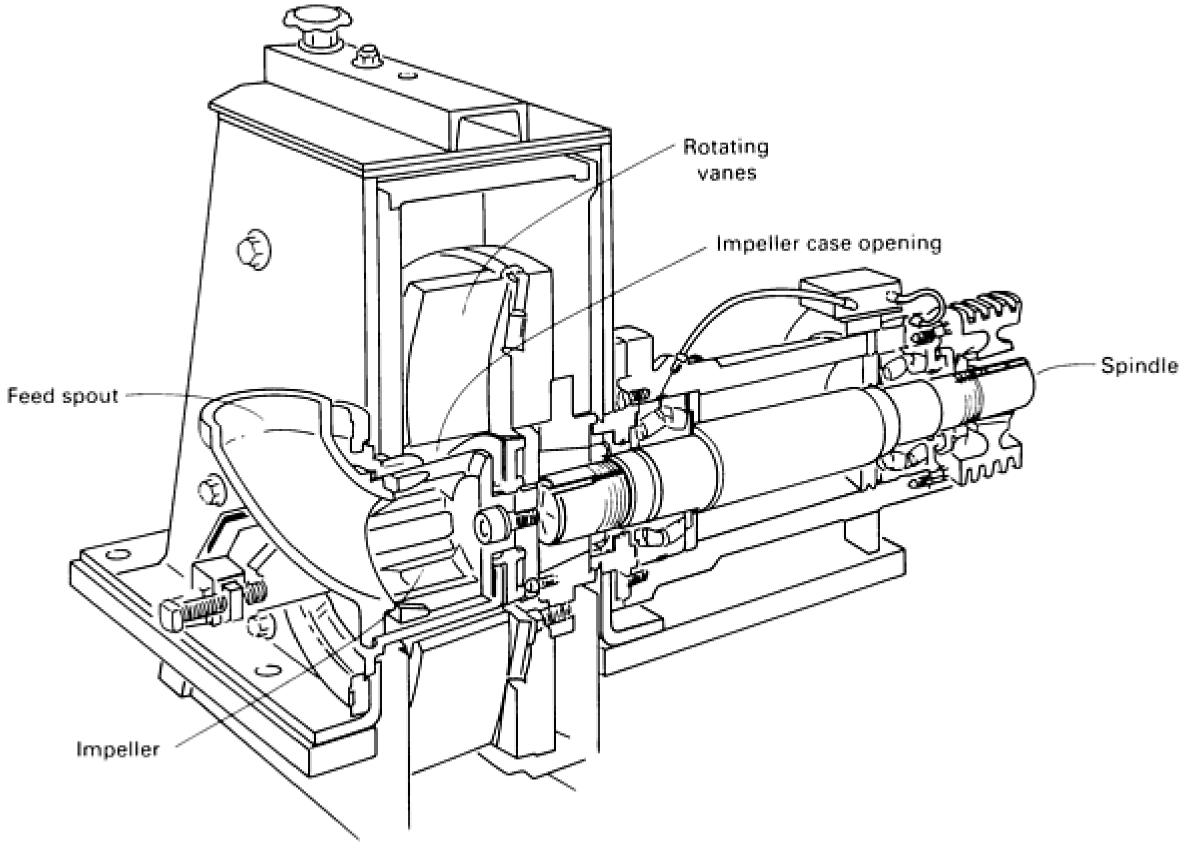

Fig. 15 Cutaway view of curved-vane centrifugal wheel showing primary components involved in feeding and accelerating the abrasive blast medium.

The rotating vanes discharge the abrasive at high velocity according to the velocity diagrams shown in Fig. 12 and 13. Figure 12 shows the velocity diagram of a 495 mm (19 $\frac{1}{2}$ in.) diam straight-vane wheel rotating at 2250 rpm. Figure 13 shows the velocity diagram of a 457 mm (18 in.) diam curved-vane wheel operating at 2100 rpm. Velocity calculations for both vane types are given in the discussion "Types of Centrifugal Wheels" in this section of this article. The 31° 40' discharge angle shown in Fig. 13 has been shown mathematically to be an optimum abrasive discharge angle (Ref 2). Figure 16 shows the approximate abrasive velocity versus rpm for centrifugal wheels most commonly used in the United States.

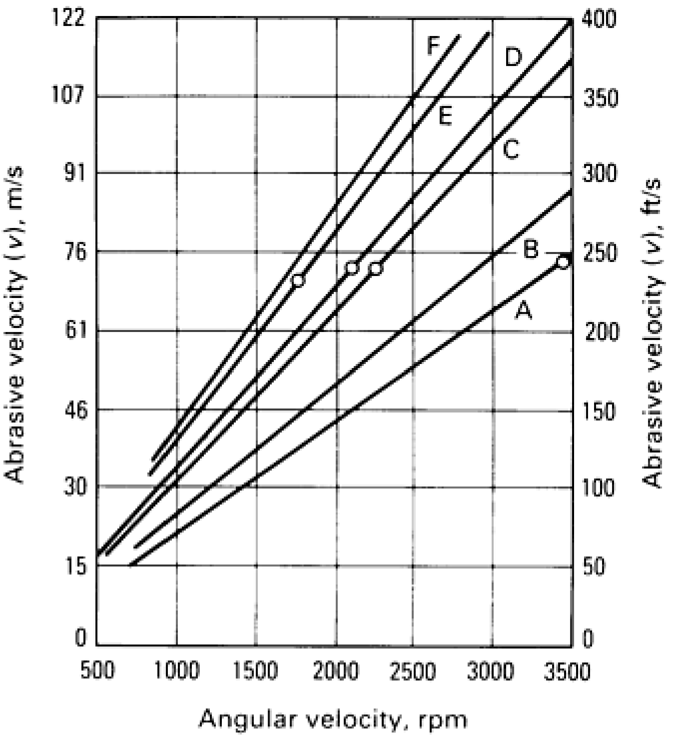

Fig. 16 Plot of abrasive velocity versus angular velocity for both straight-vane and curved-vane centrifugal wheels. Straight vane: A, 330 mm (13 in.); B, 381 mm (15 in.); C, 495 mm (19 $\frac{1}{2}$ in.); and E, 610 mm (24 in.). Curved vane: B, 330 mm (13 in.); D, 457 mm (18 in.); and F, 559 mm (22 in.). Note that B applies to both a 381 mm (15 in.) straight-vane wheel and a 330 mm (13 in.) curved-vane wheel. Also shown are the standard angular velocities (indicated by a circle) at which some are normally operated.

Abrasive flow rates are dependent on the power available to accelerate the abrasive from zero to its discharge velocity after overcoming the idling hp due to windage, bearing friction, and so on, and the power used to overcome friction of the abrasive on the wheel parts as it passes through the wheel. The following results are given in English units (Ref 3):

$$P = \frac{W.v^2}{2g\ .\ 3600} \quad \textbf{(Eq 7)}$$

where W is pounds of abrasive thrown per hour, g is 32.17, and v is abrasive velocity (ft/s). Then

$$hp = \frac{P}{550} \quad \textbf{(Eq 8)}$$

Consider, for example, a typical 19 $\frac{1}{2}$ in. diam wheel, shown in Fig. 15, driven by a 60 hp motor at 2250 rpm. The flow, W, measured at 60 hp--with the hp being determined accurately with a motor analyzer--is 94,350 lb/h; v, the abrasive velocity, is measured at 240 ft/s; hp_{idle} is measured at 4.5 hp. The hp required to accelerate 94,350 lb/h to 240 ft/s is:

$$hp = \frac{(94350)(240)^2}{(2)(32.17)(3600)550} = 42.66$$

Because it is known that hp_{idle} = 4.5, the remaining hp = 60 - (42.66 + 4.5). Therefore, the energy expended due to friction is 12.84. The total power consumption is 42.66 + 4.5 + 12.84, which totals 60 hp and represents 71.1, 7.5, and 21.4%, respectively, of the motor's 60 hp output.

Laboratory tests run on 13 in. curved-vane, 18 in. curved-vane, 19 $\frac{1}{2}$ in. straight-vane, and 24 in. straight-vane wheels have shown that the average flow in lb/h/hp_{net} to be approximately 1700 lb/h/hp at an abrasive velocity of 240 ft/s, where $hp_{net} = hp_{motor} - hp_{idle}$. Thus for any other abrasive velocity, the flow is:

$$1700\left(\frac{240}{v}\right)^2 \qquad \textbf{(Eq 9)}$$

For example, given a 15 in. wheel at an abrasive velocity of 283 ft/s, the flow is:

$$1700\left(\frac{240}{283}\right)^2 = 1223 lb/h/hp_{net}$$

The total flow with a 60 hp motor is 1223 (60 - 3.1 hp_{idle}) = 69,589 lb/h.

It can be seen in Fig. 17 that as the abrasive velocity is reduced, the flow per hp increases; conversely, as the velocity increases, the flow per hp decreases.

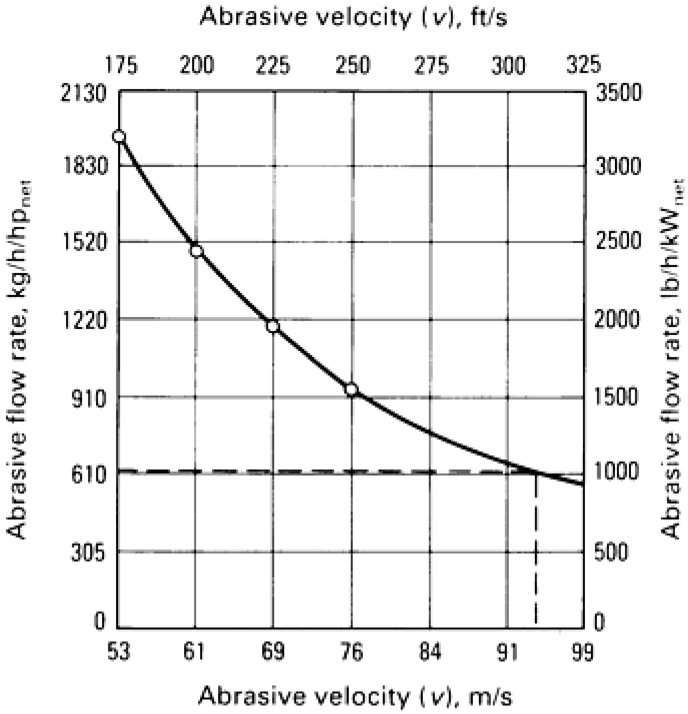

Fig. 17 Plot of abrasive flow rate versus abrasive velocity at hp_{net}. Inverse relationship of these variables is given in English units by flow rate (in lb/h/hp_{net}) being equal to 1700 $[240/v]^2$.

Abrasive Distribution in the Wheel Pattern. As a general rule, most vendors and users of blast equipment think of a blast pattern as the pattern produced on a steel sheet that has been blasted for several seconds. The pattern on the sheet is visually examined, and it is determined that the pattern is either a long pattern or a short pattern. A blue area produced in the plate because of the heat generated is called the hot spot. While this system is suitable for targeting or directing the

hot spot to a specific area on the part or parts to be cleaned, it does not indicate the distribution of the abrasive in the wheel pattern.

Figure 18 shows some typical wheel stream patterns that show the percentage of abrasive distribution in every $7\frac{1}{2}°$ segment of the wheel stream. For example, the short pattern, curve C, has much more of its abrasive in the most intense, or hot spot, $7\frac{1}{2}°$ segment than does the long pattern, curve A.

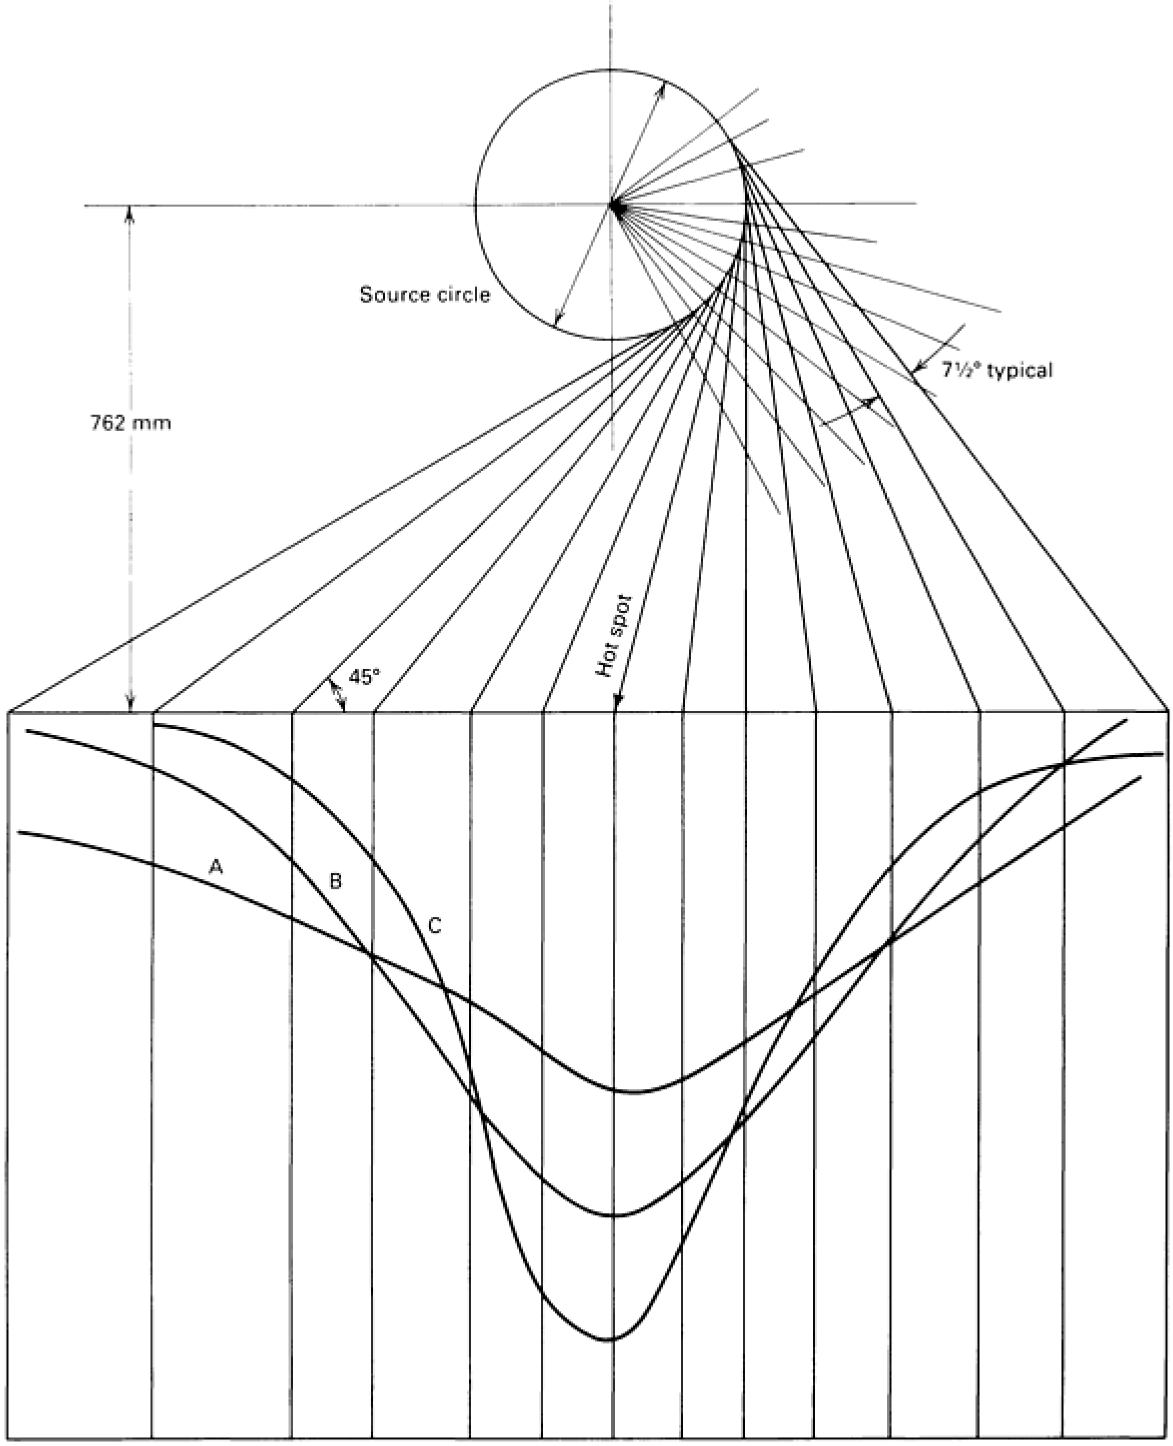

Fig. 18 Plots of abrasive distribution produced by typical centrifugal wheel patterns at $7\frac{1}{2}°$ increments of the

wheel. The axis of the wheel is located 762 mm (30 in.) from the sample sheet. Typical patterns obtained by varying the size and vanes of the wheels and using either rectangular or modified triangular slot configuration on the impeller case or control cage: A, a 610 mm (24 in.) straight-vane wheel with rectangular case slots, a 457 mm (18 in.) curved-vane wheel and a 495 mm (19 $\frac{1}{2}$ in.) straight-vane wheel with modified triangular case slots; B, a 457 mm (18 in.) curved-vane wheel or a 495 mm (19 $\frac{1}{2}$ in.) straight-vane wheel with rectangular case slots; and C, a special impeller (made to specifications in U.S. Patent 4,164,104).

Knowing this distribution enables the manufacturer to apply the centrifugal wheel blast stream more optimally onto the work to be cleaned. Users of existing machines in some cases can profit by having their machines evaluated by blast-cleaning manufacturers to determine whether a different wheel stream distribution would increase their cleaning rates.

The pattern distribution can be changed several ways. Pattern B in Fig. 18 can be considered a standard pattern. This pattern is produced using an impeller case or control cage with a rectangular slot (Fig. 19). Pattern A is generally a pattern from a 610 mm (24 in.) diam wheel with a rectangular slot. An equivalent pattern with a smaller curved-vane or straight-vane wheel can be obtained by using a triangular or modified triangular slot in the case (Fig. 19). Shorter patterns such as C can be obtained by using a patented impeller-to-vane configuration (Ref 4). Some manufacturers also shorten the rectangular slot to shorten the pattern. This is only marginally effective, and then only if the case opening is overly large to begin with.

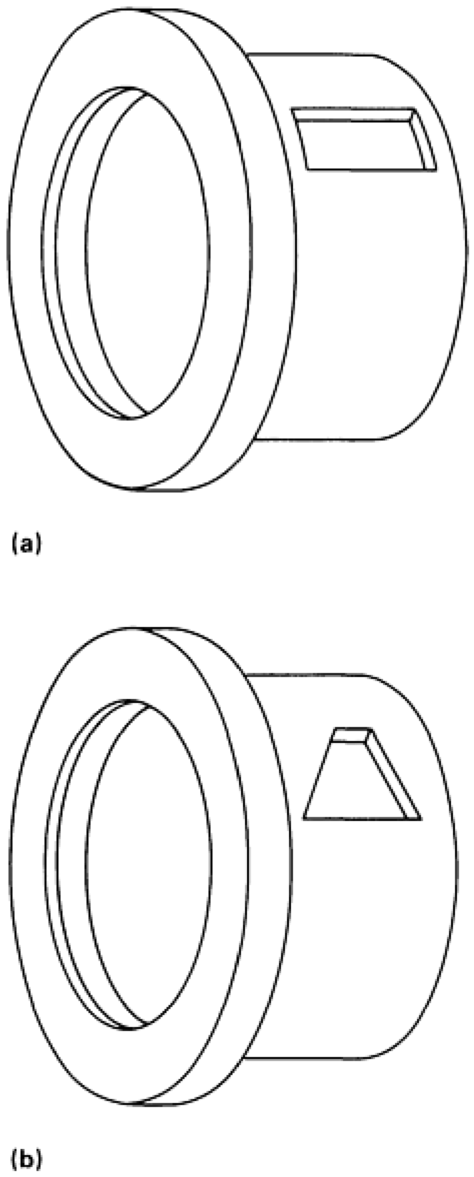

Fig. 19 Abrasive pattern distribution is altered by (a) rectangular slot or (b) modified triangular slot, located on an impeller case or control cage.

Figure 1(b) shows a typical barrel application in which a long pattern (curve B) may improve cleaning. Figure 20 shows a typical hanger-type machine application in which a short pattern may be more effective. Figure 14(a) shows a hanger application in which a wider canted-vane transverse pattern is more effective than a standard vane (Fig. 14b).

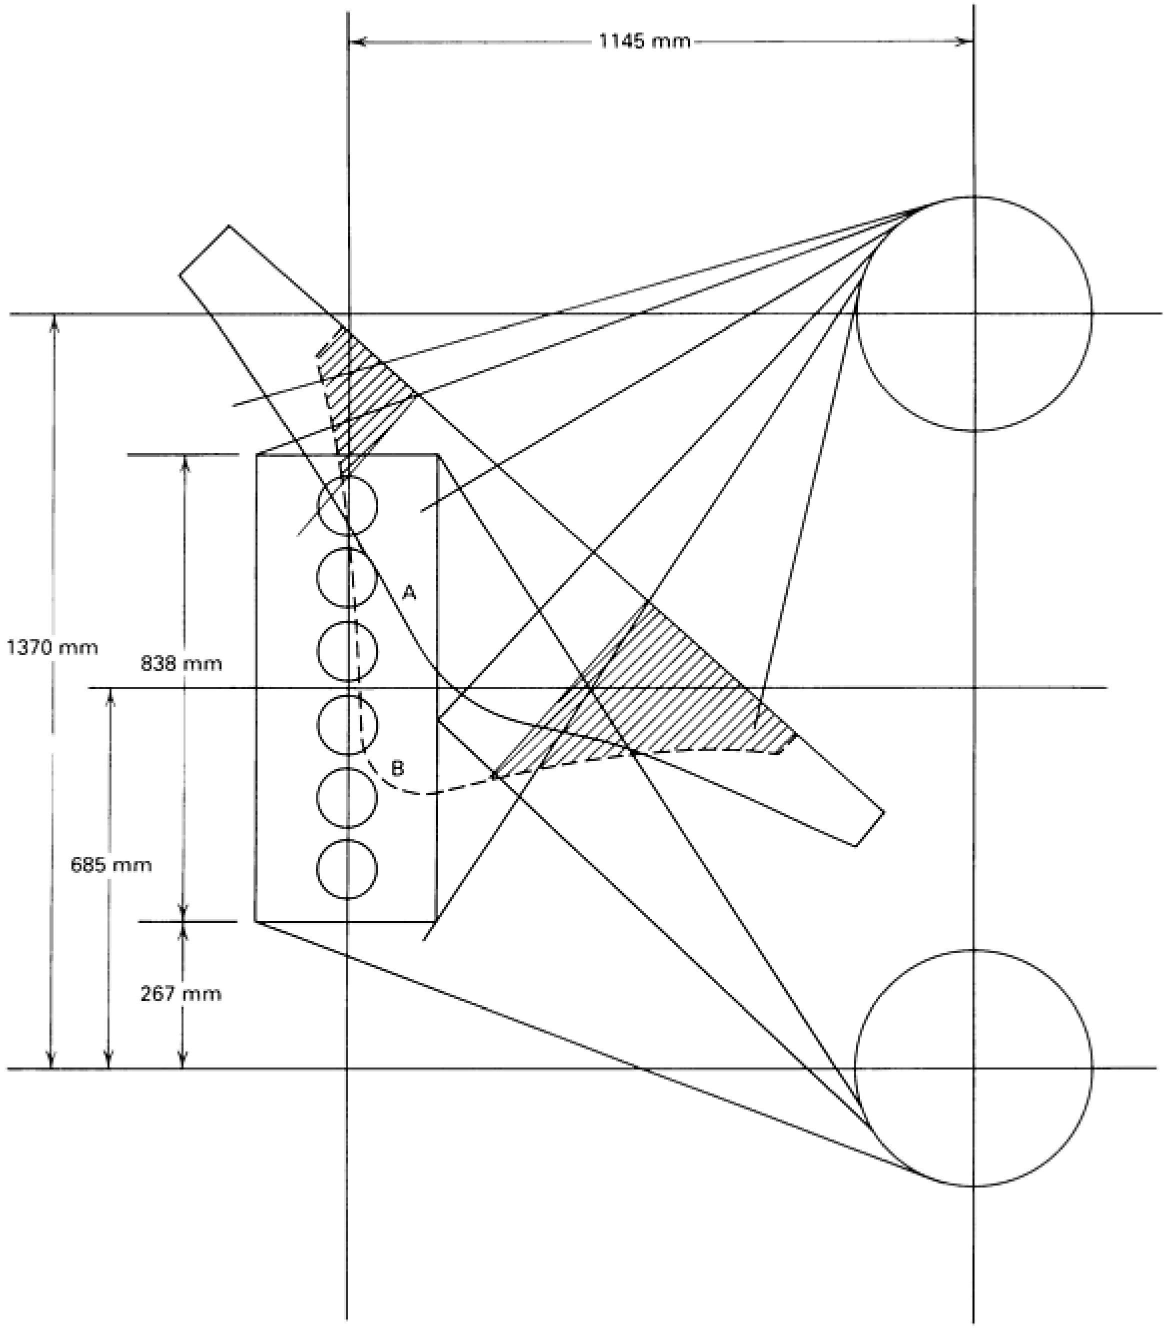

Fig. 20 Wheel pattern coverage provided by two centrifugal wheels working in tandem on a motor casting: A, long pattern, in which 47% of the abrasive impacts the workpiece while 53% misses the part as indicated by the shaded area; B, short pattern, in which 71% of the abrasive impacts the workpiece while only 29% misses the part as indicated by the hatched area.

Angle of Impact of the Abrasive. Laboratory testing has shown that in removing steel scale, if the impacts per square inch are the same, the cleaning rate varies directly with the sine of the impact angle (measured from the horizontal). It is not known whether this relationship holds true when blasting a relatively rough casting surface covered with sand; however, it does suggest that the angle of impact of most of the blast stream in any blast application should be kept as high as possible, preferably 45° or more (cleaning ability of the abrasives declines dramatically at impact angles below 30°). This is especially true when large, flat surfaces are being cleaned such as those encountered with large castings.

Abrasive Parameters. As a general rule, the choice of abrasive size and shape for a given cleaning job is based on past experience with similar castings or by a trial and error specimen blast by the vendor at his demonstration facility.

Both methods meet, for the most part, industry needs; however, as with all modern technologies, a better understanding of the dynamics of abrasive blasting can result in a more efficient application of a blast medium to a part.

Cleaning efficiency is determined by supplying a sufficient amount of energy per particle to crush or dig out a surface contaminant and a sufficient number of impacts per area unit to completely remove all the surface contaminant. Figure 21 shows the particles per pound for different size abrasives. In practice, a given shot size consists of a mix of several sizes. However, these charts can be useful in determining the approximate shot size needed in certain cases.

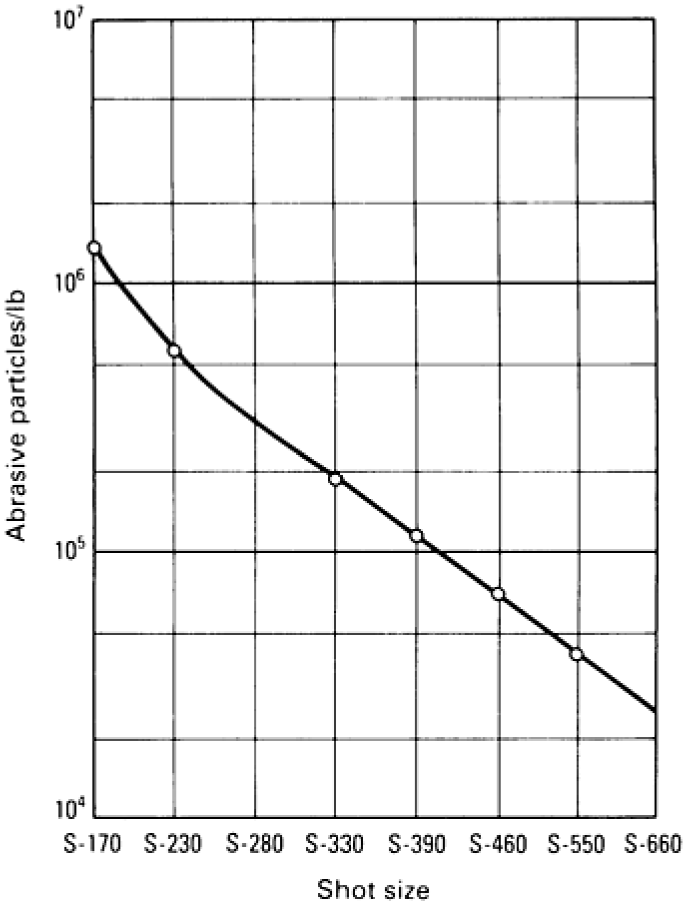

Fig. 21 Abrasive particles per pound versus shot size.

The following equation can be used to obtain the abrasive particle count per pound:

$$particles/lb = \frac{1}{\left[\frac{p\,(size)^3}{6}\right]0.28} \qquad \textbf{(Eq 10)}$$

Thus, for an S-280 shot size (the nominal size is approximated as 0.0280 in.), Eq 10 becomes:

$$particles/lb = \frac{1}{\left[\frac{3.14(0.0280)^3}{6}\right]0.28} = \frac{6.824}{(0.0280)^3} = 3.12 \text{ x } 10^5 = 312000$$

For example, given a tumbling barrel machine with a 457 mm (18 in.) curved-vane centrifugal wheel, driven by a 37 kW (50 hp) motor, using S-460 shot, at an abrasive velocity of 73 m/s (240 ft/s), the capacity of the abrasive system is 45 Mg/h (100,000 lb/h). Assuming that the parameters, such as the stream pattern, impact intensity, and coverage are optimum, the only way to increase production of this machine is to increase the wheel hp.

The flow in kg/h (lb/h) for a 457 mm (18 in.), 37 kW (50 hp), curved-vane wheel at 73 m/s (240 ft/s) is 36,600 (80,600), whereas, if we increase the motor output to 56 kW (75 hp), the flow equals 55.8 Mg/h (123,000 lb/h), which is a 10.4 Mg/h (23,000 lb/h) higher flow rate than the abrasive system can handle. A possible solution to this follows.

Because the wheel is V-belt driven, angular velocity of the wheel rpm and the velocity of the abrasive can be increased. Because the impact intensity of S-460 at 73 m/s (240 ft/s) is assumed to be optimum, Fig. 22 shows that if the velocity of S-390 is increased to approximately 93.6 m/s (307 ft/s), the energy per particle 0.0173 J (0.0128 ft · lbf) is equal to the energy of an S-460 particle at 73 m/s (240 ft/s). Figure 17 shows that for 93.6 m/s (307 ft/s) velocity, the flow is 631 kg/h/kW (1039 lb/h/hp). If the speed of the wheel rpm is increased to 2700 rpm, the total flow will be 33.4 Mg/h (73,665 lb/h), well within the 45 Mg/h (100,000 lb/h) abrasive-system capacity. At 37 kW (50 hp), total impact per second for S-460 is (Fig. 21):

$$\left(\frac{70000\,particles}{lb}\right)\left(\frac{80600\,lb/h}{3600}\right) = 1567222\,impacts/s$$

At 56 kW (75 hp) impacts per second for S-390 is 2,352,921, or 2,352,921/1,567,222 = 1.50. This is 50% more impacts each at the same S-460 impact energy per particle. Thus, we have increased the cleaning energy and coverage by 50% by changing only the speed, horsepower, and abrasive size, without having to change the abrasive handling system.

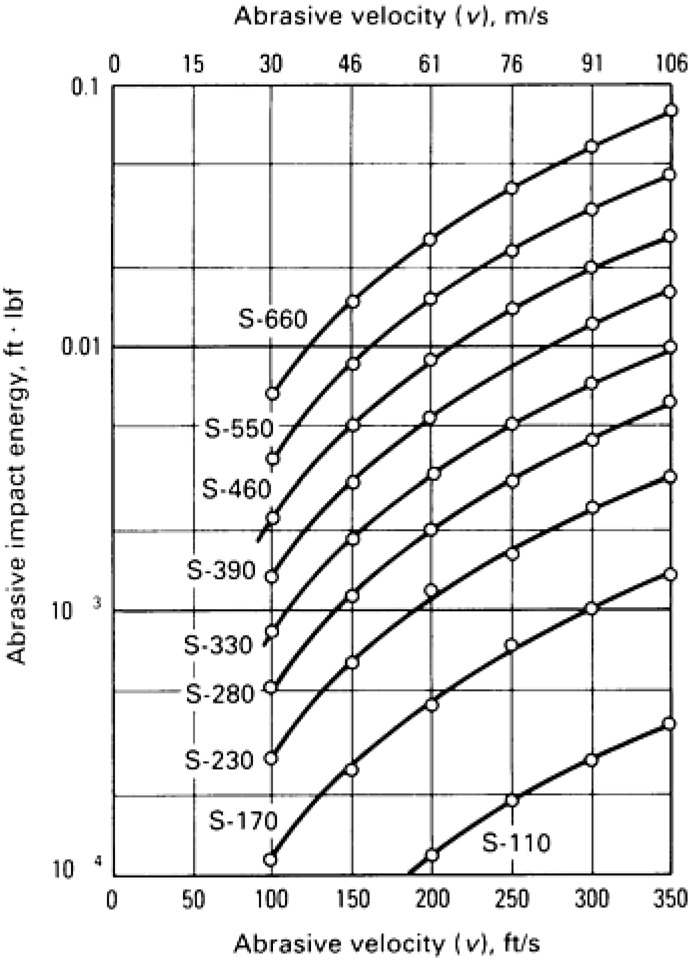

Fig. 22 Abrasive impact energy versus abrasive velocity for various shot sizes. Impact intensity at 73 m/s (240

ft/s) is considered standard.

V-belt driven wheels in the 457 to 533 mm (18 to 21 in.) diam range usually cannot be safely operated above the 2500 to 2700 rpm range (this can be checked with the equipment manufacturer) or above a maximum abrasive velocity of approximately 85 to 95 m/s (280 to 310 ft/s). It can be seen from Fig. 22 that only with sizes S-660 to S-330 can the abrasive size be reduced one size and retain the same kinetic energy per particle as at 73 m/s (240 ft/s). Of course, it may not be necessary or desirable to have the energy levels the same, and in reality it is impossible to regulate energy levels precisely. However, these graphs give an approximate idea of the energy changes made when the abrasive velocity and abrasive size are changed.

All of the above assumes that each abrasive size contains all the same size particles. As already pointed out in the tables in the discussion in "Abrasives" in this section of this article, a designated abrasive size, for example, S-460, contains a mix of sizes within a specified range. Therefore, the above illustration is not precise; however, it is useful as an approximate way to determine size changes that may be required when abrasive velocity is changed.

Other factors to consider when changing abrasive velocity to a higher speed are abrasive breakdown and wear on machine components. For example, if S-460 is used at 73 m/s (240 ft/s), the flow is 1035 $kg/h/kW_{net}$ (1700 $lb/h/hp_{net}$) (Fig. 17). The breakdown at 73 m/s (240 ft/s), as obtained from test data, is 0.000285 for a breakdown per hp_{net} of (1700) (0.000285) = 0.485 lb/h (0.220 kg/h). If the abrasive velocity is changed to 94 m/s (310 ft/s), the flow will be 617 $kg/h/kW_{net}$ (1015 $lb/h/hp_{net}$). If the abrasive is changed to S-390 at 94 m/s (310 ft/s), the breakdown per hp_{net}, as obtained from test data, is (1015) (0.00051) = 0.517, or approximately $\frac{1}{2}$ $lb/hp_{net}/h$, which is approximately the same as the original S-460 breakdown. Laboratory testing has shown that the wear rate on cabinet wear liners in direct-blast operations is approximately proportional to the breakdown rate of shot.

The wear rate of chrome-molybdenum iron or Hadfield manganese steel is 2.7 times greater with S-550 shot than it is with S-110 shot. Again, these data show that if the abrasive velocity is increased, in most cases it is wise to decrease the abrasive size. This usually decreases the wear on the cabinet interior parts and also increases the abrasive coverage.

Cleaning Internal Surfaces

Many times when cleaning castings it is important to clean internal surfaces such as the water passages in engine heads and blocks or other surfaces that cannot be impacted directly because of the casting configuration. In these cases, ricocheting abrasive must do the cleaning. To clean internal surfaces, it is usually important to drain the internal passages while blasting so that pocketed abrasive does not cushion the impact. It is also important to have sufficient ricochet velocity to remove the surface contaminants effectively.

In the majority of cases, the best way to drain internal passages is to rotate the part on a horizontal axis, as is done on axial-flow machines or other machines that incorporate horizontal rotating devices. Recent laboratory tests and field experience have shown that increasing the wheel speeds improves internal cleaning significantly.

At times, the blast from a centrifugal wheel does not effectively reach into all of the internal cavities of a casting. Often, the solution to this situation is to resort to a "spot blast," that is, use of a compressed-air nozzle to direct the blast into selected casting openings. Here again high abrasive velocity can be effective. Changing from straight nozzles to long venturi nozzles can result in abrasive velocity increases of 30% or more, or, if abrasive velocity is more important than coverage, the nozzle flow can be decreased and the velocity increased. Blast equipment manufacturers can advise nozzle users on velocity increases that are possible with different types of nozzle configurations and flow rate changes.

Welding of Cast Irons and Steels*

Chairman: Ravi Menon, Teledyne McKay

Arc Welding of Cast Irons

CAST IRONS INCLUDE a large family of ferrous alloys covering a wide range of chemical compositions and metallurgical microstructures. Some of these materials are readily welded, while others require great care to produce a sound weldment. Some cast irons are considered nonweldable. Consequently, welding procedures must be suited to the type of cast iron to be welded. Various processes for joining iron castings are described in this section, as well as the advantages and disadvantages of each. Iron castings are welded to:

- Repair defects to salvage or upgrade a casting before service
- Repair damaged or worn castings
- Fabricate castings into welded assemblies

Repair of defects in new iron castings represents the largest single application of welding cast irons. Defects such as porosity, sand inclusions, cold shuts, washouts, and shifts are commonly repaired. Fabrication errors, such as mismachining and misaligned holes, are also weld repaired. Restoration of corrosion resistance, structural integrity, or wear resistance can also be achieved by weld overlaying, repair, and/or hardfacing.

Classification of cast iron weldments by design requirements aids in the selection of welding processes and consumables. Three categories of design requirements are:

- Highly stressed welds
- Non-stress-bearing welds
- Weld overlay cladding for corrosion, abrasion, and wear resistance

Highly stressed welds should have mechanical properties that are compatible with the cast iron base metal. Non-stress-bearing welds are common where restoration of proper casting size and shape is the primary concern. Both of these categories of welds may also require good machinability and color match between the weld deposit and the iron casting. Weld overlay cladding for specific surface requirements necessitates careful selection of welding consumables and the deposition process.

The welding of simple castings to form assemblies is often more economical than casting a complex shape. Iron castings can be welded to other iron castings and to steel, nickel alloys, and many wrought shapes.

Welding Metallurgy of Cast Irons

Cast irons have carbon contents in excess of 2% and silicon in excess of $\frac{1}{2}$%. Carbon can be present in the form of eutectic graphite flakes, graphite nodules caused by modifications of eutectic graphite during solidification, pearlitic iron carbide, eutectic iron carbide, or carbon retained in a solid phase such as martensite. Carbon in the form of iron carbide is in a metastable state and can transform to graphite if the kinetics are suitable. Depending on the alloy content, melting practice, and thermal treatment, cast irons represent a wide range of alloys, including the following categories:

- White
- Malleable
- Gray
- Ductile
- Compacted graphite irons

Mechanical properties and weldability are dependent on microstructure, which is directly related to the partitioning of carbon during solidification and subsequent cooling. White iron is generally considered to be unweldable because of its extreme hardness and brittleness. Ductile iron is easier to weld than gray iron, partially because of the lower levels of sulfur and phosphorus in ductile iron. Ductile iron offers superior base metal properties; however, weaknesses that are not critical in a gray iron weldment are unacceptable in a ductile iron weldment.

White iron is cast iron in which the majority of carbon occurs as the intermetallic compound cementite (Fe_3C), a very hard constituent. White iron usually consists of a pearlitic matrix with a network of eutectic carbide. Hypereutectic irons have the greatest hardness and are more brittle. Most white irons are of hypoeutectic compositions. The white iron microstructure (Fig. 1) is a function of both alloy composition and cooling rate during solidification. Unalloyed white iron castings have a hardness of about 400 to 450 HB and must be ground to achieve required size and shape.

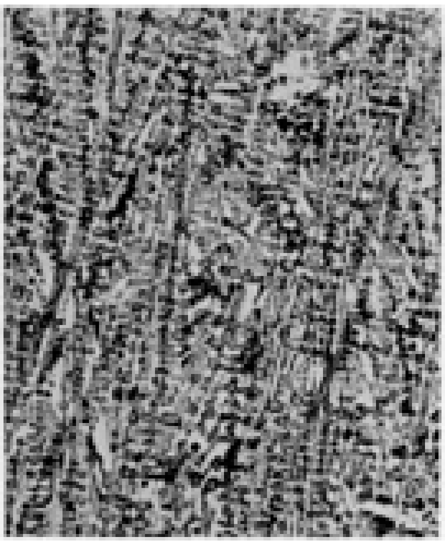

Fig. 1 Unalloyed chilled cast white iron consisting of coarse lamellar pearlite and ferrite in a matrix of M_3C carbides. 100×.

Malleable iron is heat-treated white iron in which the iron carbides are dissociated when annealed at a temperature above 870 °C (1600 °F) for periods greater than 6 h. Irregularly shaped graphite nodules are precipitated and grow in the solid iron. Figure 2 shows a typical malleable iron microstructure.

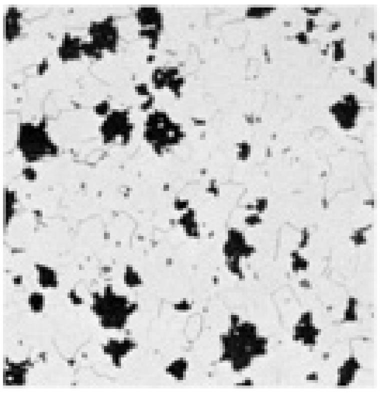

Fig. 2 ASTM A602 grade M3210, ferritic malleable iron. Two-stage annealed by holding 4 h at 955 °C (1750 °F), cooling to 705 °C (1300 °F) in 6 h, and air cooling. Type III graphite (temper carbon) nodules in a matrix of granular ferrite; small gray particles are manganese sulfide. 100×.

Gray cast irons are alloys of iron, carbon, and silicon in which the separation of excess carbon from the liquid during solidification takes the form of graphite flakes, as shown in Fig. 3. Silicon and slow cooling rates promote graphitization in the iron. The low toughness and ductility of graphitic cast iron is neither a direct result of the brittleness of the graphite flakes nor a result of the large proportion of graphite. The continuity of the ductile matrix is interrupted by the shape and distribution of these graphite flakes, resulting in low toughness and ductility. Some castings have insufficient silicon content or cool too quickly to achieve a completely graphitic structure. This results in a white iron microstructure at the surface and a gray iron microstructure at the center; such castings are called mottled iron.

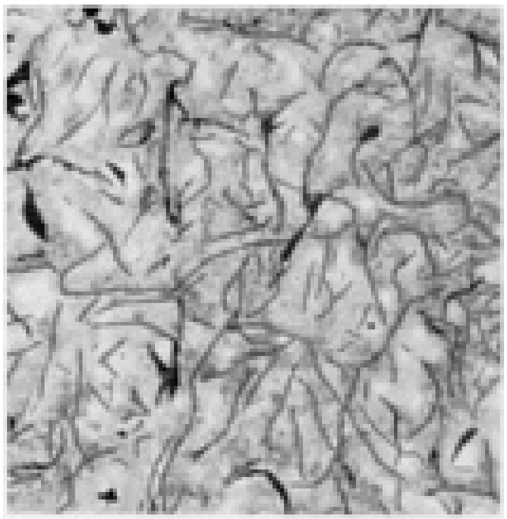

Fig. 3 Class 30 as-cast gray iron in a sand mold. Structure: type A graphite flakes in a matrix of 20% free ferrite (light constituent) and 80% pearlite (dark constituent). 100×.

Ductile cast iron, also known as nodular iron or spheroidal graphite iron, has graphite present as small spheroids instead of flakes (Fig. 4). The spheroidal graphite structure is produced by ladle or mold additions (that is, magnesium and/or rare earths such as cerium) to certain molten gray iron compositions. To achieve favorable mechanical properties, graphite in spheroidal form can be dispersed, causing minimal interruption of the continuity of the metallic matrix. Ductile cast irons combine the principal advantages of gray iron, such as excellent machinability, with the engineering advantages of steel, such as high strength, toughness, ductility, hot workability, and hardenability.

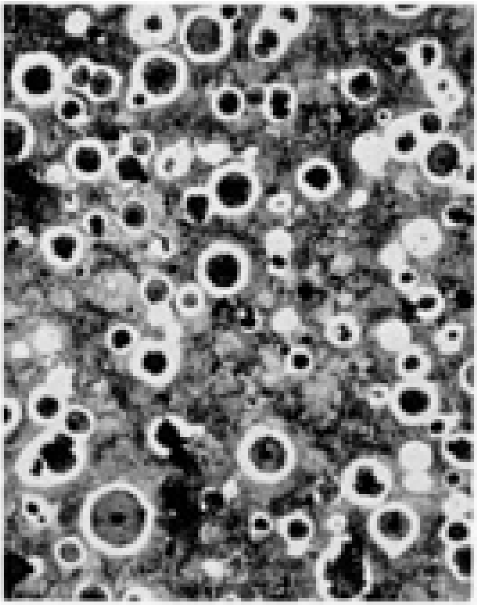

Fig. 4 Grade 80-55-06 as-cast ductile iron. Graphite nodules in envelopes of free ferrite in a matrix of pearlite. 100×.

Compacted graphite or vermicular graphite irons have structure and properties that are between those of gray and ductile irons, as shown in Fig. 5. The graphite forms interconnected flakes as in gray iron; but the flakes are thicker, and their edges are blunted. This graphite flake shape provides for higher strength levels than gray irons and greater machinability than ductile irons. Graphitic irons are classified according to their graphite shape (ASTM A 247). The matrix and graphite shape must be defined to identify the specific type of cast iron. For example, flake graphite in a pearlitic matrix is termed pearlitic gray iron.

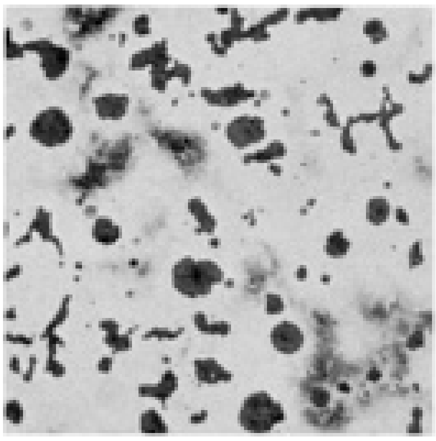

Fig. 5 Compacted graphite cast iron microstructure. Type I graphite (spherulites) and type III graphite (vermicular) in matrix of ferrite and pearlite. 100×.

Chemical composition limits for some cast irons are given in Table 1. The influence of alloy additions and contaminants on cast iron microstructure and properties is important in the selection of the proper welding process, consumables, variables, and procedures. Additional information on cast iron materials and their properties is available in the Section "Ferrous Casting Alloys" in this Volume.

Table 1 Chemical composition limits for cast irons

Type	**ASTM specification**	Compositions limits, %					
		C	**Si**	**Mn**	**S**	**P**	Other

Microstructure

Cast irons have varied microstructures and physical properties, resulting in marked differences in weldability. Variations in thermal gradients across the weldment result in varying microstructures and properties. The various microstructures are classified into different zones and regions, as shown in Fig. 6. The nature and size of these zones in cast iron weldments are determined by the thermal weld cycle, the composition of the base metal, and the welding consumables. To develop welding procedures that minimize the deleterious effects of these zones, the influence of welding variables on mechanical properties must be considered.

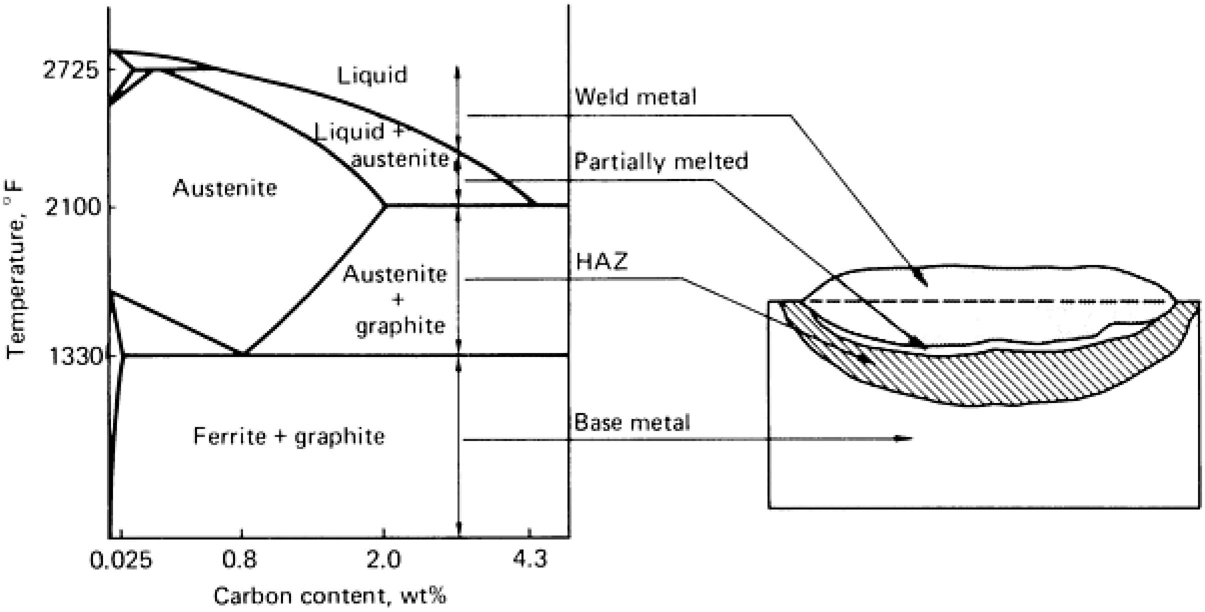

Fig. 6 Schematic representation of the zones in a typical cast iron welding.

Heat-Affected Zone (HAZ)

Welding of cast irons is characterized by rapid cooling as compared to cooling rates during casting. Consequently, properties of the weld and the sections of the casting exposed to elevated temperatures (the HAZ) differ from the remainder of the casting. Portions of the cast iron HAZ reach temperatures during welding that cause the carbon to diffuse into the austenite. Upon cooling, this austenite transforms into hard eutectoid decomposition products such as martensite. The amount of martensite formed depends on the cast iron composition and thermal treatment. Ferritic cast irons contain most of their carbon in the form of graphite, which dissolves slowly, thus producing less martensite. The highest percentage of carbon in pearlitic cast irons is finely divided into the pearlitic structure. This carbon dissolves readily, producing a large amount of martensite. The brittle martensite can be tempered to a lower strength, more ductile structure through preheating and interpass temperature control, multiplepass welding, or postweld heat treatments such as stress-relief annealing. Hardness in the HAZ ranges from 250 to 650 HB, with most of the area below 450 HB. Some welding procedures are designed to reduce the size of the HAZ and thus minimize cracking. Methods of accomplishing this are reduction of heat input, use of small-diameter electrodes, use of low-melting welding rods and wires, and use of lower preheat temperatures. Typical HAZ widths are in the range of 0.8 to 2.5 mm (0.03 to 0.10 in.).

Partially Melted Region

The partially melted region of a weldment is an extension of the HAZ that occurs where a high peak temperature has caused partial melting of the base metal near the fusion line. The effects of this region on the mechanical properties of ductile iron welds must be taken into account to produce successful welds. The liquid in the partially melted region is similar to liquid eutectic cast iron, which freezes as white iron because of the high cooling rates during the weld heat cycle. The microstructure of the partially melted region is complex and consists of a mixture of martensite, austenite, primary carbide, and ledeburite that surrounds partially dissolved nodules or flakes of graphite. If the amount of dissolved graphite is great enough to form an almost continuous molten matrix, the carbide network is also continuous; less extensive melting produces a discontinuous carbide structure. The partially melted region, which contains a great proportion of hard products, is the hardest zone in the weld.

The high hardness and consequent low toughness of the partially melted region adjacent to the fusion line create mechanical problems in the welding of cast iron. The formation of hard structures results from the transport of carbon from graphite particles into the adjacent matrix. Reduction of peak temperatures and time at high temperature is the most effective method of reducing cracking. This can be done by controlling the heat input, preheat, and interpass temperatures.

Low-melting filler materials can also alleviate fusion line cracking by reducing peak temperatures. If a weldment is sufficiently small, a large heat input may raise base metal temperatures enough to cause severe fusion line problems even though no preheat is used. Conversely, a high preheat temperature used to prevent martensite in the HAZ and to reduce the thermal expansion stresses may result in fusion line cracking even with low heat input. Therefore, trial-and-error procedure development may be necessary. A welding procedure that successfully incorporates the partially melted region and HAZ can produce joints with good mechanical properties.

Fusion Zone

The fusion zone microstructure and properties are primarily influenced by the selection of the welding consumables. The fusion zone composition consists of melted welding electrode or wire with some dilution from the iron casting. The weld pool is mixed during the welding process to produce a relatively uniform composition within each weld bead. Dilution should be kept to a minimum. The fusion zone should be machinable, below 300 HB in hardness. If color match between the weld and the base metal is important, filler metal compositions that match the cast iron must be used.

Welding Procedures and Processes

More than 90% of all industrial welding of cast iron is done by arc welding processes. Arc welding has a lower heat input than oxyfuel gas welding because of a faster welding speed and higher deposition rate. The welding operation can be automated to varying degrees, and distortion due to welding heat is more readily controlled. Arc welding achieves temperatures in excess of those required for fusion of the base metal (~3000 °C, or 6000 °F). The intensity of the heat source allows the necessary fusion while heating only a small portion of the weldment. This may cause high cooling rates and may result in large thermal expansion and contraction stresses. However, arc welding processes can produce welds of good quality with proper selection of the welding process, consumables, and procedures. Detailed descriptions of the various processes described below are given in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook.*

Shielded metal arc welding (SMAW), the most widely used and best known process, has the advantages of a large selection of consumables, good availability, low-cost power supplies, and all-position welding. The disadvantages include a higher cost per pound of weld metal deposited and an associated low rate of deposition. These disadvantages are not important in a low-volume or maintenance application.

Gas metal arc welding (GMAW) has limited use, and its advantages include a high deposition rate and efficiency. Several disadvantages are limited selection of consumables, shielding gas, higher power source cost, and need for wire-feeding equipment. Gas metal arc welding can be operated in various metal transfer modes, including globular, pulsing, spray, and short circuiting. The spray transfer mode is characterized by a relatively high heat input, high deposition rate, and use in high-volume operations, but can be used only in the flat or horizontal position. The short circuiting transfer mode is characterized by lower heat input, moderate deposition rate, and the capability of operating in all positions.

Flux cored arc welding (FCAW), which is growing in usage, has advantages and disadvantages similar to those of gas metal arc welding in the spray transfer mode. The slag coverage provides the advantages of better protection during cooling, improved wetting of the bead at corners, an out-of-position weld capability, and chemical refinement of the weld deposit. In many applications, flux cored arc welding has higher deposition rates than gas metal arc welding, particularly for out-of-position welding. Disadvantages include the added step of removing the slag and a lower deposition efficiency.

Gas tungsten arc welding (GTAW) is generally used to repair smaller parts. Advantages include the capacity to operate at low power levels, all-position capability, and superior control of heat input. Gas tungsten arc welding is the only process that can be used to repair a broken part without the addition of filler metal. Some disadvantages are the very low deposition rate, expensive and complicated power supply, the need for greater welder skill level, and the need for a shielding gas.

Submerged arc welding (SAW) has several advantages: very low fume, no arc flash, very high deposition rate and efficiency, and low cost per pound of deposit. Disadvantages include expensive equipment, the need for flux, and operation in the flat position only. This process generates the highest heat input for welding processes used for cast irons, which leads to the greatest dilution and widest HAZ. However, when comparing the same size wire, it has a lower heat input than gas metal arc welding in the spray transfer mode. Submerged arc welding has limited application to iron castings and is usually used for weld overlay cladding of cast iron.

Consumables

Filler Metals for Shielded Metal Arc Welding of Cast Irons. A variety of covered electrodes are used for the shielded metal arc welding of iron castings. Economic considerations and weld requirements determine the appropriate product for each application. Electrodes designed specifically for welding iron castings are described in American Welding Society (AWS) Specification A5.15.

Covered electrodes utilizing a cast iron rod as the core are classified by AWS as ECI. They are of comparative low cost and produce a weldment with chemical and mechanical properties similar to those of the base metal. Color match is excellent; however, ease of operation of these products is marginal, and appropriate procedures must be followed closely to ensure weld quality. If a cast iron electrode is used, graphite flakes or spheroids form in the weld during cooling. The ductility of a repaired malleable or ductile iron casting may be less than that of an unrepaired part.

Electrodes using steel as a core wire but depositing a cast iron type of deposit are similar in usage to the ECI electrodes. These products, classified as ESt, are generally of higher quality because they are produced by extrusion techniques. Welding procedures must be followed closely to avoid brittle or cracked weldments. Because of their ease of operation, widespread availability, and low cost, low-hydrogen types of covered electrodes, for example, E7015, E7106, E7018, and E7028, are used for welding iron castings. Color match is excellent. When these steel products are deposited on cast iron, the resulting first-pass weld deposit has a high carbon content of approximately 0.8 to 1.5%. The weldment is a high-carbon steel and can be quite brittle and crack sensitive. As a result, the use of these products is limited to cosmetic repairs in nonstructural areas and applications where machining is not required.

Austenitic stainless steel electrodes such as AWS A5.4 classes E308, E309, E310, and E312 have seen some application for welding iron castings. However, because of chromium carbide formation in the weld and tearing due to differences in strength and coefficient of expansion, use of these products is marginal, and extreme care should be exercised with their use.

Nickel-base electrodes have been widely accepted for the welding of iron castings. Unlike iron, nickel has a low solubility for carbon in the solid state. Thus, as the weld pool solidifies and cools, carbon is rejected from the solution and precipitates as graphite. This reaction increases the volume of the weld deposit, thus offsetting shrinkage stresses and lessening the likelihood of fusion zone cracking.

Electrodes classified as ENi-CI utilize a commercially pure nickel-core wire and thus produce a deposit of high nickel content. Even when highly diluted by the base metal, the deposit remains ductile and machinable. ENiFe-CI electrodes produce a nickel-iron deposit and, as a result, have four distinct advantages over the ENi-CI electrodes:

- The deposits are stronger and more ductile; this increased strength level makes the product suitable for welding the higher strength gray and ductile irons, as well as for many dissimilar-metal joint applications
- Nickel-iron deposits are more tolerant of phosphorus than nickel deposits; thus, ENiFe-CI electrodes are preferred for welding gray iron castings with higher phosphorus contents
- The coefficient of expansion of the nickel-iron deposit is somewhat less than that of the nickel deposit; therefore, nickel-iron products can be used to weld heavier sections while still avoiding fusion line cracking due to expansion differences
- ENiFe-CI electrodes are generally less expensive than ENi-CI electrodes

Welding current ranges for the shielded metal arc welding of cast iron with nickel-iron and nickel electrodes are given in Table 2. For nickel-iron electrodes, the welding current should be reduced 5 to 15 A for overhead welding and 10 to 20 A for vertical welding from the values listed in Table 2.

Table 2 Welding current ranges for the shielded metal arc welding of cast iron with nickel-iron and nickel electrodes

For welding in the flat position, current for overhead welding should be 5-15 A less than shown; for vertical welding, 10-20 A.

Electrode diameter	**ENiFe-CI electrodes[a]**	ENi-CI electrodes[b]

mm	in.	Current (dc)(c), A	Current (ac), A	Current (dc)(c), A	Current (ac), A
2.5	$\frac{3}{32}$	40-70	40-70	40-80	**40-80**
3.2	$\frac{1}{8}$	70-100	70-100	80-110	**70-110**
4.0	$\frac{5}{32}$	100-140	110-140	110-140	**110-150**
4.5	$\frac{3}{16}$	**120-180**	**130-180**	**120-160**	**120-170**

(a) Percentage composition, based on analysis of deposit on standard test pad: 2.00 C, 4.00 Si, 1.00 Mn, 0.03 S, 45-60 Ni, 2.50 Cu, 1.00 other, rem Fe.

(b) Percentage composition, based on analysis of deposit on standard test pad: 2.00 C, 4.00 Si, 1.00 Mn, 0.03 S, 8.00 Fe, 85 min Ni, 2.50 Cu.

(c) Either polarity

Electrodes with a nickel-copper deposit classified as ENiCu-A and ENiCu-B have limited use for welding iron castings. Because of the sensitivity of their deposit to iron dilution, they have been replaced for the most part by the ENi-CI and ENiFe-CI products.

Copper-Base Electrodes. Bronze covered electrodes, which are of the copper-tin or copper-aluminum type, are used for welding iron castings. A low melting point allows their use at low current level, thus minimizing dilution and the effect of heat on the base metal. Although deposits are soft and machinable, color match is poor. Care must be exercised when using these electrodes because excessive dilution and contamination readily cause cracking.

Filler Metals for Gas Metal Arc, Gas Tungsten Arc, and Submerged Arc Welding of Cast Irons. In general, bare wires of chemical composition similar to that of the covered electrodes are used for cast iron welding. The same cautions hold for the solid wire as those listed for the covered electrodes.

Carbon steel filler metals are used for welding iron castings because they are economical and readily available. Because the diluted weld deposit is brittle, use of these products is limited to cosmetic, non-stress-bearing, and nonmachined welds. American Welding Society Specification A5.18 class ER70S-6 materials are the most frequently used products. The high silicon content of the wire (0.80 to 1.15% Si) helps deoxidize the weld pool and improves weld metal flow and wetting of the base metal.

Austenitic stainless steel filler metals are sometimes applied to the welding of iron castings. However, their use should be limited because of the same problems that occur with stainless steel electrodes. These products are classified in AWS A5.9.

American Welding Society Specification A5.14 class ENi-1 nickel wire is commonly used for welding iron castings. As discussed previously, the deposits are relatively strong, machinable, and free of fissuring. Nickel-iron and nickel-iron-manganese filler metals are sold under proprietary labels. Because these products are not classified by specification, they

should be judged on their own merits. Welding condition ranges for the gas metal arc welding of cast irons with nickel-iron and nickel wire electrodes are given in Table 3.

Table 3 Welding conditions for the GMAW and FCAW of cast iron

Electrode	**Wire diameter**		**Process**	**Voltage**	Current
	mm	**in.**			
Spray transfer					
Nickel-iron wire	1.1	0.045	GMAW[(a)]	30-32	**170-260 DCEP**
	2.0	0.078	FCAW[(b)]	28-30	**275-325**
	2.4	0.093	FCAW[(b)]	28-32	**300-375**

(a) Pure argon shielding gas.

(b) Self-shielding, but CO_2 shielding is optional

Filler Metals for Flux Cored Arc Welding of Cast Irons. Flux cored filler metal products that produce deposits with compositions paralleling covered electrodes are available. Because they combine the best features of coated electrodes and solid wire processes, they are increasing in popularity and variety. Welding condition ranges for the welding of cast iron with nickel-iron flux cored electrodes are given in Table 3.

A proprietary nickel-iron-manganese flux cored filler metal is gaining widespread use for welding iron castings. This filler metal produces a deposit that is similar in composition to ENiFe-CI except for a higher level of manganese. It is extremely crack resistant and capable of high deposition rates. Applications are similar to those of ENiFe-CI.

Steel flux cored electrodes, specified in AWS A5.20 and A5.22 are also used to weld iron castings. Use of these electrodes is subject to the same precautions as described for covered electrodes with similar composition.

Preparation for Welding

Proper preparation of the casting prior to welding is extremely important. When a defect is being repair welded, the defect must first be removed, usually by grinding, gouging, or machining. Attempting to weld over a defect, instead of removing it completely, usually results in poor weld quality. When the defect is a crack contained within the material, a 3.2 mm ($\frac{1}{8}$ in.) diam hole should be drilled at each end of the crack prior to preparation to prevent crack propagation. Air carbon arc gouging is successfully used on iron castings for removing defects; however, at least 1.6 mm ($\frac{1}{16}$ in.) of additional material should be removed from the arc-gouged surface by grinding to eliminate the resultant high-hardness layer.

The second step consists of inspecting the area to ensure that the defect has been completely removed prior to welding. The liquid penetrant inspection process is an excellent method of detecting small defects (cracks, pores, shrinkage) that are not readily visible to the naked eye. Low-phosphorus-containing penetrants should be used with nickel consumables.

When the defect is completely removed, the preparation of the joint should be completed. A minimum of 60° included angle is generally required for virtually all of the filler metals and processes listed in this section, and 70° is recommended for most of them. Ends of narrow grooves completely contained within a surface should be beveled to facilitate good fusion in those areas. The size of the weld joint must be kept to a minimum to reduce stress levels resulting from mismatch of thermal contraction rates between weld metal and base metal. The load-carrying ability of a cast iron weldment can be improved through proper joint design. Joints with incomplete penetration reduce load-carrying cross-sectional thicknesses and create potential stress concentrations beneath the weld bead. If possible, the weld joint should be located away from a highly stressed area, especially where there is a change in section thickness. If possible, welded joints should be loaded in compression, torsion, or shear rather than in tension or bending.

Prior to welding, the casting should be thoroughly cleaned in the area of the weld. If the casting was exposed to dirt, grease, or paint in service, these contaminants must be completely removed from the weld joint, including the back or root side of any full-penetration welds. Repeated degreasing with a good solvent is necessary for castings exposed to grease and oil. Heating the casting to 370 to 480 °C (700 to 900 °F) for 15 to 30 min aids removal of oil and grease impregnated in the casting, followed by mechanical cleaning and additional degreasing with solvent. The surface (skin) of the casting should also be removed in the immediate area of the weld, because of contaminants (burned-in sand, dirt, paint) that cause poor-quality welds. All liquid penetrant and developer applied during the inspection operations should be completely removed before welding.

Prior to repair welding, all closed chambers within the casting should be vented before heating to prevent pressure buildup, and distortion and stresses caused by heating and cooling should be minimized. Drilling small holes into cored areas and forming internal passages for venting relieves excessive pressure buildup. Welding a groove from both sides minimizes distortion. If this is not possible, the part must be restrained during welding to minimize distortion. Peening or preheating can be used to prevent cracking of the weld during cooling.

Preheat and Interpass Temperature

In many cases, preheating is not needed to produce an acceptable weld, but can be used to reduce the thermal gradient and conductivity and to decrease the rate of cooling. Preheating is also useful in reducing differential mass effects, such as those encountered when welds are made between light and heavy sections. A thorough analysis and judicious use of preheating for each shape enable the welder to obtain a uniform cooling rate and thus reduce cooling stresses (Fig. 7). A fundamental preheating rule is illustrated in Fig. 7; the preheat is applied in a manner such that upon cooling, the weld is under compressive stress. Preheating in the areas indicated in Fig. 7(b) expands the metal. Thus, the crack is expanded. After welding, the weld is in compression as the part cools and the metal shrinks (Fig. 7d).

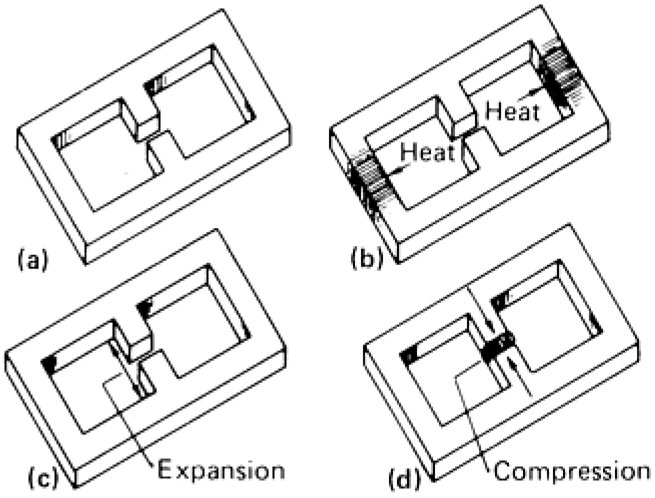

Fig. 7 Preheating of castings. The specific part should be heated such that the weld is under compressive stress upon cooling.

The major concerns with use of excessive preheat temperature are the resulting amount of unnecessary base metal melted, a larger HAZ, and the formation of massive continuous carbides along the fusion line. Cast iron welding requires careful selection of a preheat temperature if the weldment is expected to have the same mechanical properties as the unaffected base metal. Advantages of preheating are most evident in the welding of gray iron. Continuous carbides are not a major concern, because gray iron is already brittle due to its discontinuous flake graphite microstructure. The influence of preheating on the hardness of gray iron weldments made by shielded metal arc welding using ENiFe-CI (nickel-iron) type electrodes is listed in Table 4. Preheating of gray iron is effective in reducing excessive thermal contraction mismatch, thus avoiding fracture during cooling.

Table 4 Effect of preheat on hardness of shielded metal arc welds in class 20 gray iron welded with 4.8 mm ($\frac{3}{16}$ in.) nickel-iron (ENiFe-CI) electrodes

Preheat temperature		Hardness, HB		
°C	**°F**	**Weld**	**HAZ**	Base metal
No preheat		342-362	426-480	**165-169**
105	225	297-362	404-426	**165-169**
230	450	305-340	362-404	**169**
315	**600**	**185-228**	**255-322**	**169-176**

The actual preheating temperature range that is best suited to a specific application depends on the hardenability of the base metal, the size and complexity of the weldment, and the type of electrodes to be used. Table 5 lists typical preheat temperatures necessary to achieve a specific type of microstructure in the HAZ of cast iron.

Table 5 Influence of preheat on HAZ of cast irons

Preheat temperature		Resulting microstructure
°C	**°F**	
20	70	**Martensite**
100	210	**Pearlite transformation occurs.**
200	390	**A greater proportion of martensite and carbides are replaced by pearlite.**
300	570	**Almost all martensite is replaced by pearlite.**
400	**750**	**All martensite is prevented.**

Preheat temperatures for both gray and ductile iron are usually above the martensite start, M_s, temperature; however, to prevent martensite formation in the HAZ, temperatures for gray iron are typically higher than those for ductile iron. If preheat is required, a temperature of 370 °C (700 °F) is typically used for welding gray iron. Temperatures in the 595 to 650 °C (1100 to 1200 °F) range may be necessary when welding very heavy sections because of the heat sinks caused by the large mass of metal. Temperatures as high as 870 °C (1600 °F) can be used in some cases, as in the welding of high-alloy cast irons. The amount of area preheated and the time of preheating become more significant with increasing size of the part to be welded.

When welding ductile iron, the selection of an optimum preheating temperature is more complex. Preheating is not always beneficial or necessary. Preheat temperatures as low as 150 to 175 °C (300 to 350 °F) are preferred when high thermal stresses are expected. At temperatures above 315 °C (600 °F), continuous carbides often form along the fusion line. Preheat temperatures above 315 °C (600 °F) may be necessary, however, for production welding where higher deposition rates are required and for welding of heavy sections. Also, temperatures as high as 480 to 705 °C (900 to 1300 °F) can be used to offset the chill effect caused by decreasing carbon content in the liquid metal when producing a spheroidal-graphite cast iron fusion zone. In such cases, heat input must be reduced to minimize the formation of continuous carbides. The choice of a preheat temperature depends on several factors, and no single temperature is satisfactory for all base metal shapes and compositions under all welding conditions.

The martensite formed in the weld deposit and the HAZ behaves in the same way as the martensite in a quenched steel. Martensite can be transformed into softer products by tempering. In multiple-pass weldments, some tempering of the previous layers occurs as each subsequent layer is deposited, causing a fluctuation in hardness measured over the height of the joint. Heat of welding in single-pass arc welding does not temper the martensite enough to provide reasonable machinability or reduce the danger of postweld cracking. Welds should be made with at least two passes to produce good machinability. The interpass temperature should exceed the preheat temperature by more than 40 °C (100 °F) to prevent additional martensite formation and to capitalize on the tempering effect of later deposits. The alternative to tempering is to decrease the amount of martensite by reducing heat input to produce a narrower HAZ.

Welding Techniques

Heat Input. One method of controlling or minimizing heat input is by the selection of the type of weld bead deposited. Of the two predominant types of weld beads, stringer and weave, the stringer bead is preferred because heat input is minimized. If weave beads are required, the weave should not exceed two or three times the electrode diameter.

Short Weld Sequence. Another method for controlling weld heat buildup is to deposit small weld beads in various portions of the weld joint and to allow each weld bead to cool to approximately 40 °C (100 °F), as shown in Fig. 8. A sequence of short welds helps to avoid the cumulative stresses that occur with long weld beads. Peening these short welds

before they cool deforms or works the metal and reduces stress. This technique allows the welder to deposit a weld bead in another location while a previous weld bead cools.

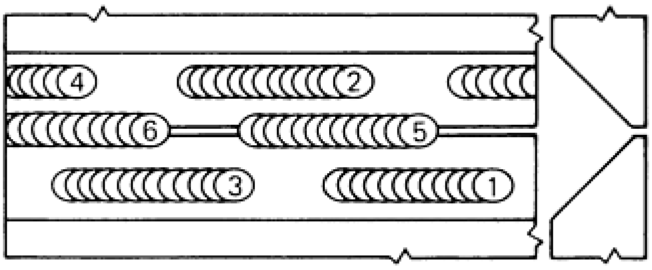

Fig. 8 Use of short weld beads to avoid cumulative stresses.

The backstep technique reduces transverse and longitudinal weld shrinkage stress. This technique utilizes short weld beads, which are deposited as shown in Fig. 9. The first weld bead is deposited with a short length of about 50 to 75 mm (2 to 3 in.) and 50 to 75 mm (2 to 3 in.) inward from the edge of the weld joint. Subsequent weld beads are deposited inward from the previously deposited weld bead. All weld beads should overlap and should be deposited in the same direction.

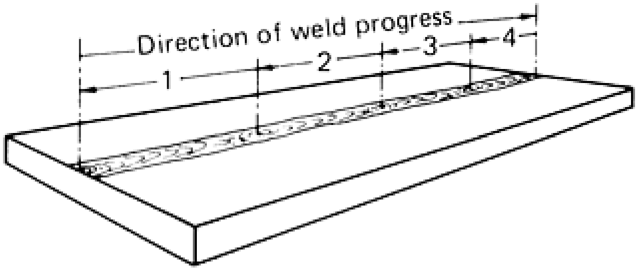

Fig. 9 Backstep sequence.

The block and cascade techniques can also be used to minimize shrinkage stresses in large weld grooves. The block sequence utilizes a longitudinal buildup of intermittent weld blocks joined by subsequent weld blocks (Fig. 10). It reduces longitudinal weld stresses, but does not minimize transverse weld stresses. Both longitudinal and transverse shrinkage stresses are reduced with the cascade sequence (Fig. 11). The cascade technique uses a combined longitudinal and overlapping weld bead buildup sequence, as each succeeding bead tempers the one beneath or adjacent to it. The cumulative heating effect of subsequent passes provides additional tempering.

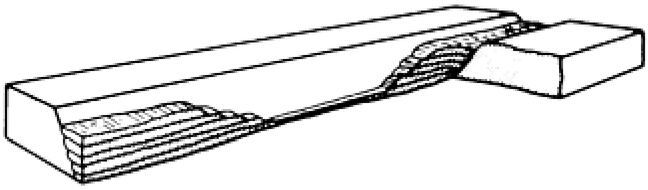

Fig. 10 Block sequence to minimize weld stress.

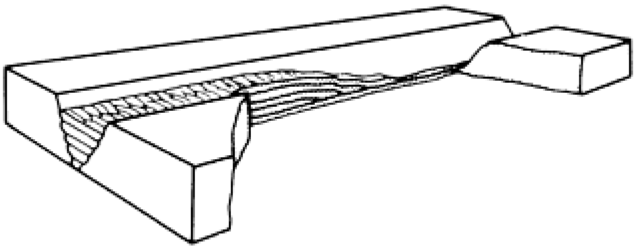

Fig. 11 Cascade sequence of reducing weld stress.

Peening. The principal effects of peening are relief of shrinkage stress, minimizing of distortion, and refinement of microstructure. Peening is best performed at temperatures that turn the metal a dull red. Peening performed below a dull red heat cold works the metal and increases susceptibility to cracking. Peening should be performed with a 13 or 19 mm ($\frac{1}{2}$ or $\frac{3}{4}$ in.) diam round-nosed hammer. Repeated moderate blows should be used instead of a few heavy blows. After peening, all slag should be removed by wire brushing before starting subsequent passes.

Welding Practices

The following general practices have been found to be useful in the welding process:

- When no preheat is used, the interpass temperature should not exceed 95 °C (200 °F)
- When preheat is used, the interpass temperature should not exceed the preheat temperature by more than 40 °C (100 °F)
- To minimize welding stresses, a backstep sequence should be used with stringer beads no more than 50 to 75 mm (2 to 3 in.) in length; each deposit should be allowed to cool to approximately 40 °C (100 °F) before making subsequent deposits
- Avoid melting more of the casting than is necessary
- Whenever possible, deposit two or more layers for best machinability
- Always strike the arc in the weld groove, never on the casting
- The arc length should be kept as short as possible, typically 3 to 5 mm ($\frac{1}{8}$ to $\frac{3}{16}$ in.)

Postweld Heat Treatment

Postweld heat treatment may be done for several reasons and can take many forms. The most common treatments are intended to eliminate the hard structures and thermal stresses formed during welding. Practical considerations may require the finished weldment to cool to room temperature before the postweld heat treatment can be started. When heat treatment is not applied immediately after welding, the casting must be cooled slowly from the welding temperature to room temperature by covering it with insulating materials. Heat treatment should be started as soon as possible, especially when brittle structures and high thermal stresses are present. In such cases, the likelihood of cracking increases as temperature decreases, and welds may fail catastrophically.

The simplest postweld heat treatments for gray, compacted graphite and ductile irons are stress relief and/or tempering, for which 1 or 2 h at 595 to 650 °C (1100 to 1200 °F) is usually sufficient. A heating and cooling rate of 55 °C/h (100 °F/h) above 315 °C (600 °F) is recommended. Holding times and postweld heat treatment temperatures are specified in Table 6. Furnace cooling rates specified in Table 6 to at least 315 °C (600 °F) are recommended before air cooling. This treatment also tempers the martensite and bainite transformation products and reduces hardness of the products by a considerable degree. When carbides are present, a full anneal may be necessary. Longer times may be needed for dissolving massive continuous carbides formed at high peak temperatures.

Table 6 Recommended postweld heat treatment practice for various types of graphitic cast irons

Treatment	**Temperature**		**Holding time, min/mm (h/in.) of thickness**	Cooling rate
	°C	**°F**		
Gray iron				
Stress relief	595-650	1100-1200	3.5 (1.5)	**Furnace cool to 315 °C (600 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Ferritize anneal	705-760	1300-1400	2.4 (1)	**Furnace cool to 315 °C (600 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Full anneal	790-900	1450-1650	2.4 (1)	**Furnace cool to 315 °C (600 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Graphitizing anneal	900-955	1650-1750	1-3 h, plus 2.4 min/mm (1 h/in.)	**Furnace cool to 315 °C (600 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Normalizing anneal	870-955	1600-1750	1-3 h, plus 2.4 min/mm (1 h/in.)	**Air cool from annealing temperature to below 480 °C (900 °F); may require stress relief**
Ductile iron				
Stress relief				
Unalloyed	510-565	950-1050	3.5 (1.5)	**Furnace cool to 315 °C (600 °F), at 55 °C/h (100 °F/h) in air from 315 °C (600 °F) to room temperature.**
Low alloy	565-595	1050-1100		
High alloy	540-650	1000-1200		
Austenitic	620-675	1150-1250		
Ferritize anneal	900-955	1650-1750	1 h plus 2.4 min/mm (1 h/in.)	**Furnace cool to 690 °C (1275 °F), hold at 690 °C (1275 °F) for 5 h plus 2.4 min/mm (1 h/in.) of thickness, furnace cool to 345 °C (650 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Full anneal	870-900	1600-1650	2.4 (1)	**Furnace cool to 345 °C (650 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**
Normalizing and tempering anneal	**900-940**	**1650-1725**	**4.8 (2)[(a)]**	**Fast cool with air to 540 to 650 °C (1000 to 1200 °F), furnace cool to 345 °C (650 °F) at 55 °C/h (100 °F/h), air cool to room temperature.**

(a) Minimum holding time

The weldment can be fully softened by a ferritize annealing process, as specified in Table 6 for gray and ductile iron. This treatment results in a ferritic matrix and tends to dissociate iron carbide and transports the carbon to the graphite. This structure has maximum machinability and ductility. This practice is common for the 60-43-18 and 65-45-12 grades of ductile iron.

Other recommended postweld heat treatment annealing practices are listed in Table 6 for the various types of graphitic cast iron. In critical applications that require radiographic inspection after heat treatment, castings are inspected before heat treatment to save unnecessary costs if an internal defect is present. Additional heat treatment information on specific cast irons can be found in *Heat Treating,* Volume 4 of the *ASM Handbook.*

Gray Irons

Because gray iron has graphite in flake form, carbon can be easily introduced into the weld pool, thus causing weld metal embrittlement. Consequently, techniques that minimize base metal dilution are recommended. Care must be taken to compensate for shrinkage stresses, and the use of low-strength filler metals helps reduce cracking without sacrificing overall joint strength.

Gray iron weldments are susceptible to the formation of porosity. This can be controlled by lowering the amount of dilution of the weld metal or by slowing the cooling rate so the gas has time to escape. Preheating helps reduce porosity and reduces the cracking tendency. A minimum preheat of 205 °C (400 °F) is recommended, but 315 °C (600 °F) is generally used.

The most common arc welding electrodes for gray iron are nickel and nickel-iron types (AWS A5.15 class ENi-CI and ENiFe-CI). These electrodes have been used with or without preheating and/or postweld heat treatment. The cast iron (ECI) and steel (ESt) types must be used with high preheats (540 °C, or 1000 °F) to avoid cracking and hard deposits. The copper-aluminum (ECuAl-Al) and copper-tin (ECuSn) types are used, but color match is poor. Copper-base welds have quality comparable to that of a brazed joint, and a preheat temperature of at least 150 °C (300 °F) must be employed. The strength of these joints is often poor, partially because of the difference in thermal expansion between the copper alloy and the gray iron. Typical tensile properties for weldments of various grades of gray iron are given in Table 7 as a function of welding process and consumable.

Table 7 Approximate tensile strength and color match obtainable in welded joints in gray iron using different processes

Based on results reported from various tests and on production experience

Process	**Filler metal**	**Base metal class**	**Tensile strength of joint**[(a)]		Color match
			MPa	**ksi**	
SMAW	ENi-CI	30	170-205	25-30	**Fair**

(a) Approximate strength expected if good welding procedures and skilled operators are used. Wide variations in strength may occur as a result of variation in welding practice or in base metal condition or size.

(b) These filler metals are not classified, but wire coils and rods of compositions equivalent to ENi-CI and ENiFe-CI are obtainable.

Ductile Irons

Ductile cast irons have greater weldability than gray irons, but require specialized welding procedures and filler materials. Pearlitic ductile iron produces a larger amount of martensite in the HAZ than ferritic ductile iron and is generally more susceptible to cracking.

Shielded metal arc welding using an ENiFe-CI (nickel-iron) electrode is the most common technique for welding ductile cast irons. Shielded metal arc welding with an ENiFe-CI electrode sometimes employs a 150 to 205 °C (300 to 400 °F) preheat; preheats up to 315 °C (600 °F) are used on large castings. Most ductile iron castings, however, do not require preheating. Electrodes should be baked according to the manufacturer's recommendation to minimize hydrogen damage and porosity. Direct current electrode positive (DCEP) is usually used at a current sufficient to produce stringer beads with a moderate traveling speed. If machinability or optimum joint properties are desired, castings should be annealed immediately after welding. Transverse joint properties of typical ductile iron weldments are listed in Table 8.

Table 8 Transverse joint properties of typical SMAW ductile iron weldments using ENiFe electrodes

(a) 595-650 °C (1100-1200 °F) for various times.

Gas metal arc welding utilizing short arc transfer with nickel (AWS ERNi-1) filler metal and pure argon shielding has been successfully used for welding ductile cast irons. Recommended welding current is 130 to 160 A at 18 to 24 V. Based on the wire-feed rate, these controls produce a short arc transfer mode, which reduces heat input and reduces the amount of HAZ carbides and martensite, but requires a preheat of 200 °C (400 °F) on heavier (>13 mm, or $\frac{1}{2}$ in.) wall castings. Ferritic ductile iron, however, can usually be welded without preheat. Typical transverse tensile strength properties obtained in 25 mm (1 in.) thick pearlitic and ferritic ductile iron test plates using this process are listed in Table 9.

Malleable Irons

During welding, the ductility of the HAZ of malleable iron is severely reduced because graphite dissolves and precipitates as carbide. Although postweld annealing softens the hardened zone, minimal ductility is regained. Despite these limitations, for certain applications, malleable iron castings can be welded satisfactorily and economically if precautions are taken. Malleable iron castings should not be repaired by welding to correct a failure caused by overstressing of the part.

Because most malleable iron castings are small, preheating is seldom used. If desired, small welded parts can be stress relieved at temperatures up to 540 °C (1000 °F). For heavy sections and highly restrained joints, preheating at

temperatures up to 150 to 205 °C (300 to 400 °F) and postweld malleablizing annealing are recommended. However, this costly practice is not always followed, especially when the design of the assembly is based on reduced strength properties of the welded joint. Because no welding procedure can satisfy all types of service conditions, each application for welding malleable iron assemblies should be carefully reviewed and tested before production is begun.

Ferritic malleable grades 32510 and 35018 have the highest weldability of the malleable irons, even though impact strength is reduced. Pearlitic malleable irons, because of their higher combined carbon content, have lower impact strength and higher cracking susceptibility when welded. Small leaks, gas holes, and other small casting defects can be repaired in grades 32510 and 35018 by arc welding. If a repaired area must be machined, arc welding should be done with a nickel-base electrode. Shielded metal arc welding using low-carbon steel and low-hydrogen electrodes at low amperage produces satisfactory welds in malleable iron. If low-carbon steel electrodes are used, the part should be annealed to reduce any increased hardness in the weld (due to carbon pickup) and in the HAZ.

White and Alloy Cast Irons

Chilled and white cast irons are abrasion-resistant cast irons having structures free of graphitic carbon. Because of their extreme hardness and brittleness, they are generally considered unweldable. Alloy irons are used in applications requiring good abrasion, corrosion, or heat resistance properties. The most important consideration of welding alloy cast iron is to achieve equivalent service properties.

Because abrasion-resistant cast irons (such as ASTM A532) have limited resistance to thermal shock, welding is generally not recommended. Welding is sometimes employed in repair operations or to attach parts to other machine components. Gas welding is preferred over arc welding because of the lessened tendency toward cracking.

Arc welding can be done with a type 310 stainless steel electrode (25Cr-20Ni) if the welded area is not subject to abrasion. This electrode minimizes cracking in the parent metal. If the welded area is subject to abrasion, an electrode that produces weld metal of the same abrasion resistance as the base metal should be used. In either case, the casting should be preheated from 315 to 480 °C (600 to 900 °F) and slowly cooled after welding by covering with insulating material. Stress relieving at 205 °C (400 °F) should follow. Unless welding is done very carefully, the weld metal may exhibit very fine cracks that may cause failure if the casting is subjected to heavy loads in service. Under most operating conditions, however, the repaired casting should perform satisfactorily.

Corrosion- and Heat-Resistant Cast Irons

Corrosion-resistant cast irons are high-silicon, high-chromium, or high-nickel irons. Specifications for many of these irons permit welding for the repair of minor casting defects. For more extensive welding, the effect of welding on the service properties of the casting should first be determined; applications of this group of cast irons are highly specialized. Because weld deposits usually need to duplicate base metal compositions, filler metals may not be generally available.

Heat-resistant cast irons provide high strength at elevated temperatures, as well as resistance to scaling. They are normally produced as flake-graphite irons, but can also be produced with the free carbon in the form of nodules or spheroids. Heat-resistant cast irons can be welded for repair of minor casting defects, but much like corrosion-resistant irons, the effects of welding on service properties must be determined before extensive welding is undertaken.

Oxyacetylene Welding of Cast Irons

Oxyacetylene welding (OAW) is widely used on gray iron, to a smaller extent on ductile iron, and only to a minor extent on malleable iron. Cast iron filler metal is melted together with the base metal to form the joint. An oxyacetylene flame has a maximum temperature of about 3300 °C (6000 °F), which is several thousand degrees less than that of a welding arc. Oxyacetylene welding is therefore slower than arc welding and results in greater total heat input and wider HAZs. This heat results in expansion and localized stress, particularly in large castings. For this reason, high preheats of 595 to 650 °C (1100 to 1200 °F) are generally used for the oxyacetylene welding of cast irons. However, for local repairs and small unrestrained castings, lower preheat temperatures, often as low as 425 °C (800 °F), are used. Depending on the mass, composition, and structure of the casting, postheating requirements vary from slow cooling for complete stress relief (620 °C, or 1150 °F) to full annealing (900 °C, or 1650 °F). Because of higher preheat, and thus lower cooling rates, oxyacetylene welding produces less hardening of the HAZ than arc welding. Cast irons that are preheated, welded, and slow cooled are readily machinable, which can be important in repair work.

Oxyacetylene welding is not recommended for the joining of malleable iron (see the discussion "Welding of Malleable and White Irons" in this section). Good results have been obtained in oxyacetylene welding ferritic ductile iron with ductile iron rods. In production welding, however, the speed of oxyacetylene welding cannot compare with that of arc welding. In addition, welds deposited by oxyacetylene welding cannot compare with that of arc welding. In addition, welds deposited by oxyacetylene welding with cast iron rods usually are less machinable than nickel or nickel-iron welds deposited by arc welding. Porosity, which is a common problem in oxyacetylene welding, can be minimized by using a slightly reducing flame.

As a general practice, oxyacetylene welding has been used on cast irons for:

- Repair of minor casting defects in gray iron and ductile iron. Minor surface blemishes in malleable irons are sometimes repaired; generally, however, oxyacetylene welding of malleable iron is avoided whenever possible
- Repair of service-incurred wear and damage mostly on gray and ductile irons
- Production of gray and ductile iron weldments involving either two parts made of cast iron, or one of cast iron and one of another metal, usually steel

Repair of Casting Defects

One of the most common applications of welding cast iron is the repair of rough gray iron castings. Although the majority of this repair work is done by oxyacetylene welding, some is done by arc welding (see the discussion "Arc Welding of Cast Irons" in this section). If repair welding is confined to the correction of small defects that affect only the appearance of the casting, inferior mechanical properties and machinability of the weld are of no consequence. The defect must be in an unstressed area that requires no machining and, as a result, should not extend through the section. Typical defects include sand holes, porosity, washouts, cold shuts, and shift. Reclaiming defective castings by repair welding is common practice.

Castings that have defects resulting from machining errors can also be repaired by oxyacetylene welding, provided that the heat of welding does not cause distortion. Arc welding is usually preferred to oxyacetylene welding for correction of machining errors because arc welding is faster, has a lower total heat input (and therefore causes less distortion), and produces welds with adequate properties. Good color match of weld and base metal generally is an additional requirement.

Repair of Damaged Castings

Iron castings that have become cracked, broken, or worn in service are regularly repaired by oxyacetylene welding. Braze welding is used in many applications because of its simplicity and low preheat requirements and because color match is seldom important in such repair (see the article "Oxyacetylene Braze Welding of Steel and Cast Irons" in *Welding, Brazing, and Soldering*, Volume 6 of the 9th Edition of *Metals Handbook*). If welding must be done under adverse conditions, extra care and attention to procedural detail are required. Because repair of damaged castings is often a major welding operation, in that a considerable mass of base metal is subjected to high temperatures, preheating is required. A temporary oven around the part or a means of providing localized heating may be needed, depending on size and shape of the part, the required temperature, and the duration of heating.

Repair of Worn Castings by Hardfacing

Oxyacetylene welding is often used to repair (build up by hardfacing) specific areas of worn gray or ductile iron castings. Malleable iron castings are not well suited to repair by hardfacing.

The choice of a welding process depends largely on service requirements and the equipment available. If the properties obtained are acceptable, braze welding is the logical choice because the casting is far less likely to crack than when arc or oxyacetylene welded. The choice between arc and oxyacetylene welding for repairing worn castings by hardfacing usually depends on the equipment available. Similar results can be obtained with both processes.

The cost of repairing worn castings must be weighed against the cost of replacing them. Consider the cost of building up cast iron, a relatively cheap material, with costly hardfacing alloys. In practice, however, there are considerations other than just the price of the casting, such as delays in getting replacement castings and downtime for replacing a casting in a machine. Repair by hardfacing eliminates procurement delays. A casting surface that has been hardfaced by welding often lasts two to five times as long as the original surface. Mill-roll journals, rolling-mill guides, wire-spinning rolls, and cast components of mills that process abrasive materials such as cement and clay products are typical applications of repair by hardfacing.

The overlay (hardfacing) material applied to castings by oxyacetylene welding usually contains at least 3.0%, and more often 4.0 to 5.0%, C. This usually equals or exceeds the carbon content of the base metal. In addition to having high carbon contents, most hardfacing materials also have high alloy contents. Most hardfacing materials are proprietary alloys; three typical ones have nominal (iron-base) compositions:

- 3.9C-32.0Cr-6.0Mo
- 4.1C-16.0Cr-2.0Ni-8.0Mo-1.0V
- 4.3C-16.0Cr-6.0Ni-8.0Mo

Hardfacing alloys such as these are available in rod form for oxyacetylene welding.

Preheating of the casting prior to welding the overlay minimizes cracking. For castings having reasonably uniform sections, a preheat of 345 to 370 °C (650 to 700 °F) is sufficient; however, for castings having a wide variation in section thickness, preheating in the range of 595 to 650 °C (1100 to 1200 °F) is generally recommended. Time at preheating temperature should be sufficient to ensure that the casting has been uniformly heated.

Postheating is not necessary, but the welded casting must be cooled slowly. In preferred practice, the welded casting is immediately placed in a furnace maintained at or near the preheating temperature used and then cooled in the furnace. If a furnace is not available, the welded casting should be buried immediately in an insulating material such as lime or spent carburizing compound and should be allowed to remain buried until it has cooled to near room temperature.

Preparation of Castings

If a casting to be repaired has been in service, preparation of the casting for welding requires, in addition to edge preparation, the removal of surface contaminants. Oil, grease, and paint should be removed with solvents, commercial cleaners, or paint removers. Impregnated oil or other volatile matter can be eliminated by heating the casting or weld groove to approximately 480 °C (900 °F)--a dull red heat--for about 15 min and then wire brushing, grinding, or rotary filing to remove the residue. Casting skin on surfaces adjacent to the joint area can be removed by grinding, chipping, shot-blasting, or rotary filing. Defects such as porosity, inclusions, and cold shuts should be gouged out, and the bottom of the cavity should be well rounded rather than V-shaped.

Completely broken sections should be dressed to form a single-V joint, with a 2 to 3 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) root face to align the parts. Gas welding requires a V-groove with an included angle of 60 to 90° to permit proper manipulation of the torch and welding rod. For heavy sections, a double-V joint should be prepared whenever feasible, with a root face at or near the center of the workpiece.

Preheating

Adequate preheating decreases the rate of cooling of the weld metal and adjacent base metal, thus minimizing the formation of brittle microstructures in the zone around the weld that might cause cracking immediately after welding or in service. Softer, less brittle microstructures are obtained with high rather than low preheat temperatures. Recommended preheats are discussed in the discussions "Gray Irons" and "Ductile Irons" in this section.

To ensure that the preheat temperature is maintained throughout the welding operations, it may be necessary to insulate the heated casting. Heat input from welding must not be permitted to increase the interpass temperature above the maximum preheat temperature, or welding must be stopped until the temperature drops to the preheat range. The temperature should be measured by contact pyrometers or temperature-indicating crayons at or near the weld zone and at one or more other places as required.

Postweld Heat Treatment

Postweld heat treatment can be either stress relieving or full annealing. Stress relieving at 620 °C (1150 °F) and then furnace cooling to 370 °C (700 °F) or lower is recommended whenever feasible. Full annealing at 900 °C (1650 °F) produces greater softening of the weld zone and more nearly complete stress relief, but it also lowers the tensile strength of all but the softest irons.

Welding Rods

Cast iron rods used in the welding of cast iron should contain enough carbon and silicon to allow for losses of these elements during welding. The silicon content of the filler metal must be high enough to permit carbon to precipitate as free carbon during solidification and to promote a soft, machinable matrix as the weld cools to room temperature. Chemical compositions of cast iron filler metals used for the oxyacetylene welding of cast iron are given in Table 11.

Table 11 Chemical compositions of cast iron filler metals used for OAW of cast iron (AWS A5.15)

Classification	Composition, %							
	C	**Si**	**Mn**	**Ni**	**Mo**	**P**	**S**	Ce
RCI	3.25-3.50	2.75-3.00	0.60-0.75	Trace	Trace	0.50-0.75	0.10 max	...
RCI-A	3.25-3.50	2.00-2.50	0.50-0.70	1.20-1.60	0.25-0.45	0.20-0.40	0.10 max	...

Rods made of cast iron are usually 610 mm (24 in.) long and 6 mm ($\frac{1}{4}$ in.) square, although rods 3 to 12 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) square are available. The RCI filler metals and a number of proprietary rod compositions are used for welding gray irons of classes 20 to 35 (140 to 240 MPa, or 20 to 35 ksi, tensile strength). Gray irons that have tensile strengths of 240 to 275 MPa (35 to 40 ksi) can be welded with RCI-A filler metal, which is similar to RCI but also contains 1.20 to 1.60% Ni and 0.25 to 0.45% Mo. Many proprietary rods contain chromium, nickel, molybdenum, copper, or vanadium, either singly or in combination, to produce high-strength welds; carefully controlled procedure is required with these rods to avoid obtaining a hard weld deposit. Two basic types of welding rods have been successfully used for welding ductile iron: RCI-B, which is generally higher in carbon and silicon content and lower in manganese than the gray iron rods and contains cerium as a nodularizing agent, and proprietary rods in which magnesium is used as the nodularizing agent.

Fluxes

A flux is required in the oxyacetylene welding of cast iron to increase the fluidity of the fusible iron-silicate slag and to aid in the removal of the slag. Fluxes for gray iron rods are usually composed of borates or boric acid, soda ash, and small amounts of other compounds such as sodium chloride, ammonium sulfate, and iron oxide.

Fluxes suitable for welding ductile iron rod are similar to those used for welding gray iron, but are formulated to produce a slag with a lower melting point. Some proprietary fluxes contain inoculants.

Welding of Gray Iron

The oxyacetylene welding of gray iron is generally done for repair, but can also be done for production of simple assemblies. The cavity is first prepared for welding by the usual methods (see the discussion "Preparation of Castings" in this section) and then tested by liquid penetrant or magnetic-particle inspection to ensure freedom from defects.

The casting is preferably preheated to 620 °C (1150 °F) in a furnace and then covered with heat-retaining material, exposing only the cavity to be welded. If a furnace is not available, the casting can be covered with heat-retaining material and locally heated by gas flame.

A high-velocity torch that produces a concentrated flame pattern similar to that used for welding low-carbon steel should be used. The cavity surface is dusted with a thin layer of flux, the heated rod is dipped in flux and positioned in the cavity, and both are heated with an oxyacetylene torch adjusted for a neutral or slightly reducing flame. The rod and a small area of the cavity soften under the flame, and as the rod melts off and combines with the base metal, the torch and rod are slowly moved along the cavity. The flame should be directed at the bottom of the cavity with the tip held 6 to 3 mm ($\frac{1}{4}$ to $\frac{1}{8}$ in.) from the metal until a molten pool up to 25 mm (1 in.) long begins to form. The torch is moved from side to side until the walls of the cavity start to melt into the pool. This process is continued until the entire cavity is filled with weld metal 2 to 3 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) thick. Playing the welding flame back over the previously deposited metal to retard its cooling rate will reduce residual stress and permit escape of entrapped gas.

Postweld stress relieving is recommended, particularly for complex castings or where accurate machining will follow. Immediately after completion of welding, the casting should be placed in a furnace heated to the same temperature as the casting and gradually heated to 595 to 650 °C (1100 to 1200 °F), where it is held for 1 h per inch of thickness. The casting can then be cooled to 260 °C (500 °F) or below at a rate no faster than 25 °C/h (50 °F/h). When the welded casting is not stress relieved, it should be cooled slowly either in a furnace or by covering it with heat-retaining material, sand, or some other insulated material.

When class 30 irons are preheated to 600 to 620 °C (1100 to 1150 °F) before oxyacetylene welding, some fine pearlite and ferrite are present in the final weld metal and in the HAZ; weld tensile strength approaching 205 MPa (30 ksi) and hardness less than 200 HB can be obtained. When class 40 irons are oxyacetylene welded under similar preheat conditions, higher proportions of fine pearlite, less ferrite, and some cementite are present, and weld strength may reach 240 MPa (35 ksi), with hardness as high as 200 HB. Although higher strength irons containing chromium and molybdenum have been welded, welding rods compatible with these irons are not readily available. Welding is generally not attempted in gray iron stronger than class 50 because of the high probability of cracking.

Difficulty in machining is seldom encountered if high preheat and interpass temperatures are used. Class 40 irons can usually be oxyacetylene welded to a hardness of 200 HB or less in weld metal and the HAZ. Cast iron welding rods provide good color match.

Welding of Ductile Iron

Oxyacetylene welding is often used for the repair of defects in ductile iron castings. It has also been successfully used for the hardfacing of specific areas on castings to increase abrasion resistance. The oxyacetylene welding of ductile iron has been most successful using a ductile iron rod.

The repair of ductile iron castings is complicated by the fact that the only way to obtain graphite in nodular form in the weld deposit is to cause it to precipitate from the liquid. Processes have been developed to cause nodularization by introducing magnesium or cerium, or both, into the weld zone by means of a special cast iron filler rod or special flux. Filler metal RCI-B should be used for welding ductile iron.

Magnesium and cerium are carbide formers and consequently must not be present in amounts beyond those required for nodularization. If these elements are present in excessive amounts, a postweld ferritizing anneal is necessary to restore ductility to the weld area; annealing reduces the strength of pearlitic irons and causes distortion of machined surfaces.

Joint preparation and joint cleanliness require the same careful attention and the same procedures described earlier for welding gray iron. Preheating practice and interpass temperatures are essentially the same for welding ductile iron as those described for gray iron.

In welding ductile iron, a reducing flame is used to minimize oxidation of the volatile nodularizing elements contained in both the base metal and the welding rod. The welding tip should produce a concentrated flame pattern. The weld area or the complete casting is first preheated to a dull red, and flux is applied to the bottom of the weld groove. Heat is directed at the bottom of the weld groove until a pool begins to form. Walls adjacent to the weld groove are then softened to blend into the pool. The recommended length of the molten pool should be limited to 25 mm (1 in.). A major problem in the welding of ductile iron is the complete loss of ductility in the HAZ.

Welding of Malleable and White Irons

The effect of oxyacetylene welding on malleable iron is to create a wide HAZ of white iron, the material from which the malleable iron was originally produced by applying a malleablizing heat treatment. Because of the hardness and brittleness of the white iron, base metal properties are lost, and the joint is prone to cracking. The hardened zones in either ferritic or pearlitic malleable iron can be reduced by annealing, but only by processing the casting through a special heat-treating procedure for which the original foundry is best equipped.

Oxyacetylene welding is used in the foundry repair of small defects on rough castings while the casting is in the white iron condition, before malleablizing. White iron welding rods are used, which are cast by the foundry to match the base metal composition, after allowing for constituent losses in deposition. Repair procedures are the same as for gray iron except that, after welding, the casting is given its normal malleablizing heat treatment.

Braze welding, using a copper alloy welding rod, is a more satisfactory method of obtaining relatively strong, machinable joints in malleable iron. Because the base metal is not melted in braze welding, peak temperatures are relatively low, and there is very little hardening in the HAZ. Color match between the weld and the base metal is poor, however, and the service temperature of the casting is limited to about 260 °C (500 °F). Details of the process are given in the article "Oxyacetylene Braze Welding of Steel and Cast Irons" in *Welding, Brazing, and Soldering,* Volume 6 of the 9th Edition of *Metals Handbook.*

Gas metal arc welding with bare wire steel electrodes has been used in joining malleable iron where end uses do not require full base metal strength properties. This process produces high peak temperatures, which are of short duration because of high welding speed. Heat-affected zones are therefore narrow. This process is discussed in the discussion "Arc Welding of Cast Irons" in this section.

Welding of Cast Steels

The welding of cast steels is done for many reasons. These include, but are not limited to, repair welding (the upgrading of castings to meet strict quality control standards), cast-weld construction, and weld overlay and facing applications.

Repair of steel castings is necessitated when discontinuities are present that exceed the allowable limits set by the standards to which the casting is being manufactured. Repair of the casting may involve cutting or gouging out the defect, followed by welding with a filler material that is compatible with the base casting composition and strength. The need to produce castings to high quality control standards has involved the use of welding to upgrade castings, especially in regions where narrow and complicated cross sections make it difficult to achieve perfect feeding. Such regions in castings must be removed and replaced with weld metal. To improve the integrity of a fabricated component, it may be necessary to join a casting to another casting or a wrought component. Finally, weld overlay and facing considerations are similar to those in wrought steels, in which the surface properties are to be significantly different from the base material properties. The use of hardfacing materials or corrosion-resistant overlays is the situation typically encountered.

In all of the above-mentioned instances where cast steels are involved with welding, the procedures involved are similar to those for wrought steels; therefore, few standards have been established that deal exclusively with the welding of cast steels. A list of typical specifications covering the welding of steel and alloy castings is summarized in Table 12.

Welding Processes

Many of the processes commonly used in the welding of wrought steels are utilized in welding operations involving cast steels. These include shielded metal arc welding, gas metal arc welding, gas tungsten arc welding, submerged arc welding (all of which were described earlier in the section "Arc Welding of Cast Irons" in this article), and electroslag welding (ESW). The shielded metal arc process (also referred to as stick welding) is the most versatile and popular of the processes for both repair and joining, while the submerged arc and electroslag processes are more suitable for joining operations. Detailed descriptions of these processes can be found in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Weldability

Weldability, as defined by the American Welding Society, is the capacity of a material to be welded under the fabrication conditions imposed, into a specific, suitably designed structure, and to perform satisfactorily in the intended service. When welding cast steels, the procedures generally used are those that are commonly recommended and used for equivalent-composition wrought steels. However, the unique features of castings versus wrought materials should be taken into account--for example, segregation, porosity, and shrinkage in castings and banded structures in wrought steels. In this section, procedures will be outlined for the welding of cast steels with emphasis on comparison with the weldability of equivalent composition wrought steels.

Welding of Cast Carbon and Low-Alloy Steels

In general, the procedures used for welding wrought carbon and low-alloy steels can be used for cast steels of similar composition. During the welding of as-cast as well as wrought components, a problem commonly encountered in the HAZ is hydrogen-assisted cracking. The three most important factors affecting the susceptibility of a steel to hydrogen-assisted cracking are:

- The composition and therefore the hardenability
- The amount of diffusible hydrogen introduced into the weld during the welding process
- Restraint (stresses associated with welding)

Hydrogen-assisted cracking in the HAZ of a steel is generally found to occur after the weld has cooled to room temperature. Therefore, it is also referred to as cold cracking. Cold cracks need not occur immediately after welding; their formation may be delayed for even up to 1 week after welding has been completed. Therefore, these types of cracks are sometimes referred to as delayed cracks. To avoid confusion, the term hydrogen-assisted cracking will be adopted throughout this section to refer to cold, as well as delayed, cracking. The factors affecting the tendency of a steel toward hydrogen-assisted cracking are summarized in Fig. 12.

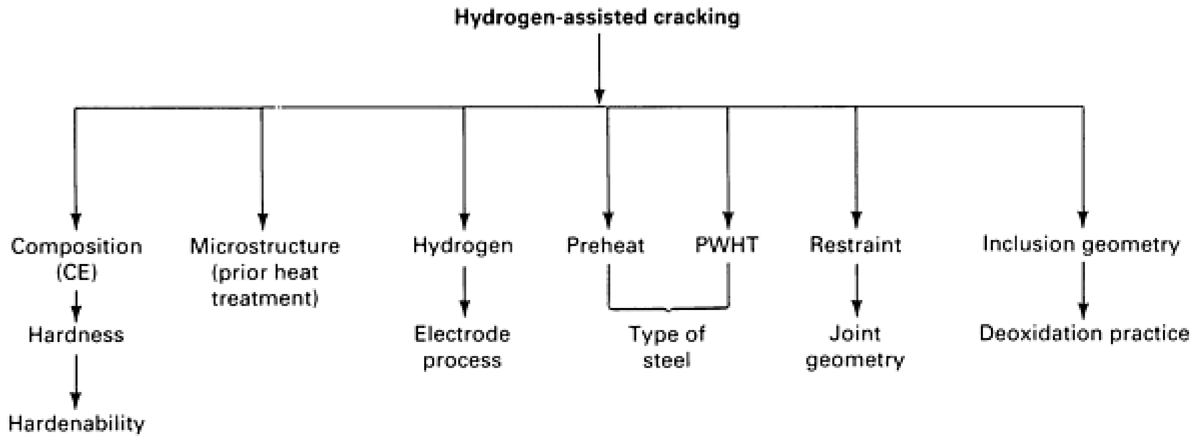

Fig. 12 Factors affecting hydrogen-assisted cracking.

Hydrogen-assisted cracks can be observed either in the weld metal or the HAZ. These cracks can be longitudinal or transverse in relation to the weld (Fig. 13). Longitudinal cracks in the HAZ of the base metal that occur a short distance

from the weld line are called underbead cracks. Toe cracks originate from the toe of the weld. The toe is a discontinuity in the cross section and therefore acts as a stress concentrator for crack initiation.

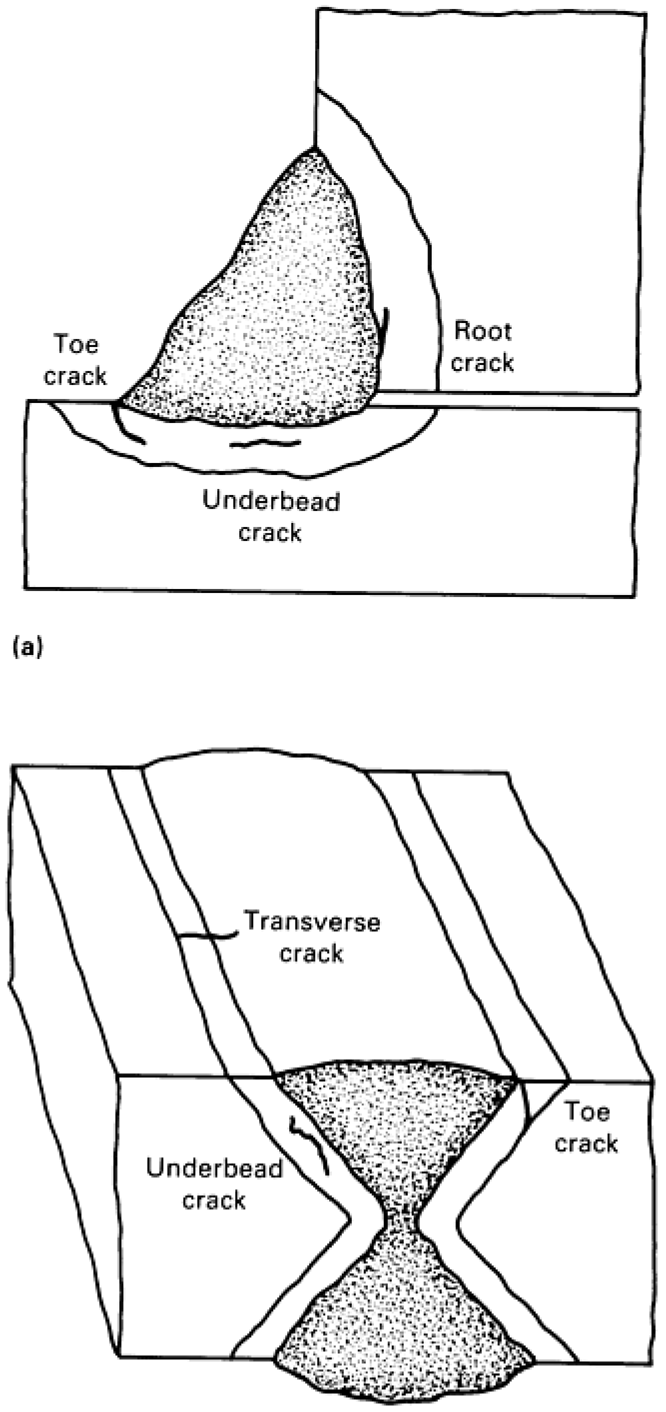

Fig. 13 Hydrogen-assisted cracks in HAZs of fillet (a) and butt welds (b). Source: Ref 6.

It is recognized that the HAZ microstructure governs, to a considerable extent, the susceptibility to hydrogen-assisted cracking. In general, the harder the microstructure, the greater the susceptibility, with twinned martensitic structures being the most susceptible. Other factors that affect the susceptibility to hydrogen-assisted cracking of the HAZ are the hydrogen content of the weldment and the stresses (restraint or applied) acting on the weldment. Considering the situation in which all of the above factors are identical for equivalent composition cast and wrought steels, the reasons for possible differences in hydrogen-assisted cracking between cast and wrought materials may arise from the intrinsic differences between the two types of materials. Cast steels are, in general, coarse grained and exhibit relatively isotropic properties compared to their wrought counterparts. Inclusion morphologies in cast steels are generally globular compared to the elongated, stringered inclusions found in wrought steels. Further, as-cast steels may have regions of segregation or may have regions of porosity or interdendritic shrinkage.

The effects of composition on hydrogen-assisted cracking are usually summarized by using a carbon equivalent (CE) to normalize the chemical composition. However, the CE formulas commonly used do not take into account the effects of such factors as prior microstructure or sulfur content, which have been reported to affect the susceptibility of steels to hydrogen-assisted cracking. Attempts have been made to include the hydrogen content into the formulas; however, this entails the precise knowledge of diffusible hydrogen contents for each type of welding process employed. Other elements, such as aluminum (acid soluble and total) and sulfur, do not fall in the category of those that can be included to calculate the carbon equivalent, because they do not have a significant, direct influence on hardenability. The aluminum content, however, has been reported to influence hydrogen-assisted cracking as well as HAZ toughness because of its influence on grain-coarsening characteristics and nucleation/precipitation reactions in the HAZ. Further, the aluminum content, together with the sulfur content, influences the inclusion morphology and distribution. The sulfur content can be taken to be a rough guide to the volume fraction of inclusions present; however, the morphology is determined by the deoxidation practice used prior to casting of the ingot and by the subsequent thermomechanical treatment.

A commonly proposed formula for carbon equivalent is:

$$CE = \%C + \frac{Mn}{6} + \frac{\%Cr + \%Mo + \%V}{5} + \frac{\%Cu + \%Ni}{15} \quad \textbf{(Eq 1)}$$

Recently, an extensive investigation has determined that for normalized cast steels with carbon equivalents up to 0.47 as calculated by:

$$CE = \%C + \frac{Mn}{6} + \frac{\%Si}{24} + \frac{\%Cr}{12} + \frac{\%Mo}{10} + \frac{\%Ni}{40} \quad \textbf{(Eq 2)}$$

a preheat of 40 °C (100 °F) is sufficient to prevent hydrogen-assisted cracking in the HAZ when welded under high-hydrogen conditions with E6010 type electrodes (Ref 4). These results are based on test results using the Battelle Underbead Cracking Test with steels in the range of carbon contents up to 0.35%, manganese contents up to 1.25%, silicon contents up to 0.7% and (%Cr + %Mo + %Ni + %V + %Cu) up to 0.59%. Increasing carbon equivalents, and therefore increasing hardenabilities, require higher preheat temperatures to avoid hydrogen-assisted cracking. A relationship between hardenability and the preheat temperature required to prevent hydrogen-assisted cracking for the above group of cast-and-normalized steels under high-hydrogen conditions is shown in Fig. 14. The change in microstructure with an increase in carbon equivalent from 0.37 to 0.58 is shown in Fig. 15. The microstructure changes from mixed ferrite, pearlite, bainite, and martensite (CE = 0.37) to almost completely martensite (CE = 0.58). The existence of underbead cracking (Fig. 15c) confirms the greater susceptibility of the high-CE steel. In general, a hardness level below 35 HRC (325 HB) in the HAZ will lessen the probability of hydrogen-assisted cracking. The above research also determined that as-cast steels require preheat temperatures 28 °C (50 °F) higher than cast-and-normalized steels to avoid hydrogen-assisted cracking under high-hydrogen conditions. A change from acid to basic melting practice did not decipherably alter susceptibility to hydrogen-assisted cracking.

Preheating has several functions. Preheating:

- Reduces the cooling rate and thus promotes higher-temperature transformation products, which result in a relatively lower HAZ hardness
- Promotes the diffusion of hydrogen away from the HAZ
- Aids in the reduction of residual stresses

A question frequently asked is, What preheat temperature should be used to weld a particular steel casting? It is clear that the first approach should be based on composition. Welding Research Council (WRC) Bulletin 191 provides guidelines in the selection of preheat temperatures for cast as well as wrought steels. An updated version of this bulletin is included in Ref 5. The approach in WRC Bulletin 191 is conservative and differentiates between low and non-low hydrogen processes. Material thickness is also taken into account as a factor; thickness will govern the cooling rate and state of stress in the weldment. Table 13 compares the preheat temperatures suggested by American Society for Testing and

Materials (ASTM) specifications with those recommended by WRC Bulletin 191 for a selection of cast steels. The ASTM specifications appear to assume low hydrogen conditions. Several other methodologies exist for determining preheat temperatures, most notably, Ref 6 and AWS Structural Welding Code D1.1 (1987). A detailed discussion of these procedures is beyond the scope of this section.

Table 13 Comparison of ASTM recommended preheat temperatures with those in WRC 191 for selected cast carbon and low-alloy steels

Steel--ASTM specification		**Minimum ASTM recommendation, low H_2, 25 mm (1 in.) thickness**		WRC 191 minimum recommendation, 25 mm (1 in.) thickness

Stress-Relief and Postweld Heat Treatment

Stress-relief treatments are those treatments that are conducted at subcritical temperatures to reduce residual stresses. Postweld heat treatments also reduce HAZ hardness and thus improve ductility and toughness. The need for such treatments depends on the particular welding task under consideration. In fabrications involving large and extensive welds, intermediate subcritical heat treatments can reduce the buildup of stresses. The removal of residual stresses is also

important in maintaining the dimensional stability of a casting. Stress relieving can also improve brittle fracture characteristics for service at low temperatures.

Postweld heat treatments combine stress relief and reduction of HAZ hardness. However, weld metals are generally lower in carbon content than the casting and therefore tend to soften more than the casting during heat treatment. Therefore, a filler metal of higher alloy is often desirable. A welding technique that increases dilution of the weld metal from the base metal can also increase the amount of carbon and alloying elements in the weld metal. Gas metal arc, submerged arc, and flux cored arc welding will usually result in enough dilution of the weld metal so that postweld heat treatment will result in relatively uniform properties across the weldment. The toughness of the HAZ and its response to heat treatment strongly depend on carbon equivalent of the parent cast steel.

Typical microstructures of simulated grain-coarsened HAZs in the cast-and-normalized steels described in Fig. 15 are shown in Fig. 16 and 17. Figure 16 shows untempered grain-coarsened HAZs, while Fig. 17 shows the grain-coarsened HAZs after postweld heat treatment at 650 °C (1200 °F) for 1 h. For the steel with CE = 0.37, the toughness before and after postweld heat treatment remained relatively unchanged at about 11 J (8 ft · lbf). The presence of extensive amounts of proeutectoid ferrite on the grain boundaries both before (Fig. 16a) and after (Fig. 17a) postweld heat treatment is the reason for the relatively low toughness. For the steel with CE = 0.47, a significant improvement in toughness is obtained after postweld heat treatment--from 15 to 79 J (11 to 58 ft · lbf). The cast steel with CE = 0.58 improved in toughness from 4 J (3 ft · lbf) in the as-welded condition to 80 J (59 ft · lbf) in the postweld heat treated condition. For the steels with CE = 0.47 and 0.58, postweld heat treatment resulted in the tempering of the bainitic/martensitic microstructures, which resulted in an improvement of the toughness. The results of these tests demonstrate that microstructures that are not susceptible to hydrogen-assisted cracking may not necessarily possess good aswelded or postweld heat treatment toughnesses. The presence of upper temperature transformation products on prior-austenite grain boundaries is especially detrimental to the impact properties of the HAZ. It should also be noted that the susceptibility to hydrogen-assisted cracking is not governed by the location of the microconstituents in the HAZ, but rather by the type and volume fraction of constituents in the HAZ.

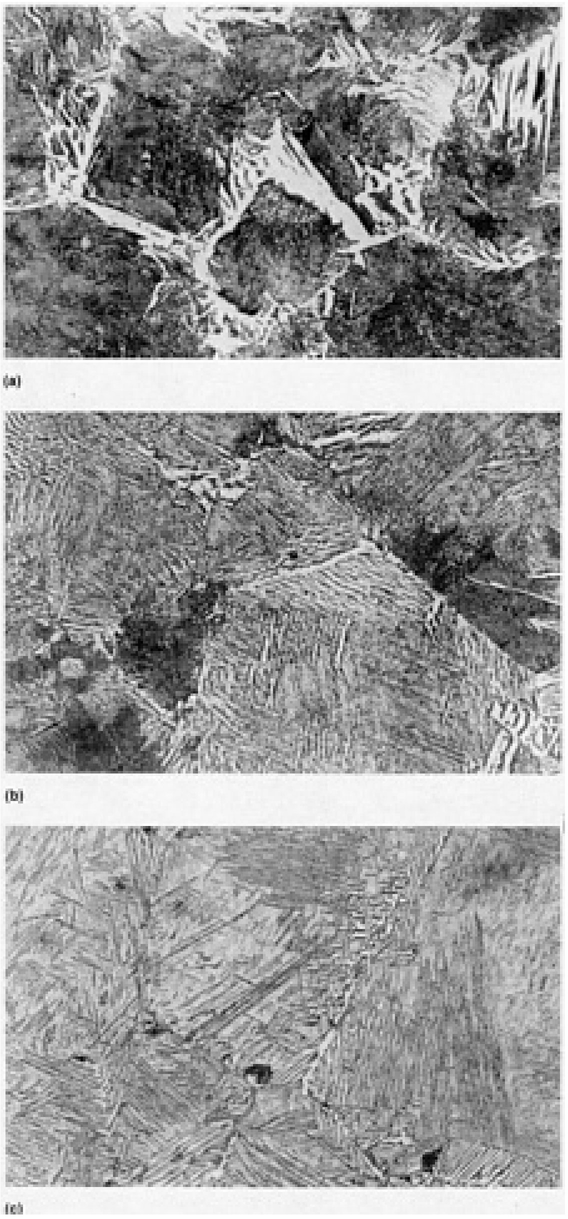

Fig. 16 Microstructures of simulated grain-coarsened HAZs in cast-and-normalized carbon-manganese-silicon steels in the thermal cycled condition. 2 kJ/mm (50 kJ/in.), 1315 °C (2400 °F) peak temperature. (a) CE = 0.37. (b) CE = 0.47. (c) CE = 0.58. Picral etch. 500×.

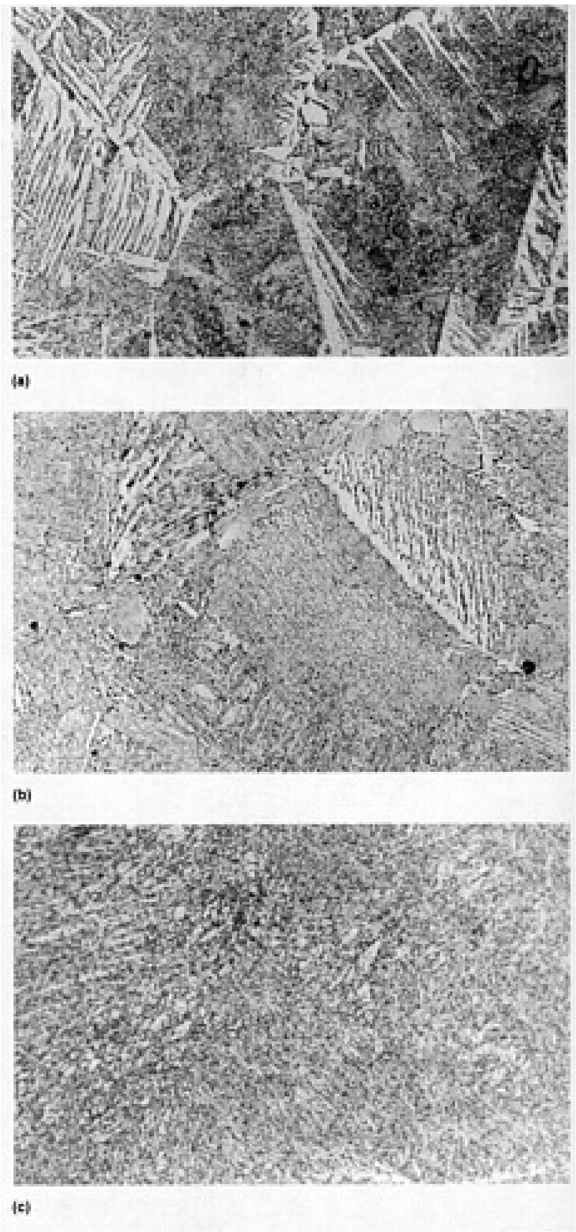

Fig. 17 Microstructures of simulated grain-coarsened HAZs (same steels as in Fig. 16) in the thermal cycled and postweld heat treatment conditions. 2 kJ/mm (50 kJ/in.), 1315 °C (2400 °F) peak temperature. Postweld heat treatment: 650 °C (1200 °F) for 1 h. (a) CE = 0.37. (b) CE = 0.47. (c) CE = 0.58. Picral etch. 500×.

The ASME Boiler and Pressure Vessel Code Section IX and ASTM Standard A 488 provide good guidelines for choosing stress-relieving and postweld heat treatment schedules. Additional information can also be found in the article "Residual Stresses and Distortion" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook.*

Comparative Weldability of Cast and Wrought Steels

Although general recommendations indicate that the weldabilities of cast and wrought steels are similar, considerable differences of opinion exist in the welding literature. Extensive work conducted at Battelle during the late 1940s and early 1950s indicated that cast steels are more resistant to the occurrence of underbead hydrogen-assisted cracking when

compared to wrought steels of equivalent composition. Although no reasons were given for this difference in weldability, the following can be hypothesized:

- The porosity and microshrinkage associated with cast steels may provide sinks for hydrogen
- The transformation behavior in the HAZ may be affected by localized variations in elemental concentration resulting from segregation
- The globular inclusion morphology in cast steels differs from that in wrought steels, where the inclusions are usually elongated

Recent research has shown that the elongated inclusion morphology in wrought steels renders them more susceptible to hydrogen-assisted cracking when compared to equivalent-composition cast steels (Ref 4). This research also determined that cast steels that have been critically deoxidized to have type II inclusions (eutectic sulfides) present at the substructure and grain boundaries are more susceptible to hydrogen-assisted cracking than those deoxidized to have type I (globular sulfides) or type III (angular sulfides) present in them. Typical examples of crack association with type II inclusions in the grain-coarsened and partially refined HAZs are shown in Fig. 18. Thus, it appears that inclusion morphology resulting from a given composition and deoxidation practice can influence the susceptibility to HAZ cracking of cast carbon and low-alloy steels.

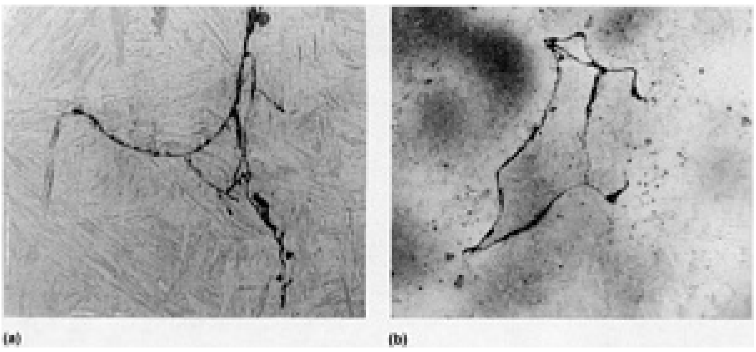

Fig. 18 Hydrogen-assisted cracking associated with type II inclusions in A216-WCB steel. (a) Grain-coarsened HAZ. 2000×. (b) Partially refined HAZ. 200×. Picral etch.

Wear-Resistant Manganese Steels

The use of austenitic manganese steels as castings or as a weld deposit is a common method of providing a tough wear-resistant surface on component faces that are subject to abrasion and wear. The role of welding is in casting repair, overlaying, and joining between manganese castings or manganese castings to carbon or alloy steels. During the welding of such castings, exposures at temperatures above 315 °C (600 °F) for extended periods of time result in embrittlement accompanied by a drastic decrease in ductility. At a temperature of 425 °C (800 °F), an exposure period of only 2 h may be enough to cause embrittlement. Preheating of the casting is therefore not recommended and in any case should be restricted to 40 °C (100 °F) maximum. Interpass temperatures should be held to 315 °C (600 °F) maximum. Welding processes, such as gas welding, that involve slow heating and cooling periods are to be avoided.

Cast Stainless Steels

As for carbon and low-alloy steels, the general principles and procedures applicable for wrought stainless steels are also applicable for cast stainless steels. The CF-8 (cast equivalent of AISI 304) and CF-8M (cast equivalent of AISI 316) steels are easily weldable. However, precautions must be taken to avoid sensitization. These include controlling the interpass temperature to 150 °C (300 °F) and the use of stringer bead welding techniques. When higher temperatures and severe corrosive environments are encountered, it may be necessary to solution heat treat the casting at 1095 °C (2000 °F) to put the carbides that precipitated during welding into solution. The use of stabilized grades such as CF-8C (cast equivalent of AISI 347) can help in avoiding a solution heat treatment. Another approach is the use of CF-3 and CF-3M grades, which restrict the carbon content to 0.03% maximum and reduce the probability of sensitization. As alloy grades become richer, the structure becomes fully austenitic, and hot cracking is a potential problem. The problem can be alleviated by using low heat inputs and interpass temperatures as well as by peening the weld.

In general, cast stainless steels can be welded with filler metals recommended for equivalent-composition wrought stainless steels. Table 14 compares cast and equivalent wrought stainless steels and suggests filler metal compositions.

Table 14 Filler metals suggested for cast stainless alloys

Base metal--Alloy Castings Institute casting alloy designation	**Similar to wrought alloy type**	Suggested filler metal
CA-6NM	410NiMo	**410NiMo**
CA-15	12Cr	**410, 410NiMo**
CA-40	420	**410, 410NiMo**
CB-7Cu	Precipitation hardening	**630**
CB-30	431	**312**
CF-3	304L	**308L**
CF-3M	316L	**316L**
CF-8	304	**308**
CF-8M	316	**316, 317**
CF-8C	347	**347**
CF-12M	316	**316, 317**
CF-20	302	**308**
CH-20	309	**309**
CG-8M	317	**317**
CK-20	310	**310**
CN-7M	20Cr-30Ni-Mo-Cu	**320**
HC	446	**446, 312**
HD	327 (28Cr,5Ni) (Duplex)	**Similar composition with enhanced nickel to improve ductility**

HE	312	**312**
HF	320B, 308HiC	**308**
HH	309	**309**
HI	28Cr-15Ni	**309**
HK	310H	**310H**
HT	330	**330**
HU	**19Cr-39Ni**	**330**

In the dissimilar-metal welding between cast austenitic and cast or wrought ferritic steels, the choice of filler metal is dictated by the temperature and stresses involved in service. Moderate temperatures (<315 °C, or 600 °F) and stresses can allow the use of high-alloy austenitics such as type 309 or 310. Higher temperatures and stresses will entail the use of high-nickel weld metal. The welding process and technique must be adapted to reduce dilution of the weld metal by the base metal.

Hot Isostatic Pressing of Castings

John M. Eridon, Howmet Corporation

Introduction

HOT ISOSTATIC PRESSING (HIP) is a process that subjects a component to both elevated temperature and isostatic gas pressure in an autoclave. The most widely used pressurizing gas is argon. For the processing of castings, argon is applied at pressures between 103 and 206 MPa (15 and 30 ksi), with 103 MPa (15 ksi) being the most common. Process temperatures vary from 480 °C (900 °F) for aluminum castings to 1315 °C (2400 °F) for single-crystal nickel-base superalloys.

When castings are hot isostatically pressed, the simultaneous application of heat and pressure virtually eliminates internal voids and microporosity through a combination of plastic deformation, creep, and diffusion. The elimination of internal defects leads to improved nondestructive testing ratings, increased mechanical properties and reduced data scatter.

The HIP process was invented in the mid-1950s at Battelle Columbus Laboratories. The process was specifically developed as a gas pressure diffusion bonding technique for cladding nuclear fuel elements (Ref 1). In 1965, the use of hot isostatic pressing for improving the fatigue life of cast aluminum diesel engine pistons was investigated (Ref 2). Although it was shown that a significant increase in fatigue life could be achieved, the limited availability of commercial production HIP vessels prevented its implementation. In 1967, hot isostatic pressing was evaluated as a means of improving the quality of both titanium and superalloy investment castings for use in the aerospace industry. Further investigations into the effect of hot isostatic pressing on titanium and superalloy castings were conducted in the early 1970s; these investigations demonstrated that significant improvements in mechanical properties could be obtained (Ref 3, 4).

Initially, most of the castings being hot isostatically pressed were critical aerospace components, such as turbine blades and structural hardware for aircraft gas turbine engines. These relatively expensive components could accept the high added cost of the HIP process. Recently, however, the cost of hot isostatic pressing has been reduced to the point at which it is affordable for castings in less critical applications. This reduction in cost has resulted from the increased number and size of vessels dedicated to the hot isostatic pressing of castings and from improvements in equipment (shortened process cycle times).

Equipment

Hot isostatic presses are available in many sizes with varying process capabilities. Sizes vary from small 102 mm (4 in.) diam laboratory units to 1524 mm (60 in.) diam production-size vessels. Units with temperature capability to 2200 °C (3990 °F) and pressure capability to 310 MPa (45 ksi) are available from commercial autoclave manufacturers. A schematic illustrating the construction of a typical hot isostatic press is shown in Fig. 1. A detailed description of HIP equipment can be found in the article "Hot Isostatic Pressing of Metal Powders" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook.*

Reduced Cycle Time. One of the more significant advancements in HIP equipment has been the introduction of furnace designs that allow uniform rapid cooling from the HIP temperature. Original furnace designs were capable of slow cooling only. The advent of rapid-cool furnace designs allowed reductions in floor-to-floor cycle times of approximately 4 to 6 h, depending on unit size and load mass. However, the early rapid-cool designs were not able to achieve uniform cooling rates over the entire load of parts. Recently, furnaces capable of rapid uniform cooling over the entire load have been introduced (Table 1). Cooling rates are sufficiently rapid to allow the solution heat treatment of many alloys at the end of the HIP cycle, thus eliminating the need for additional post-HIP solution heat treatments.

Table 1 Cooling rates for rapid-cool and rapid uniform cool HIP furnaces

Vessel is 500 mm (19 in.) in diameter and 1500 mm (59 in.) long with a 500 kg (1100 lb) load.

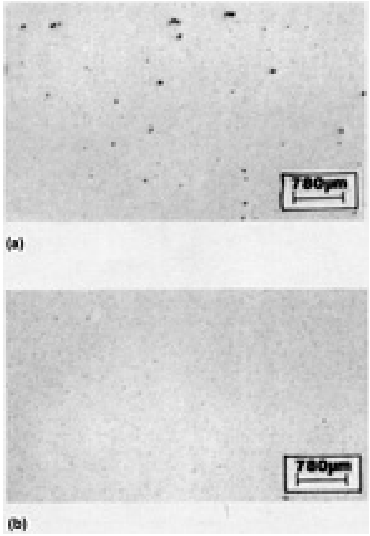
Effect of HIP on the Mechanical Properties of Castings

Nickel-Base Superalloys. In the past 15 years, hot isostatic pressing has become an integral part of the manufacturing process for high-integrity aerospace castings. The growth of hot isostatic pressing has paralleled the introduction of advanced nickel-base superalloys and increasingly complex casting designs, both of which tend to increase levels of microporosity. In addition, to optimize mechanical properties, turbine engine manufacturers have become more stringent in allowances for microporosity. The requirement for reduced porosity levels and increased mechanical properties has been achieved in many cases through the use of hot isostatic pressing.

The first production use of hot isostatic pressed castings for critical rotating parts in an aircraft gas turbine occurred in the mid-1970s. Figure 2 shows the effect of hot isostatic pressing on porosity levels and rupture properties for investment cast René 80. As can be seen, the elimination of porosity and subsequent increase in both the 760 °C (1400 °F)/603 MPa (87.5 ksi) and the 980 °C (1800 °F)/190 MPa (27.5 ksi) rupture lives are evident. Figure 3 shows the effects of hot isostatic pressing on the rupture properties of Alloy IN738. The data were obtained on test bars machined from land-based industrial gas turbine blades. Of significant interest is the improvement in mechanical properties of hot isostatic pressed material at the -2σ limits (σ = standard deviation).



Mechanical properties	**Before HIP**	After HIP
At 760 °C (1400 °F)/603.3 MPa (87.5 ksi)		
Rupture life, h	57.4	**137.9**

Titanium. One of the earliest successes of hot isostatic pressing as applied to aerospace castings was with investment cast titanium. Because of the high reactivity of molten titanium, most investment cast titanium aerospace components are produced in a vacuum furnace utilizing a consumable arc skull remelting process. This process does not allow superheating of the melt; therefore, the ability to produce sound castings with consistent mechanical properties is limited. As shown in Fig. 4 and 5, the application of hot isostatic pressing to investment cast Ti-6Al-4V results in improved room-temperature low-cycle and high-cycle fatigue properties and improved impact strength. The improved properties obtainable with hot isostatic pressing have allowed investment cast titanium components to meet stringent requirements for aerospace and other critical applications.

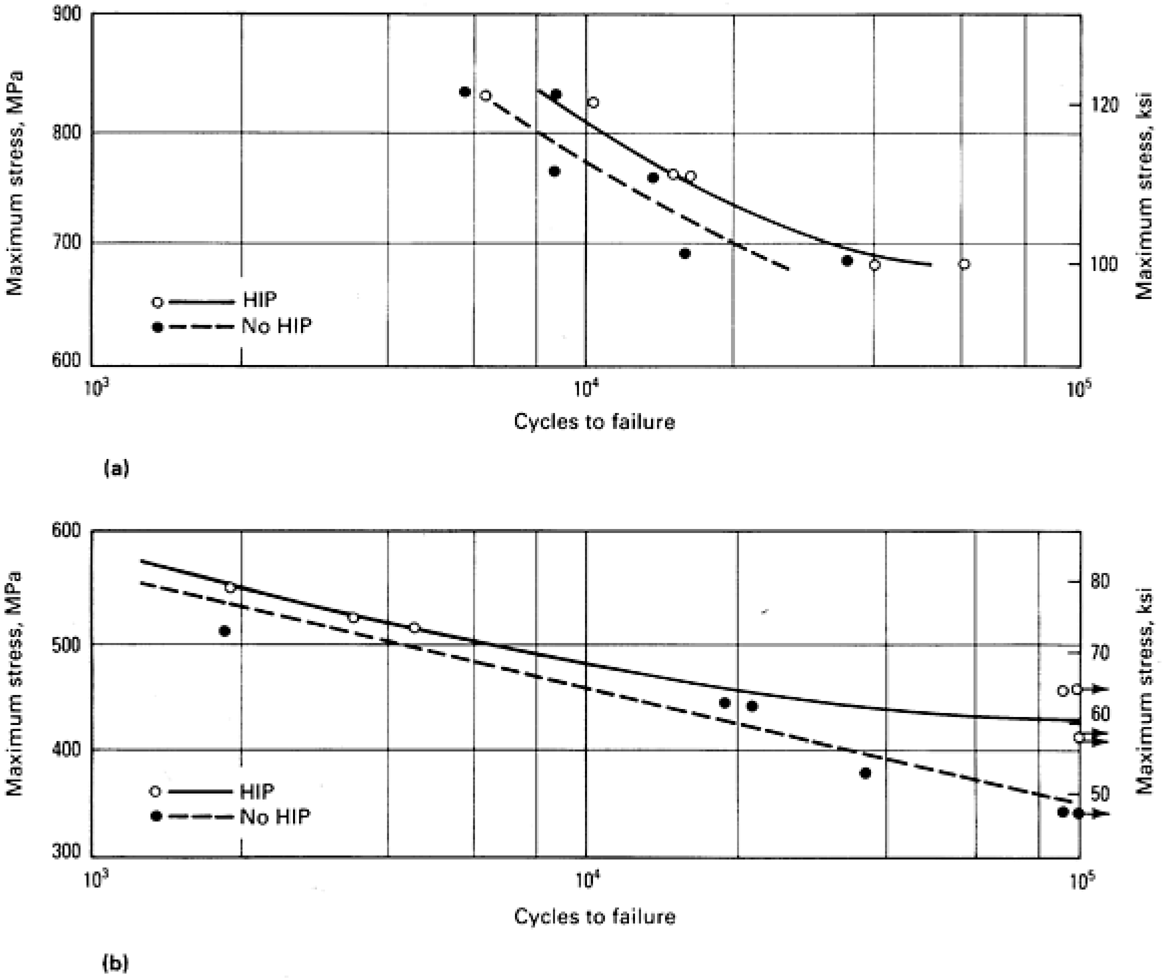

Fig. 4 Effect of hot isostatic pressing on room-temperature fatigue properties of investment cast and annealed Ti-6Al-4V. HIP conditions: 900 °C (1650 °F) and 103 MPa (15 ksi) for 2 h. Test conditions: maximum stress ratio *R* = 0.1, frequency = 0.3 Hz for low-cycle fatigue and 60 Hz for high-cycle fatigue, and theoretical stress concentration factor K_t = 1.0. (a) Low-cycle fatigue. (b) High-cycle fatigue. Source: Ref 5

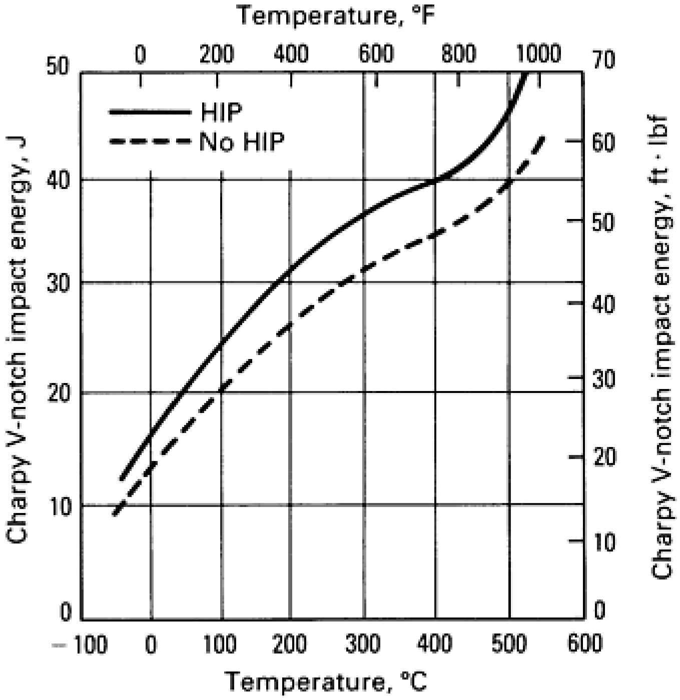

Fig. 5 Charpy V-notch impact energy for hot isostatically pressed and non-hot isostatically pressed Ti-6Al-4V investment castings. Source: Ref 5

Aluminum Alloys. As previously mentioned, the improvement in the fatigue life of cast aluminum pistons as a result of hot isostatic pressing was investigated in 1965. Pistons were processed at or near the solution temperature of the alloy for 2 to 3 h under a pressure of 103 MPa (15 ksi). Figure 6 shows the effect of hot isostatic pressing on eliminating internal porosity in sand cast aluminum alloy A356. Tensile data comparing the effects of hot isostatic pressing on aluminum alloys A356, A357, and A201 are presented in Table 2. The statistical treatment of these data reveals the reduction in data scatter obtainable with hot isostatic pressing. The effect of hot isostatic pressing on the fatigue life of A201 is shown in Fig. 7.

Stainless Steels. The effect of hot isostatic pressing on the room-temperature tensile properties of investment cast Custom 450 precipitation-hardening stainless steel is demonstrated in Table 3. The hot isostatically pressed material displays enhanced properties at both average and -2σ limits compared to the non-hot isostatically pressed material. Data for this comparison were obtained using test specimens machined from airframe support brackets. The hot isostatically pressed brackets were processed at 1120 °C (2050 °F) and 103 MPa (15 ksi) for 4 h to obtain closure of internal porosity. The hot isostatically pressed and non-hot isostatically pressed brackets were both heat treated to the H1050 condition.

Process Considerations

Parameter Selection. In selecting HIP process parameters for a particular alloy, the primary objective is to use a combination of time, temperature, and pressure that is sufficient to achieve closure of internal voids and microporosity in the casting. There are also material considerations for avoiding such deleterious effects as incipient melting, grain growth, or degradation of constituent phases such as carbides.

If encountered, incipient melting can be avoided by pre-HIP homogenization heat treatments or by lowering HIP temperatures. If the temperature is lowered, an increase in processing pressure may be required for obtaining closure in certain alloys. For example, hafnium-bearing nickel-base superalloys such as C-101 and MAR-M247, when cast with heavy sections (for example, integral wheels), have been found to undergo incipient melting when hot isostatically pressed at 1205 °C (2200 °F) and 103 MPa (15 ksi) for 4 h. To prevent incipient melting and still obtain closure, the HIP parameters were changed to 1185 °C (2165 °F) and 172 MPa (25 ksi) for 4 h. This trade-off between temperature and pressure can also be used to prevent grain growth and to prevent or limit carbide degradation while obtaining closure of microporosity.

Time at temperature and pressure will obviously affect processing cost. For most alloys, 2 to 4 h is sufficient. Exceptions are massive section sizes, which require additional thermal soaking time. General processing guidelines for several alloy types are given in Table 4.

Table 4 General HIP processing parameters for various cast alloys

Alloy type	**Temperature range**		**Pressure**		Time, h
	°C	**°F**	**MPa**	**ksi**	
Magnesium alloys	370-400	700-750	103	15	**2-4**

Gas Purity. Surface contamination of castings can occur unless extremely pure argon pressurizing gas is used. Impurities such as hydrogen, nitrogen, oxygen, carbon monoxide, water vapor, and hydrocarbons in parts per million concentrations have been found to cause deleterious surface reactions in certain alloys. For nickel-base superalloys, nitrogen forms brittle carbonitrides, oxygen forms surface and intergranular oxides, and carbon compounds (carbon monoxide, methane, and so on) can cause surface carburization. In titanium alloys, oxygen causes the formation of an α case. To prevent contamination, the purity of the process gas should be verified by gas chromatography before each HIP cycle. To assess the entire gas supply system, sampling should be conducted on the gas as it exits the hot isostatic pressing vessel.

Distortion of castings during the hot isostatic pressing process typically results from two sources: the thermal cycle and the deformation associated with void closure. Because hot isostatic pressing is a thermal treatment, the same type of distortion as would occur in a normal heat treat cycle will also occur during hot isostatic pressing. In addition, if large voids exist in the casting, surface depressions may develop as a result of material displacement during void closure. If small, uniformly distributed voids are present in a casting, a dimpled surface may be evident after hot isostatic pressing. Such a condition is typical in many sand cast aluminum parts. In most cases, however, no void-induced distortion can be detected after hot isostatic pressing.

Surface defects in a casting cannot be closed during hot isostatic pressing, because no pressure differential can be established at the defect. To prevent the opening of any subsurface defects prior to hot isostatic pressing, castings should be hot isostatically pressed before the use of any aggressive metal removal techniques such as abrasive blasting, chemical cleaning, or machining. For certain castings, it may be desirable to leave substantial gate witnesses to prevent the opening of pipe shrinkage that leads into the casting. In weldable alloy systems, surface defects can be repair welded before hot isostatic pressing if nondestructive testing techniques can identify the defect. Alloys that are not readily weldable, such as superalloys, can be repaired by vacuum brazing or other techniques to seal surface defects prior to hot isostatic pressing.

Casting Salvage. When hot isostatic pressing is used to salvage scrap castings, the presence of surface-connected porosity must be considered. The surface integrity of the scrap castings must be assessed in order to determine if the components are suitable for hot isostatic pressing. If extensive surface-connected porosity is present, an economic analysis should be conducted to determine if the combined costs of sealing surface defects and hot isostatic pressing are economically viable.

Post-HIP Heat Treatment. Most of the HIP furnaces in production are of the slow-cool type, with cooling rates of approximately 4 to 11 °C (7 to 20 °F) per minute. Alloys that need fast cooling for the development of properties will require post-HIP heat treatments. Stainless steels that are susceptible to sensitization must be solution annealed and fast cooled in order to maintain corrosion resistance. Alloy steels can be normalized to refine the grain size of castings that experience grain growth during hot isostatic pressing. The thermal soak time employed during hot isostatic pressing may allow homogenization treatments for certain alloys to be shortened or eliminated.

New Foundry Process Applications

Fine-Grain Castings. One of the most significant foundry advancements made possible through the use of hot isostatic pressing has been the development of fine-grain superalloy castings. In the late 1960s, experiments were conducted on a grain refinement technique for integral turbine wheels. The technique used the mechanical motion of a mold to shear dendrites from the solidifying metal. These dendrites then acted as nucleation sites for additional grains. However, the process was not commercially introduced, because it produced castings with unacceptable levels of porosity.

In the mid-1970s, developmental work on this process resumed when it was realized that hot isostatic pressing could be used to eliminate residual casting porosity. The process that developed from this work, known as Grainex, results in ASTM grain sizes as fine as No. 2. A further development, the Microcast-X process, has led to a greater refinement in grain size (ASTM No. 3 to 5). Figure 8 compares the microstructures of grain-refined rotors with those of a conventionally cast part.

Casting Replacement of Forgings and Fabrications

The demonstrated ability of hot isostatic pressing to increase mechanical properties and to reduce data scatter has made it possible for castings to replace more expensive wrought and fabricated components. For example, bearing supports were originally produced from AISI 4340 or AM355 bar stock (Ref 8). A substantial amount of machining was required to produce the support. By converting to a near-net shape hot isostatically pressed investment casting, it was possible to produce a support that met the performance requirements and reduced machining costs.

In another case, a Ti-6Al-4V flap (Fig. 9) originally fabricated from welded sheet stock was converted into a less expensive cast and hot isostatically pressed component. Similarly, the four separate IN718 forgings and spinnings shown in Fig. 10(a) are welded together to produce a turbine casing for a helicopter engine (Ref 8). By changing to a net shape investment cast and hot isostatically pressed design (Fig. 10b), it was possible to eliminate many manufacturing and inspection operations. The cast part is less expensive than the assembled forgings and meets performance requirements.

Casting Refurbishment

The hot sections of industrial and aircraft gas turbine engines contain turbine blades that are produced primarily as investment castings in nickel-base superalloys. During engine operation, turbine blades develop both internal and external damage. Internal damage may consist of creep, grain-boundary cavitation, and microcracking, all of which can be closed with hot isostatic pressing to rejuvenate the blade. After traditional refurbishment processes such as coating and heat treatment, blades can be returned to service. Investigations conducted under Air Force contract have demonstrated the feasibility of this process (Ref 9, 10). Tables 5 and 6 present stress rupture properties obtained on rejuvenated René 80 and directionally solidified MAR-M200 + Hf turbine blades. In addition, because turbine blades are manufactured from alloys that contain strategic materials, extending the blade life with hot isostatic pressing can reduce the consumption of these important materials.

Table 5 Stress rupture life of new and HIP-rejuvenated René 80 first-stage turbine blade castings

Blade condition	Stress rupture life, h

	760 °C (1400 °F) and 621 MPa (90 ksi)		980 °C (1800 °F) and 183 MPa (26.5 ksi)

Testing and Inspection of Casting Defects

By the ASM Committee on Nondestructive Inspection of Castings*

Introduction

GENERAL INSPECTION PROCEDURES for castings are established at the foundry to ensure conformance with customer drawings and documents, which are frequently based on various government, technical society, or commercial specifications. For a foundry to ensure casting quality, inspection procedures must be efficiently directed toward the prevention of imperfections, the detection of unsatisfactory trends, and the conservation of material--all of which ultimately lead to reduction in costs. Inspectors should be able to assess on sight the probable strong and weak points of a casting and know where weaknesses and faults would most likely be found.

Inspection of castings normally involves checking for shape and dimensions, coupled with aided and unaided visual inspection for external discontinuities and surface quality. Chemical analyses and tests for mechanical properties are supplemented by various forms of nondestructive inspection, including leak testing and proof loading, all of which are used to evaluate the soundness of the casting. These inspections add to the cost of the product; therefore, the initial consideration must be to determine the amount of inspection needed to maintain adequate control over quality. In some cases, this may require full inspection of each individual casting, but in other cases sampling procedures may be sufficient.

Methods for Determining Surface Quality. Cracks and other imperfections at the surface of a casting can be detected by a number of inspection techniques, including visual inspection, chemical etching, liquid penetrant inspection, eddy current inspection, and magnetic particle inspection (which can also reveal discontinuities situated immediately below the surface). All inspection methods require clean and relatively smooth surfaces for effective results.

Methods for Detecting Internal Discontinuities. The principal nondestructive methods used for detecting internal discontinuities in castings are radiographic, ultrasonic, and eddy current inspection. Of these methods, radiography is the most highly developed technique for detailed inspection; it can provide a pictorial representation of the form and extent of many types of internal discontinuities. Ultrasonic inspection, which is less universally applicable, can give qualitative indications of many discontinuities. It is especially useful in the inspection of castings of fairly simple design, where the signal pattern can be most reliably interpreted. Ultrasonic inspection can also be used to determine the shape of graphite particles in cast iron. Eddy current and other closely related electromagnetic methods are used to sort castings for variations in composition, surface hardness, and structure.

Methods for Dimensional Inspection. There are a number of techniques used to determine the dimensional accuracy of castings. These include manual checks with micrometers, manual and automatic gages, coordinate-measuring machines, and three-dimensional automatic inspection stations (machine vision systems). This section will discuss the use

of coordinate-measuring machines. Additional information on methods for dimensional inspection will be provided in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Casting Defects

Although foundrymen favor referring to the deviations in less-than-perfect castings as discontinuities, these imperfections are more commonly referred to as casting defects. Some casting defects may have no effect on the function or the service life of cast components, but will give an unsatisfactory appearance or will make further processing, such as machining, more costly. Many such defects can be easily corrected by shot blast cleaning or grinding. Other defects that may be more difficult to remove can be acceptable in some locations. It is most critical that the casting designer understand the differences and that he write specifications that meet the true design needs.

Classification of Casting Defects. Foundrymen have traditionally used rather unique names, such as rattail, scab, buckle, snotter, and shut, to describe various casting imperfections (such terms are defined in the "Glossary of Terms" in this Volume). Unfortunately, foundrymen may use different nomenclature to describe the same defect. The International Committee of Foundry Technical Associations has standardized the nomenclature, starting with the identification of seven basic categories of casting defects:

- Metallic projections
- Cavities
- Discontinuities
- Defects
- Incomplete casting
- Incorrect dimension
- Inclusions or structural anomalies

In this scheme, the term discontinuity has the specific meaning of a planar separation of the metal, that is, a crack.

Table 1 presents some of the common defects in each category. In general, defects that can serve as stress raisers or crack promoters are the most serious. These include preexisting cracks, internal voids, and nonmetallic inclusions. The causes of these defects and their correction and prevention are discussed in the Section "Design Considerations" in this Volume.

Table 1 International classification of common casting defects

No.	**Description**	**Common name**	Sketch
Metallic Projections			
A 100:	Metallic projections in the form of fins or flash		
A 110:	Metallic projections in the form of fins (or flash) without change in principal casting dimensions		

A 111	Thin fins (or flash) at the parting line or at core prints	Joint flash or fins	A 112	Projections in the form of veins on the casting surface	Veining or finning	A 113	Network of projections on the surface of die castings	Heat-checked die	A 114[a]	Thin projection parallel to a casting surface, in re-entrant angles	Fillet scab	A 115	Thin metallic projection located at a re-entrant angle and dividing the angle in two parts	Fillet vein	A 120:	Metallic projections in the form of fins with changes in principal casting dimensions		
A 123[a]	Formation of fins in planes related to direction of mold assembly (precision casting with waste pattern); principal casting dimensions change	Cracked or broken mold	A 200:	Massive projections		
A 210:	Swells		
A 212[a]	Excess metal in the vicinity of the gate or beneath the sprue	Erosion, cut, or wash	
A 213[a]	Metal projections in the form of elongated areas in the direction of mold assembly	Crush	A 220:	Projections with rough surfaces		
A 221[a]	Projections with rough surfaces on the cope surface of the casting	Mold drop or sticker	A 222[a]	Projections with rough surfaces on the drag surface of the casting (massive projections)	Raised core or mold element cutoff	A 223[a]	Projections with rough surfaces on the drag surface of the casting (in dispersed areas)	Raised sand	A 224[a]	Projections with rough surfaces on other parts of the casting	Mold drop	A 225[a]	Projections with rough surfaces over extensive areas of the casting	Corner scab	A 226[a]	Projections with rough surfaces in an area formed by a core	Broken or crushed core	Cavities			
B 100:	Cavities with generally rounded, smooth walls perceptible to the naked eye (blowholes, pinholes)		
B 110:	Class B 100 cavities internal to the casting, not extending to the surface, discernible only by special methods, machining, or fracture of the casting		

B 111[a]	Internal, rounded cavities, usually smooth-walled, of varied size, isolated or grouped irregularly in all areas of the casting	Blowholes, pinholes	B 112[a]	As above, but limited to the vicinity of metallic pieces placed in the mold (chills, inserts, chaplets, etc.)	Blowholes, adjacent to inserts, chills, chaplets, etc.	B 113[a]	Like B 111, but accompanied by slag inclusions (G 122)	Slag blowholes	B 120:	Class B 100 cavities located at or near the casting surface, largely exposed or at least connected with the exterior		
B 121[a]	Exposed cavities of various sizes, isolated or grouped, usually at or near the surface, with shiny walls	Surface or subsurface blowholes	B 122[a]	Exposed cavities, in re-entrant angles of the casting, often extending deeply within	Corner blowholes, draws	B 123	Fine porosity (cavities) at the casting surface, appearing over more or less extended areas	Surface pinholes	B 124[a]	Small, narrow cavities in the form of cracks, appearing on the faces or along edges, generally only after machining	Dispersed shrinkage	B 200:	Cavities with generally rough walls, shrinkage		

B 210:	Open cavity of Class B 200, sometimes penetrating deeply into the casting		
B 211(a)	Open, funnel-shaped cavity; wall usually covered with dendrites	Open or external shrinkage	B 212(a)	Open, sharp-edged cavity in fillets of thick castings or at gate locations	Corner or fillet shrinkage	B 213(a)	Open cavity extending from a core	Core shrinkage	B 220:	Class B 200 cavity located completely internal to the casting		
B 221(a)	Internal, irregularly shaped cavity; wall often dendritic	Internal or blind shrinkage	B 222(a)	Internal cavity or porous area along central axis	Centerline or axial shrinkage	B 300:	Porous structures caused by numerous small cavities		
B 310:	Cavities according to B 300, scarcely perceptible to the naked eye		
B 311(a)	Dispersed, spongy dendritic shrinkage within walls of casting; barely perceptible to the naked eye	Macro- or micro-shrinkage, shrinkage porosity, leakers	Discontinuities			

C 100:	Discontinuities, generally at intersections, caused by mechanical effects (rupture)		
C 110:	Normal cracking		
C 111[a]	Normal fracture appearance, sometimes with adjacent indentation marks	Breakage (cold)	C 120:	Cracking with oxidation		
C 121[a]	Fracture surface oxidized completely around edges	Hot cracking	C 200:	Discontinuities caused by internal tension and restraints to contraction (cracks and tears)		
C 210:	Cold cracking or tearing		
C 211[a]	Discontinuities with squared edges in areas susceptible to tensile stresses during cooling; surface not oxidized	Cold tearing	C 220:	Hot cracking and tearing		
C 221[a]	Irregularly shaped discontinuities in areas susceptible to tension; oxidized fracture surface showing dendritic pattern	Hot tearing	C 222[a]	Rupture after complete solidification, either during cooling or heat treatment	Quench cracking	C 300:	Discontinuities caused by lack of fusion (cold shuts); edges generally rounded, indicating poor contact between various metal streams during filling of the mold		
C 310:	Lack of complete fusion in the last portion of the casting to fill		

C 311[a]	Complete or partial separation of casting wall, often in a vertical plane	Cold shut or cold lap	C 320:	Lack of fusion between two parts of casting		
C 321[a]	Separation of the casting in a horizontal plane	Interrupted pour	C 330:	Lack of fusion around chaplets, internal chills, and inserts		
C 331[a]	Local discontinuity in vicinity of metallic insert	Chaplet or insert cold shut, unfused chaplet	C 400:	Discontinuities caused by metallurgical defects		
C 410:	Separation along grain boundaries		
C 411[a]	Separation along grain boundaries of primary crystallization	Conchoidal or "rock candy" fracture	C 412[a]	Network of cracks over entire cross section	Intergranular corrosion	Defective Surface			
D 100:	Casting surface irregularities		
D 110:	Fold markings on the skin of the casting		
D 111	Fold markings over rather large areas of the casting	Surface folds, gas runs	D 112	Surface shows a network of jagged folds or wrinkles (ductile iron)	Cope defect, elephant skin, laps	
D 113	Wavy fold markings without discontinuities; edges of folds at same level, casting surface is smooth	Seams or scars	
D 114	Casting surface markings showing direction of liquid metal flow (light alloys)	Flow marks	
D 120:	Surface roughness		
D 121	Depth of surface roughness is approximately that of the dimensions of the sand grains	Rough casting surface	D 122	Depth of surface roughness is greater than that of the sand grain dimensions	Severe roughness, high pressure molding defect	D 130:	Grooves on the casting surface		
D 131	Grooves of various lengths, often branched, with smooth bottoms and edges	Buckle	D 132	Grooves up to 5.1 mm (0.2 in.) in depth, one edge forming a fold which more or less completely covers the groove	Rat tail	D 133	Irregularly distributed depressions of various dimensions extending over the casting surface, usually along the path of metal flow (cast steel)	Flow marks, crow's feet	D 134	Casting surface entirely pitted or pock-marked	Orange peel, metal mold reaction, alligator skin	D 135	Grooves and roughness in the vicinity of re-entrant angles on die castings	Soldering, die erosion	D 140:	Depressions in the casting surface		

D 141	Casting surface depressions in the vicinity of a hot spot	Sink marks, draw or suck-in	D 142	Small, superficial cavities in the form of droplets of shallow spots, generally gray-green in color	Slag inclusions	D 200:	Serious surface defects		
D 210:	Deep indentation of the casting surface		
D 211	Deep indentation, often over large area of drag half of casting	Push-up, clamp-off	D 220:	Adherence of sand, more or less vitrified		
D 221	Sand layer strongly adhering to the casting surface	Burn on	D 222	Very adherent layer of partially fused sand	Burn in	D 223	Conglomeration of strongly adhering sand and metal at the hottest points of the casting (re-entrant angles and cores)	Metal penetration	D 224	Fragment of mold material embedded in casting surface	Dip coat spall, scab	D 230:	Plate-like metallic projections with rough surfaces, usually parallel to casting surface		

D 231[a]	Plate-like metallic projections with rough surfaces parallel to casting surface; removable by burr or chisel	Scabs, expansion scabs	D 232[a]	As above, but impossible to eliminate except by machining or grinding	Cope spall, boil scab, erosion scab	D 233[a]	Flat, metallic projections on the casting where mold or core washes or dressings are used	Blacking scab, wash scab	D 240:	Oxides adhering after heat treatment (annealing, tempering, malleablizing) by decarburization		
D 241	Adherence of oxide after annealing	Oxide scale	D 242	Adherence of ore after malleablizing (white heart malleable	Adherent packing material	D 243	Scaling after anneal	Scaling	Incomplete Casting			
E 100:	Missing portion of casting (no fracture)		
E 110:	Superficial variations from pattern shape		

E 111	Casting is essentially complete except for more or less rounded edges and corners	Misrun	E 112	Deformed edges or contours due to poor mold repair or careless application of wash coatings	Defective coating (tear-dropping) or poor mold repair	E 120:	Serious variations from pattern shape		
E 121	Casting incomplete due to premature solidification	Misrun	E 122	Casting incomplete due to insufficient metal poured	Poured short	E 123	Casting incomplete due to loss of metal from mold after pouring	Runout	E 124	Significant lack of material due to excessive shot-blasting	Excessive cleaning	E 125	Casting partially melted or seriously deformed during annealing	Fusion or melting during heat treatment	E 200:	Missing portion of casting (with fracture)		
E 210:	Fractured casting		
E 211	Casting broken, large piece missing; fractured surface not oxidized	Fractured casting	E 220:	Piece broken from casting		

E 221	Fracture dimensions correspond to those of gates, vents, etc.	Broken casting (at gate, riser, or vent)	E 230:	Fractured casting with oxidized fracture		
E 231	Fracture appearance indicates exposure to oxidation while hot	Early shakeout	
Incorrect Dimensions or Shape			
F 100:	Incorrect dimensions; correct shape		
F 110:	All casting dimensions incorrect		
F 111	All casting dimensions incorrect in the same proportions	Improper shrinkage allowance	F 120:	Certain casting dimensions incorrect		
F 121	Distance too great between extended projections	Hindered contraction	F 122	Certain dimensions inexact	Irregular contraction	F 123	Dimensions too great in the direction of rapping of pattern	Excess rapping of pattern	
F 125	Excessive metal thickness at irregular locations on casting exterior	Soft or insufficient ramming, mold-wall movement	F 126	Thin casting walls over general area, especially on horizontal surfaces	Distorted casting	F 200:	Casting shape incorrect overall or in certain locations		
F 210:	Pattern incorrect		
F 211	Casting does not conform to the drawing shape in some or many respects; same is true of pattern	Pattern error	F 212	Casting shape is different from drawing in a particular area; pattern is correct	Pattern mounting error	F 220:	Shift or Mismatch		
F 221	Casting appears to have been subjected to a shearling action in the plane of the parting line	Shift	F 222	Variation in shape of an internal casting cavity along the parting line of the core	Shifted core	F 223	Irregular projections on vertical surfaces, generally on one side only in the vicinity of the parting line	Ramoff, ramaway	F 230:	Deformations from correct shape		
F 231	Deformation with respect to drawing proportional for casting, mold, and pattern	Deformed pattern	
F 232	Deformation with respect to drawing proportional for casting and mold; pattern conforms to drawing	Deformed mold, mold creep, springback	F 233	Casting deformed with respect to drawing; pattern and mold conform to drawing	Casting distortion	F 234	Casting deformed with respect to drawing after storage, annealing, machining	Warped casting	Inclusions or Structural Anomalies			
G 100:	Inclusions		
G 110:	Metallic inclusions		
G 111[(a)]	Metallic inclusions whose appearance, chemical analysis or structural examination show to be caused by an element foreign to the alloy	Metallic inclusions	G 112[(a)]	Metallic inclusions of the same chemical composition as the base metal; generally spherical and often coated with oxide	Cold shot	G 113	Spherical metallic inclusions inside blowholes or other cavities or in surface depressions (see A 311). Composition approximates that of the alloy cast but nearer to that of a eutectic	Internal sweating, phosphide sweat	G 120:	Nonmetallic inclusions; slag, dross, flux		
G 121[(a)]	Nonmetallic inclusions whose appearance or analysis shows they arise from melting slags, products of metal treatment or fluxes	Slag, dross or flux inclusions, ceroxides	
G 122[a]	Nonmetallic inclusions generally impregnated with gas and accompanied by blowholes (B 113)	Slag blowhole defect	G 130:	Nonmetallic inclusions; mold or core materials		
G 131[a]	Sand inclusions, generally very close to the surface of the casting	Sand inclusions	G 132[a]	Inclusions of mold blacking or dressing, generally very close to the casting surface	Blacking or refractory coating inclusions	G 140:	Nonmetallic inclusions; oxides and reaction products		
G 141	Clearly defined, irregular black spots on the fractured surface of ductile cast iron	Black spots	G 142[a]	Inclusions in the form of oxide skins, most often causing a localized seam	Oxide inclusion or skins, seams	G 143[a]	Folded films of graphitic luster in the wall of the casting	Lustrous carbon films, or kish tracks	G 144	**Hard inclusions in permanent molded and die cast aluminum alloys**	**Hard spots**	
(a) Defects that under some circumstances could contribute, either directly or indirectly, to casting failures. Adapted from *International Atlas of Casting Defects*, American Foundrymen's Society, Des Plaines, IL

Common Inspection Procedures

Inspection of castings is most often limited to visual and dimensional inspections, weight testing, and hardness testing. However, for castings that are to be used in critical applications, such as in aerospace components, additional methods of nondestructive inspection are used to determine and to control casting quality.

Visual inspection of each casting ensures that none of its features has been omitted or malformed by molding errors, short running, or mistakes in cleaning. Most surface defects and roughness can be observed at this stage.

Initial sample castings from new pattern equipment should be carefully inspected for obvious defects. Liquid penetrant inspection can be used to detect surface defects. Such casting imperfections as shrinks, cracks, blows, or dross usually indicate the need for adjustment in the gating or foundry techniques. If the casting appears to be satisfactory upon visual inspection, internal quality can be checked by radiographic and ultrasonic inspection.

The first visual inspection operation on the production casting is usually performed immediately after shakeout or knockout of the casting. This ensures that major visible imperfections are detected as quickly as possible. This information, promptly relayed to the foundry, permits early corrective action to be taken with a minimum of scrap loss. The size and complexity of some sand castings require that the gates and risers be removed to permit proper inspection of the casting. Many castings that contain numerous internal cores or have close dimensional tolerances require a rapid but fairly accurate check of critical wall dimensions. In some cases, an indicating-type caliper gage is suitable for this work, and special types are available for casting shapes that do not lend themselves to the standard types. Ultrasonic inspection is also used to determine wall thickness in such components as cored turbine blades made by investment casting (see the article "Investment Casting" in this Volume).

Dimensional Inspection. Dimensional deviations on machined surfaces are relatively simple to evaluate and can be accurately specified. However, it is not so simple to determine the acceptability of dimensions that involve one or more unmachined surfaces. Dimensional inspection can be carried out with the aid of gages, jigs, and templates.

Most initial machining operations on castings use a cast surface as a datum; the exceptions are those large castings that are laid out, before machining, to give the required datum. Therefore, it is important that the cast surface used as a datum be reasonably true and that it be in the correct position relative to other critical machined or unmachined surfaces on the same casting, within clearly defined limits.

The cast surface used as a datum can be a mold surface, and variations can occur because of mold movement. The cast surface can be produced by a core; movement of cores is a frequent cause of casting inaccuracy. Errors involving these surfaces can produce consequential errors or inadequate machining stock elsewhere on the casting.

Where dimensional errors are detected in relation to general drawing tolerances, their true significance must be determined. A particular dimension may be of vital importance, but may have been included in blanket tolerances. This situation stresses the desirability of stating functional dimensions on drawings so that tolerances are not restricted unnecessarily.

Weight Testing. Many intricately cored castings are extremely difficult to measure accurately, particularly the internal sections. It is important to ensure that these sections are correct in thickness for three main reasons:

- There should be no additional weight that would make the finished product heavier than permissible
- Sections must not be thinner than designed to prevent detracting from the strength of the casting
- If hollow cavities have been reduced in area by increasing the metal thickness of the sections, any flow of liquid or gases is reduced

A ready means of testing for these discrepancies is by accurately weighing each casting or by measuring the displacement caused by immersing the casting in a liquid-filled measuring jar or vessel. In certain cases in which extreme accuracy is demanded, a tolerance of only ±1% of a given weight may be allowed.

Hardness testing is often used to verify the effectiveness of heat treatment applied to actual castings. Its general correlation with the tensile strength of many ferrous alloys enables a rough prediction of tensile strength to be made.

The Brinell hardness test is most frequently used for casting alloys. A combination of large-diameter ball (5 or 10 mm) and heavy load (500 to 3000 kgf) is preferred for the most effective representation because a deep impression minimizes the influence of the immediate surface layer and of the relatively coarse microstructure. The Brinell hardness test is unsuitable for use at high hardness levels (above ~600 HB), because distortion of the ball indenter can affect the shape of the indentation.

Either the Rockwell or the Vickers (136° diamond pyramid) hardness test is used for alloys of extreme hardness or for high-quality and precision castings in which the large Brinell indentation cannot be tolerated. Because of the very small indentations produced in Rockwell and Vickers tests, which use loads of 150 kg or less, results must be based on the average of a number of determinations. Portable hardness testers or ultrasonic microhardness testers can be used on large castings that cannot be placed on the platform of a bench-type machine. More detailed information on hardness testing is available in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

The hardness of ferrous castings can be related to the sonic velocity of the metal and determined from it if all other test conditions remain constant. This has been demonstrated on chilled rolls in determining the average hardness of the core.

Liquid Penetrant Inspection

Liquid penetrant inspection essentially involves a liquid wetting the surface of a workpiece, flowing over that surface to form a continuous and uniform coating, and migrating into cracks or cavities that are open to the surface. After a few minutes, the liquid coating is washed off the surface of the casting and a developer is placed on the surface. The developer is stained by the liquid penetrant as it is drawn out of the cracks and cavities. Liquid penetrants will highlight surface defects so that detection is more certain.

Liquid penetrant inspection should not be confined to as-cast surfaces. For example, it is not unusual for castings of various alloys to exhibit cracks, frequently intergranular, on machined surfaces. A pattern of cracks of this type may be the result of intergranular cracking throughout the material because of an error in composition or heat treatment, or the cracks may be on the surface only as a result of machining or grinding. Surface cracking may result from insufficient machining allowance, which does not allow for complete removal of imperfections produced on the as-cast surface, or it may result from faulty machining techniques. If imperfections of this type are detected by visual inspection, liquid penetrant inspection will show the full extent of such imperfections, will give some indication of the depth and size of the defect below the surface by the amount of penetrant absorbed, and will indicate whether cracking is present throughout the section.

Magnetic Particle Inspection

Magnetic particle inspection is a highly effective and sensitive technique for revealing cracks and similar defects at or just beneath the surface of castings made of ferromagnetic metals. The capability of detecting discontinuities just beneath the surface is important because such cleaning methods as shot or abrasive blasting tend to close a surface break that might go undetected in visual or liquid penetrant inspection.

When a magnetic field is generated in and around a casting made of a ferromagnetic metal and the lines of magnetic flux are intersected by a defect such as a crack, magnetic poles are induced on either side of the defect. The resulting local flux disturbance can be detected by its effect on the particles of a ferromagnetic material, which become attracted to the region of the defect as they are dusted on the casting. Maximum sensitivity of indication is obtained when a defect is oriented in a direction perpendicular to the applied magnetic field and when the strength of this field is just enough to saturate the casting being inspected.

Equipment for magnetic particle inspection uses direct or alternating current to generate the necessary magnetic fields. The current can be applied in a variety of ways to control the direction and magnitude of the magnetic field.

In one method of magnetization, a heavy current is passed directly through the casting placed between two solid contacts. The induced magnetic field then runs in the transverse or circumferential direction, producing conditions favorable to the detection of longitudinally oriented defects. A coil encircling the casting will induce a magnetic field that runs in the longitudinal direction, producing conditions favorable to the detection of circumferentially (or transversely) oriented defects. Alternatively, a longitudinal magnetic field can be conveniently generated by passing current through a flexible cable conductor, which can be coiled around any metal section. This method is particularly adaptable to castings of irregular shape. Circumferential magnetic fields can be induced in hollow cylindrical castings by using an axially disposed central conductor threaded through the casting.

Small castings can be magnetic particle inspected directly on bench-type equipment that incorporates both coils and solid contacts. Critical regions of larger castings can be inspected by the use of yokes, coils, or contact probes carried on flexible cables connected to the source of current this setup enables most regions of castings to be inspected.

Eddy Current Inspection

Eddy current inspection consists of observing the interaction between electromagnetic fields and metals. In a basic system, currents are induced to flow in the testpiece by a coil of wire that carries an alternating current. As the part enters the coil, or as the coil in the form of a probe or yoke is placed on the testpiece, electromagnetic energy produced by the coils is partly absorbed and converted into heat by the effects of resistivity and hysteresis. Part of the remaining energy is reflected back to the test coil, its electrical characteristics having been changed in a manner determined by the properties of the testpiece. Consequently, the currents flowing through the probe coil are the source of information describing the characteristics of the testpiece. These currents can be analyzed and compared with currents flowing through a reference specimen.

Eddy current methods of inspection are effective with both ferromagnetic and nonferromagnetic metals. Eddy current methods are not as sensitive to small, open defects as liquid penetrant or magnetic particle methods are. Because of the skin effect, eddy current inspection is generally restricted to depths less than 6 mm ($\frac{1}{4}$ in.). The results of inspecting ferromagnetic materials can be obscured by changes in the magnetic permeability of the testpiece. Changes in temperature must be avoided to prevent erroneous results if electrical conductivity or other properties, including metallurgical properties, are being determined.

Applications of eddy current and electromagnetic methods of inspection to castings can be divided into the following three categories:

- Detecting near-surface flaws such as cracks, voids, inclusions, blowholes, and pinholes (eddy current inspection)
- Sorting according to alloy, temper, electrical conductivity, hardness, and other metallurgical factors (primarily electromagnetic inspection)
- Gaging according to size, shape, plating thickness, or insulation thickness (eddy current or electromagnetic inspection)

Radiographic Inspection**

Radiographic inspection is a process of testing materials using penetrating radiation from an x-ray generator or a radioactive source and an imaging medium, such as x-ray film or an electronic device. In passing through the material, some of the radiation is attenuated, depending on the thickness and the radiographic density of the material, while the radiation that passes through the material forms an image. The radiographic image is generated by variations in the intensity of the emerging beam.

Internal flaws, such as gas entrapment or nonmetallic inclusions, have a direct effect on the attenuation. These flaws create variations in material thickness, resulting in localized dark or light spots on the image.

The term radiography usually implies a radiographic process that produces a permanent image on film (conventional radiography) or paper (paper radiography or xeroradiography), although in a broad sense it refers to all forms of radiographic inspection. When inspection involves viewing an image on a fluorescent screen or image intensifier, the radiographic process is termed filmless or real time inspection (Fig. 1). When electronic nonimaging instruments are used to measure the intensity of radiation, the process is termed radiation gaging. Tomography, a radiation inspection method adapted from the medical computerized axial tomography scanner, provides a cross-sectional view of a testpiece. All of the above terms are primarily used in connection with inspection that involves penetrating electromagnetic radiation in the form of x-rays or γ-rays. Neutron radiography refers to radiographic inspection using neutrons rather than electromagnetic radiation.

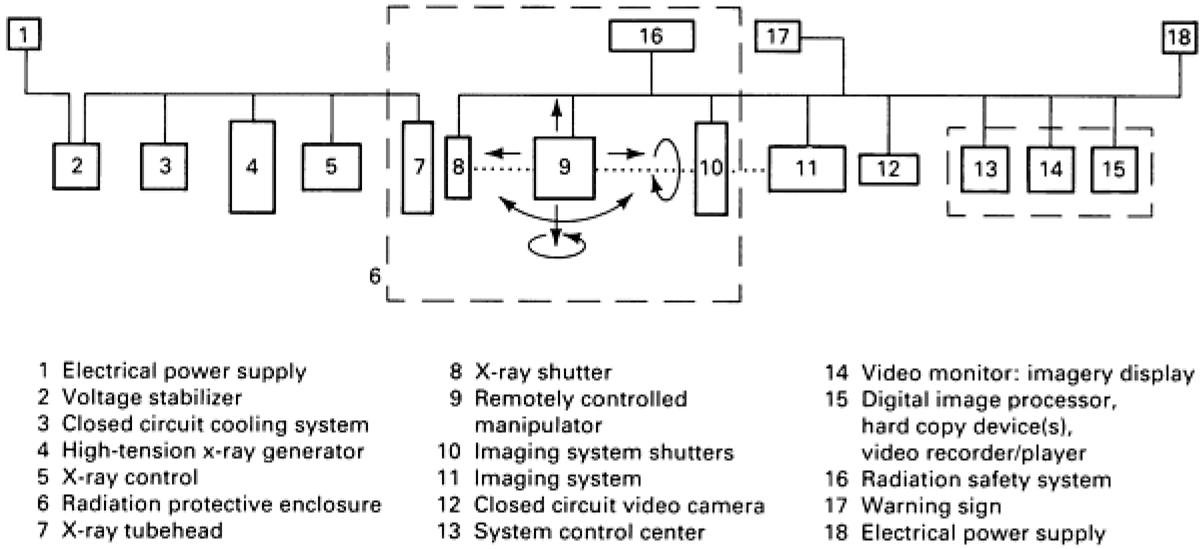

Fig. 1 Schematic of real time x-ray inspection system. Source: TFI Corporation.

The sensitivity, or the ability to detect flaws, of radiographic inspection depends on close control of the inspection technique, including the geometric relationships among the point of x-ray emission, the casting, and the x-ray imaging plane. The smallest detectable variation in metal thickness lies between 0.5 and 2.0% of the total section thickness. Narrow flaws, such as cracks, must lie in a plane approximately parallel to the emergent x-ray beam to be imaged; this requires multiple exposures for x-ray film techniques and a remote control parts manipulator for a real time system.

Real time systems have eliminated the need for multiple exposures of the same casting by dynamically inspecting parts on a manipulator, with the capability of changing the x-ray energy for changes in total material thickness. These capabilities have significantly improved productivity and have reduced costs, thus enabling higher percentages of castings to be inspected and providing instant feedback after repair procedures.

Advances. Several advances have been made to assist the industrial radiographer. These include the computerization of the radiographic standard shooting sketch, which graphically shows areas to be x-rayed and the viewing direction or angle at which the shot is to be taken, and the development of microprocessor-controlled x-ray systems capable of storing different x-ray exposure parameters for rapid retrieval and automatic warm-up of the system prior to use. The advent of digital image processing systems and microfocus x-ray sources (near point source), producing energies capable of penetrating thick material sections, have made real time inspection capable of producing images equal to, and in some cases superior to, x-ray film images by employing geometric relations previously unattainable with macrofocus x-ray systems. The near point source of the microfocus x-ray system virtually eliminates the edge unsharpness associated with larger focus devices.

Digital image processing can be used to enhance imagery by multiple video frame integration and averaging techniques that improve the signal-to-noise ratio of the image. This enables the radiographer to digitally adjust the contrast of the image and to perform various edge enhancements to increase the conspicuity of many linear indications.

Interpretation of the radiographic image requires a skilled specialist who can establish the correct method of exposing the castings with regard to x-ray energies, geometric relationships, and casting orientation and can take all of these factors into account to achieve an acceptable, interpretable image. Interpretation of the image must be performed to establish standards in the form of written or photographic instructions. The inspector must also be capable of determining if the localized indication is a spurious indication, a film artifact, a video aberration, or a surface irregularity.

Ultrasonic Inspection

Ultrasonic inspection is a nondestructive method in which beams of high-frequency acoustic energy are introduced into the material under evaluation to detect surface and subsurface flaws and to measure the thickness of the material or the distance to a flaw. An ultrasonic beam will travel through a material until it strikes an interface or defect. Interfaces and defects interrupt the beam and reflect a portion of the incident acoustic energy. The amount of energy reflected is a function of the nature and orientation of the interface or flaw as well as the acoustic impedance of such a reflector. Energy reflected from various interfaces or defects can be used to define the presence and locations of defects, the thickness of the material, or the depth of a defect beneath a surface.

The advantages of ultrasonic tests are as follows:

- High sensitivity, which permits the detection of minute cracks
- Great penetrating power, which allows the examination of extremely thick sections
- Accuracy in measurement of flaw position and estimation of defect size

Ultrasonic tests have the following limitations:

- Size-contour complexity and unfavorable discontinuity orientation can pose problems in interpretation of the echo pattern
- Undesirable internal structure--for example, grain size, structure, porosity, inclusion content, or fine dispersed precipitates--can similarly hinder interpretation
- Reference standards are required

Ultrasonic inspection is more commonly used for wrought and welded products than for castings. It should be noted, however, that slag, porosity, cold shuts, tears, shrinkage cracks, and inclusions can be detected, particularly in castings that are not complex in shape. Wall thickness examination of cored castings is also conducted by ultrasonic inspection.

Leak Testing

Castings that are intended to withstand pressures can be leak tested in the foundry. Various methods are used, according to the type of metal being tested. One method consists of pumping air at a specified pressure into the inside of the casting and then submerging the casting in water at a given temperature. Any leaks through the casting become apparent by the release of bubbles of air through the faulty portions. An alternative method is to fill the cavities of a casting with paraffin at a specified pressure. Paraffin, which will penetrate the smallest of crevices, will rapidly find any defect, such as porosity, and will show quickly as an oily or moist patch at the position of the fault. Liquid penetrants can be poured into areas of apparent porosity and time allowed for the liquid to seep through the casting wall.

Pressure testing of rough (unmachined) castings at the foundry may not reveal any leaks, but it must be recognized that subsequent machining operations on the casting may cut into porous areas and cause the casting to leak after machining. Minor seepage leaks can be sealed by impregnation of the casting with liquid or filled sodium silicate, a synthetic resin, or other suitable substance. As-cast parts can be impregnated at the foundry to seal leaks if there is to be little machining or if experience has shown that machining does not affect the pressure tightness. However, it is usually preferable to impregnate after final machining of the casting.

Inspection of Ferrous Castings

Ferrous castings can be inspected by most of the nondestructive inspection methods. Magnetic particle inspection can be applied to ferrous metals with excellent sensitivity, although a crack in a ferrous casting can often be seen by visual inspection. Magnetic particle inspection provides good crack delineation, but the method should not be used to detect other defects. Irrelevant magnetic particle indications occasionally occur on ferrous castings, especially with a strong magnetic field. For example, a properly fused-in steel chaplet can be indicated as a defect because of the difference in

magnetic response between low-carbon steel and cast iron. Even the graphite in cast iron, which is nonmagnetic, can cause an irrelevant indication.

Standard x-ray and radioactive-source techniques can be used to make radiographs of ferrous castings, but the typical complexity of shape and varying section thicknesses of the castings may require complex procedures. Radiography is sometimes used to inspect critical production castings that will be subjected to high service stresses, but it is more often used to evaluate design or casting procedures.

Ultrasonic inspection for both thickness and defects is practical with most ferrous castings except for the high-carbon gray iron castings, which have a high damping capacity and absorb much of the input energy. The measurement of resonant frequency is a good method for inspecting some ductile iron castings for soundness and graphite shape. Electromagnetic testing can be used to distinguish metallurgical differences between castings. The criteria for separating acceptable from unacceptable castings must be established empirically for each casting lot.

Gray Iron Castings

Gray iron castings are susceptible to most of the imperfections generally associated with castings, with additional problems resulting from the relatively high pouring temperatures. These additional problems result in a higher incidence of gas entrapment, inclusions, poor metal structure, interrupted metal walls, and mold wall deficiencies.

Gas entrapment is a direct result of gas being trapped in the casting wall during solidification. This gas may be in the metal prior to pouring, may be generated from aspiration during pouring, or may be generated from core and mold materials. Internal defects of this type are best detected by radiography, but ultrasonic and eddy current methods of inspection are useful when the defect is large enough to be detected by these methods.

Inclusions are casting defects in which solid foreign materials are trapped in the casting wall. The inclusion material can be slag generated in the melting process, or it can be fragments of refractory, mold sand, core aggregate, or other materials used in the casting process. Inclusions appear most often on the casting surface and are usually detected by visual inspection; however, in many cases, the internal walls of castings contain inclusions that cannot be visually detected. The internal inclusions can be detected by eddy current, radiographic, or ultrasonic inspection; radiography is usually the most reliable method.

Poor Metal Structure. Many casting defects resulting from metal structure are related to shrinkage, which is either a cavity or a spongy area lined with dendrites or is a depression in the casting surface. This type of defect arises from varying rates of contraction while the metal is changing from a liquid to a solid. Other casting defects resulting from varying rates of contraction during solidification include carbide formation, hardness variations, and microporosity.

Internal shrinkage defects are best detected by radiography, although eddy current or ultrasonic inspection can be used. Soft or hard gray iron castings are usually detected by Brinell hardness testing; electromagnetic methods have proved useful on some castings.

Interrupted Metal Walls. Included in this category are such flaws as hot tears, cold shuts, and casting cracks. Cracking of castings is often a major problem in gray iron foundries as a result of the combination of casting designs and high production rates. Visual inspection, or an aided visual method such as liquid penetrant or magnetic particle inspection, is used to detect cracks and cracklike flaws in castings.

Mold wall deficiencies are common problems in gray iron castings. They result in surface flaws such as scabs, rattails, cuts, washes, buckles, drops, and excessive metal penetration into space between sand grains. These flaws are generally detected by visual inspection.

Malleable Iron Castings

Blowholes and spikes are defects that are often found in malleable iron castings. Spikes are a form of surface shrinkage not normally visible to the naked eye but appear as a multitude of short discontinuous surface cracks when subjected to fluorescent magnetic particle inspection. Unlike true fractures, spikes do not propagate, but they are not acceptable where cyclic loading could result in fatigue failure. Spikes are usually seen as short indications about 1.6 mm ($\frac{1}{16}$ in.) long or less and never more than 75 μm (0.003 in.) deep. These defects do not have a preferred orientation but a random pattern

that may or may not follow the direction of solidification. Shrinkage or open structure in the gated area is a defect often found in malleable iron castings that may be overlooked by visual inspection, although it is readily detected by either liquid penetrant or magnetic particle inspection.

Ductile Iron Castings

Ductile iron is cast iron in which the graphite is present in tiny balls or spherulites instead of flakes (as in gray iron) or compacted aggregates (as in malleable iron). The spheroidal graphite structure is produced by the addition of one or more elements to the molten metal.

Casting defects associated with foundry practice--that is, shrinkage, voids from entrapped gas, nonmetallic inclusions, and failure to fill the mold shape--are essentially the same for ductile iron as for gray iron. Carbonnodule segregation occurs when the carbon equivalent (CE) of ductile iron [CE = % total carbon + 0.3 (%Si + %P)] is incorrect for the section thickness of the casting.

Subsurface inclusions arise from the formation of nonmetallic compounds (mainly sulfides) following inoculation of the molten iron. Slag inclusions form in ductile iron in appreciable amounts upon inoculation with magnesium because some of the magnesium ignites in the molten metal. Desulfurization also promotes slag formation.

Inspection of Aluminum Alloy Castings

Effective quality control is needed at every step in the production of an aluminum alloy casting, from selection of the casting method, casting design, and alloy to mold production, foundry technique, machining, finishing, and inspection. Visual methods, such as visual inspection, pressure testing, liquid penetrant inspection, ultrasonic inspection, radiographic inspection, and metallographic examination, can be used to inspect for casting quality. The inspection procedure used should be geared toward the specified level of quality.

Stages of Inspection. Inspections can be divided into three stages: preliminary, intermediate, and final. After tests are conducted on the melt for hydrogen content, for adequacy of silicon modification, and for degree of grain refinement, preliminary inspection may consist of the inspection and testing of test bars cast with the molten alloy at the same time the production castings are poured. These test bars are used to check the quality of the alloy and effectiveness of the heat treatment. Preliminary inspection also includes chemical or spectrographic analysis of the casting, thus ensuring that the melting and pouring operations have resulted in an alloy of the desired composition.

Intermediate inspection, or hot inspection, is performed on the casting as it is taken from the mold. This step is essential so that castings that are obviously defective can be discarded at this stage of production. Castings that are judged unacceptable at this stage can then be considered for salvage by impregnation, welding, or other methods, depending on the type of flaw present and the end use of the casting. More complex castings usually undergo visual and dimensional inspection after the removal of gates and risers.

Final inspection establishes the quality of the finished casting, using any of the methods previously mentioned. Visual inspection also includes the final measurement and comparison of specified and actual dimensions. Dimensions of castings from a large production run can be checked using gages, jigs, fixtures, or coordinate-measuring systems (described later).

Liquid penetrant inspection is extensively used as a visual aid for detecting surface flaws in aluminum alloy castings. Liquid penetrant inspection is applicable to castings made from all the aluminum casting alloys as well as to castings produced by all methods. One of its most useful applications, however, is for inspecting small castings produced in permanent molds from alloys such as 296.0, which are characteristically susceptible to hot cracking. For example, in cast connecting rods, hot shortness may result in fine cracks in the shank sections. Such cracks are virtually undetectable by unaided visual inspection, but are readily detectable by liquid penetrant inspection.

All of the well-known liquid penetrant systems (that is, water-washable, postemulsifiable, and solvent-removable) are applicable to inspection of aluminum alloy castings. In some cases, especially for certain high-integrity castings, more than one system can be used. Selection of the system is primarily based on the size and shape of the castings, surface roughness, production quantities, sensitivity level desired, and available inspection facilities.

Pressure testing is used for castings that must be leaktight. Cored-out passages and internal cavities are first sealed off with special fixtures having air inlets. These inlets are used to build up the air pressure on the inside of the casting. The entire casting is then immersed in a tank of water, or it is covered by a soap solution. Bubbles will mark any point of air leakage.

Radiographic inspection is a very effective means of detecting such conditions as cold shuts, internal shrinkage, porosity, core shifts, and inclusions in aluminum alloy castings. Radiography can also be used to measure the thickness of specific sections. Aluminum alloy castings are ideally suited to examination by radiography because of their relatively low density; a given thickness of aluminum alloy can be penetrated with about one-third the power required for penetrating the same thickness of steel.

Aluminum alloy castings are most often radiographed by an x-ray machine, using film to record the results. Real time radiography is also widely used, particularly for examining large numbers of relatively small castings, and is best suited to detecting shrinkage, porosity, and core shift. Gamma-ray radiography is also satisfactory for detecting specific conditions in aluminum castings. Although the γ-ray method is used to a lesser extent than the x-ray method, it is about equally as effective for detecting flaws or measuring specific conditions. Aluminum alloy castings are most often radiographed to detect about the same types of flaws that may exist in other types of castings, that is, conditions such as porosity or shrinkage, which register as low-density spots or areas and appear blacker on the film or fluoroscopic screen than the areas of sound metal.

Aluminum ingots may contain hidden internal cracks of varying dimensions. Depending on size and location, these cracks may cause an ingot to split during mechanical working and thermal treatment, or they may show up as a discontinuity in the final wrought product. Once the size and location of such cracks are determined, an ingot can be scrapped, or sections free from cracks can be sawed out and processed further. Because the major dimensions of the cracks are along the casting direction, they present good reflecting surfaces for sound waves traveling perpendicular to the casting direction. Thus, ultrasonic methods using a wave frequency that gives adequate penetration into the ingot provide excellent sensitivity for 100% inspection of that part of the ingot that contains critical cracks. Because of ingot thickness (up to 406 mm, or 16 in.) and the small metal separation across the crack, radiographic methods are impractical for inspection.

Ultrasonic Inspection. Aluminum alloy castings are sometimes inspected by ultrasonic methods to evaluate internal soundness or wall thickness. The principal uses of ultrasonic inspection for aluminum alloy castings include detection of porosity in castings and internal cracks in ingots.

Inspection of Copper and Copper Alloy Castings

Inspection of copper and copper alloy castings is generally limited to visual and liquid penetrant inspection of the surface, along with radiographic inspection for internal discontinuities. In specific cases, electrical conductivity tests and ultrasonic inspection can be applied, although the usual relatively large cast grain size could prevent a successful ultrasonic inspection.

Visual inspection is simple yet informative. A visual inspection would include significant dimensional measurements as well as general appearance. Surface discontinuities often indicate that internal discontinuities are also present.

For small castings produced in reasonable volume, a destructive metallographic inspection on randomly selected samples is practical and economical. This is especially true on a new casting for which foundry practice has not been optimized and a satisfactory repeat-ability level has not been achieved.

For castings of some of the harder and stronger alloys, a hardness test is a good means of estimating the level of mechanical properties. Hardness tests are of less value for the softer tin bronze alloys because hardness tests do not reflect casting soundness and integrity.

Because copper alloys are nonmagnetic, magnetic particle inspection cannot be used to detect surface cracks. Instead, liquid penetrant inspection is recommended. Ordinarily, liquid penetrant inspection requires some prior cleaning of the casting to highlight the full detail.

For the detection of internal defects, radiographic inspection is recommended. Radiographic methods and standards are well established for some copper alloy castings (for example, ASTM specifications E 272 and E 310).

As a general rule, the methods of inspection applied to some of the first castings made from a new pattern should include all those that provide a basis for judgment of the acceptability of the casting for the application intended. Any deficiencies or defects should be reviewed and the degree of perfection defined. This procedure can be repeated on successive production runs until repeatability has been ensured.

Gas Porosity. Copper and many copper alloys have a high affinity for hydrogen, with an increasing solubility as the temperature of the molten bath is increased. Conversely, as the metal cools in the mold, most of this hydrogen is rejected from the metal. Because all the gas does not necessarily escape to the atmosphere and may become trapped by the solidifying process, gas porosity may be found in the casting.

In most alloys, gas porosity is identified by the presence of voids that are relatively spherical and are bright and shiny inside. Visible upon sectioning or by radiography, they may either be small, numerous, and rather widely dispersed or fewer in number and relatively large. Regardless of size, they are seldom interconnected except in some of the tin bronze alloys, which solidify in a very dendritic mode. In these alloys, the gas porosity tends to be distributed in the interstices between the dendrities.

Shrinkage voids caused by the change in volume from liquid to solid in copper alloys are different only in degree and possibly shape from those found in other metals and alloys. All nonferrous metals exhibit this volume shrinkage when solidifying from the molten condition.

Shrinkage voids may be open to the air when near or exposed to the surface, or they may be deep inside the thicker sections of the casting. They are usually irregular in shape, compared to gas-generated defects, in that their shape frequently reflects the internal temperature gradients induced by the external shape of the casting.

Hot Tearing. The tin bronzes as a class, as well as a few of the leaded yellow brasses, are susceptible to hot shortness; that is, they lack ductility and strength at elevated temperature. This is significant in that tearing and cracking can take place during cooling in the mold because of mold or core restraint. In aggravated instances, the resulting hot tears in the part appear as readily visible cracks. Sometimes, however, the cracks are not visible externally and are not detectable until after machining. In extreme cases, the cracks become evident only through field failure because the tearing was deep inside the casting.

Nonmetallic inclusions in copper alloys, as with all molten alloys, are normally the result of improper melting and/or pouring conditions. In the melting operation, the use of dirty remelt or dirty crucibles, poor furnace linings, or dirty stirring rods can introduce nonmetallic inclusions into the melt. Similarly, poor gating design and pouring practice can produce turbulence and can generate nonmetallic inclusions. Sand inclusions may also be evident as the result of improper sand and core practice. All commercial metals, by the nature of available commercial melting and molding processes, usually contain very minor amounts of small nonmetallic inclusions. These have little or no effect on the casting. Inclusions of significant size or number are considered detrimental.

Computer-Aided Dimensional Inspection[†]

The use of computer equipment in foundry inspection operations is finding more acceptance as the power and usefulness of available hardware and software increase. The computerization of operations can reduce the man-hours required for inspection tasks, can increase accuracy, and can allow the analysis of data in ways that are not possible or practical with manual operations. Perhaps the best example of this, given the currently available equipment, is provided by the application of computer technology to the dimensional inspection of castings.

Importance of Dimensional Inspection

One of the most critical determinants of casting quality in the eyes of the casting buyer is dimensional accuracy (see the article "Dimensional Tolerances and Allowances" in this Volume). Parts that are within dimensional tolerances, given the absence of other casting defects, can be machined, assembled, and used for their intended functions with testing and inspection costs minimized. Major casting buyers are therefore demanding statistical evidence that dimensional tolerances are being maintained. In addition, the statistical analysis of in-house processes has been demonstrated to be effective in keeping those processes under control, thus reducing scrap and rework costs.

The application of computer equipment to the collection and analysis of dimensional inspection data can increase the amount of inspection that can be performed and decrease the time required to record and analyze the results. This

furnishes control information for making adjustments to tooling on the foundry floor and statistical information for reporting to customers on the dimensional accuracy of parts.

Typical Equipment

A typical equipment installation for the dimensional inspection of castings consists of an electronic coordinate-measuring machine, a microcomputer interfaced to the coordinate-measuring machine controller with a data transfer cable, and a software system for the microcomputer. This equipment is illustrated in Fig. 2. The software system should be capable of controlling the functions and storing of the coordinate-measuring machine as well as recalling and analyzing the data it collects. The software serves as the main control element for the dimensional inspection and statistical reporting of results. Such software can be purchased or, if the expertise is available, developed in-house where requirements are highly specialized.

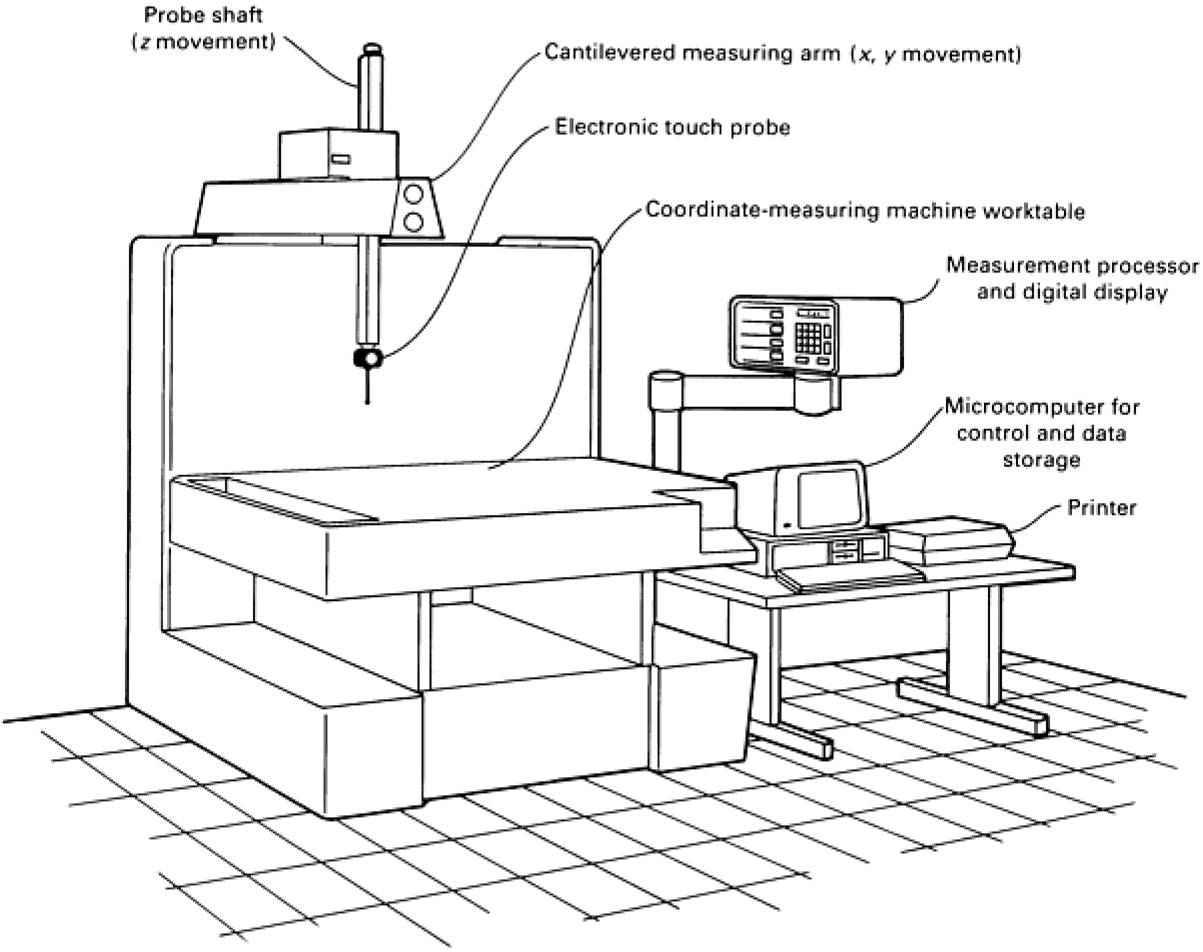

Fig. 2 Equipment used in a typical installation for the computer-aided dimensional inspection of castings showing a coordinate-measuring machine and microcomputer.

Coordinate-measuring machines typically record dimensions along three axes from datum points specified by the user. Depending on the sophistication of the controller, such functions as center and diameter finds for circular features and electronic rotation of measurement planes can be performed. Complex geometric constructions, such as intersection points of lines and planes and out-of-roundness measurements, are typically off-loaded for calculation into the microcomputer. The contact probe of the coordinate-measuring machine can be manipulated manually, or in the case of direct computer controlled machines, the probe can be driven by servomotors to perform the part measurement with little operator intervention.

The Measurement Process

Figure 3 illustrates the general procedure that is followed in applying semiautomatic dimensional inspection to a given part. The first step is to identify the critical part dimensions that are to be measured and tracked. Nominal dimensions and tolerances are normally taken from the customer's specifications and blueprints. Dimensions that are useful in controlling the foundry process can also be selected. A data base file, including a description and tolerance limits for each dimension to be checked, is then created using the microcomputer software system.

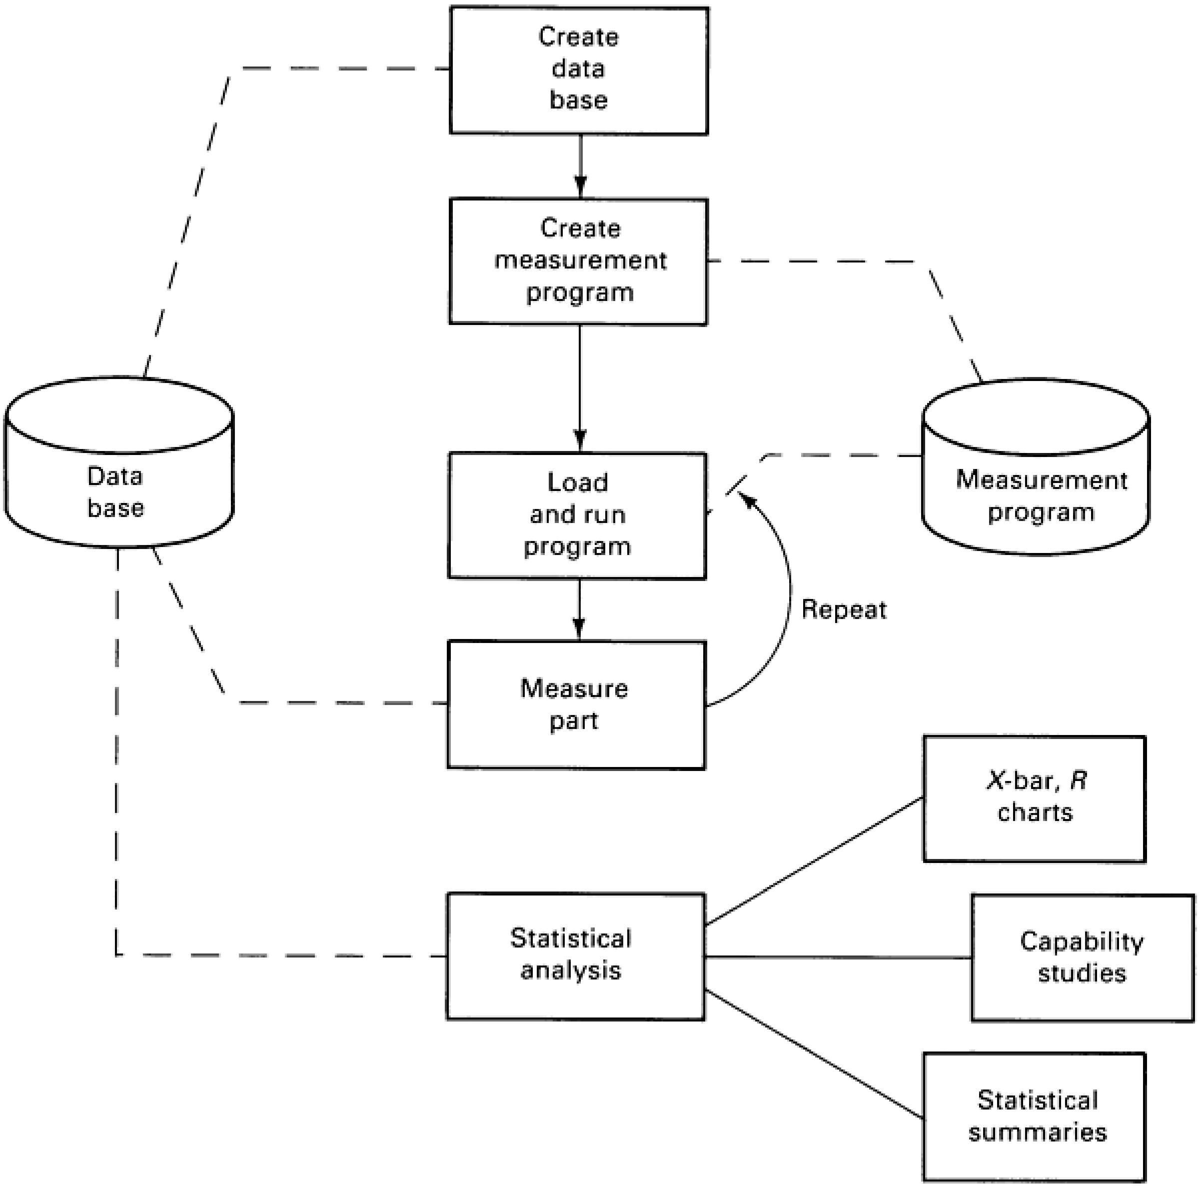

Fig. 3 Flowchart showing typical sequence of operations for computer-aided dimensional inspection.

The next step in the setup process is to develop a set of instructions for measuring the part with the coordinate-measuring machine. The instructions consist of commands that the coordinate-measuring machine uses to establish reference planes and to measure such features as center points of circular holes.

This measurement program can be entered in either of two ways. Using the first method, the operator simply types in a list of commands that he wants the coordinate-measuring machine to execute and that give the required dimensions as defined in the part data base. The second method uses a teach mode; the operator actually places a part on the worktable of the coordinate-measuring machine and checks it in the proper sequence, while the computer monitors the process and stores the sequence of commands used. In either case, the result is a measurement program stored on the microcomputer that defines in precise detail how the part is to be measured. Special commands can also be included in the measurement program to display operator instructions on the computer screen while the part is being measured.

In developing the measurement program, consideration must be given to the particular requirements of the part being measured. Customer prints will normally show datum planes from which measurements are to be made. When using a cast surface to establish a datum plane, it is good practice to probe a number of points on the surface and allow the computer to establish a best-fit plane through the points. Similarly, center points of cast holes can best be found by probing multiple points around the circumference of the hole. Machined features can generally be measured with fewer probe contacts. When measuring complex castings, maximum use should be made of the ability of the coordinate-measuring machine to electronically rotate measurement planes without physically moving the part; unclamping and turning a part will lower the accuracy of the overall layout.

Once the setup process is complete, dimensional inspection of parts from the foundry begins. Based on statistical considerations, a sampling procedure and frequency must be developed. Parts are then selected at random from the process according to the agreed-upon frequency. The parts are brought to the coordinate-measuring machine, and the operator calls up the measurement program for that part and executes it. As the part is measured, the dimensions are sent from the coordinate-measuring machine to the data base on the microcomputer. Once the measurement process is complete, information such as mold number, shift, date, or serial number should be entered by the operator so that this particular set of dimensions can be identified later. A layout report can then be generated to show how well the measured part checked out relative to specified dimensions and tolerances. Figure 4 shows a sample report in the form of a bar graph, in which any deviation from print tolerance appears as a line of dashes to the left or right of center. A deviation outside of tolerance limits displays asterisks to flag its condition. Such a report is useful in that it gives a quick visual indication of the measurement of one casting.

Statistical Analysis

The use of statistical analysis permits the mathematical prediction of the characteristics of all the parts produced by measuring only a sample of those parts. All processes are subject to some amount of natural variation; in most processes, this variation follows a normal distribution, the familiar bell-shaped curve, when the probability of occurrence is plotted against the range of possible values. Standard deviation, a measure of the distance from center on the probability curve, is the principal means of expressing the range of measured values. For example, a spread of six standard deviations (plus or minus three standard deviations on either side of the measured mean) represents the range within which one would expect

to find 99.73% of observed measurements for a normal process. This allows the natural variation inherent in the process to be quantified.

Control Charts. With statistical software incorporated into the microcomputer system, the results of numerous measurements of the same part can be analyzed to determine, first, how well the process is staying in control, that is, whether the natural variations occurring in a given measurement are within control limits and whether any identifiable trends are occurring. This is done by using a control chart (Fig. 5), which displays the average values and ranges of groups of measurements plotted against time. Single-value charts with a moving range can also be helpful. The control limits can also be calculated and displayed. With the computer, this type of graph can be generated within seconds. Analysis of the graph may show a developing trend that can be corrected by adjusting the tooling before out-of-tolerance parts are made.

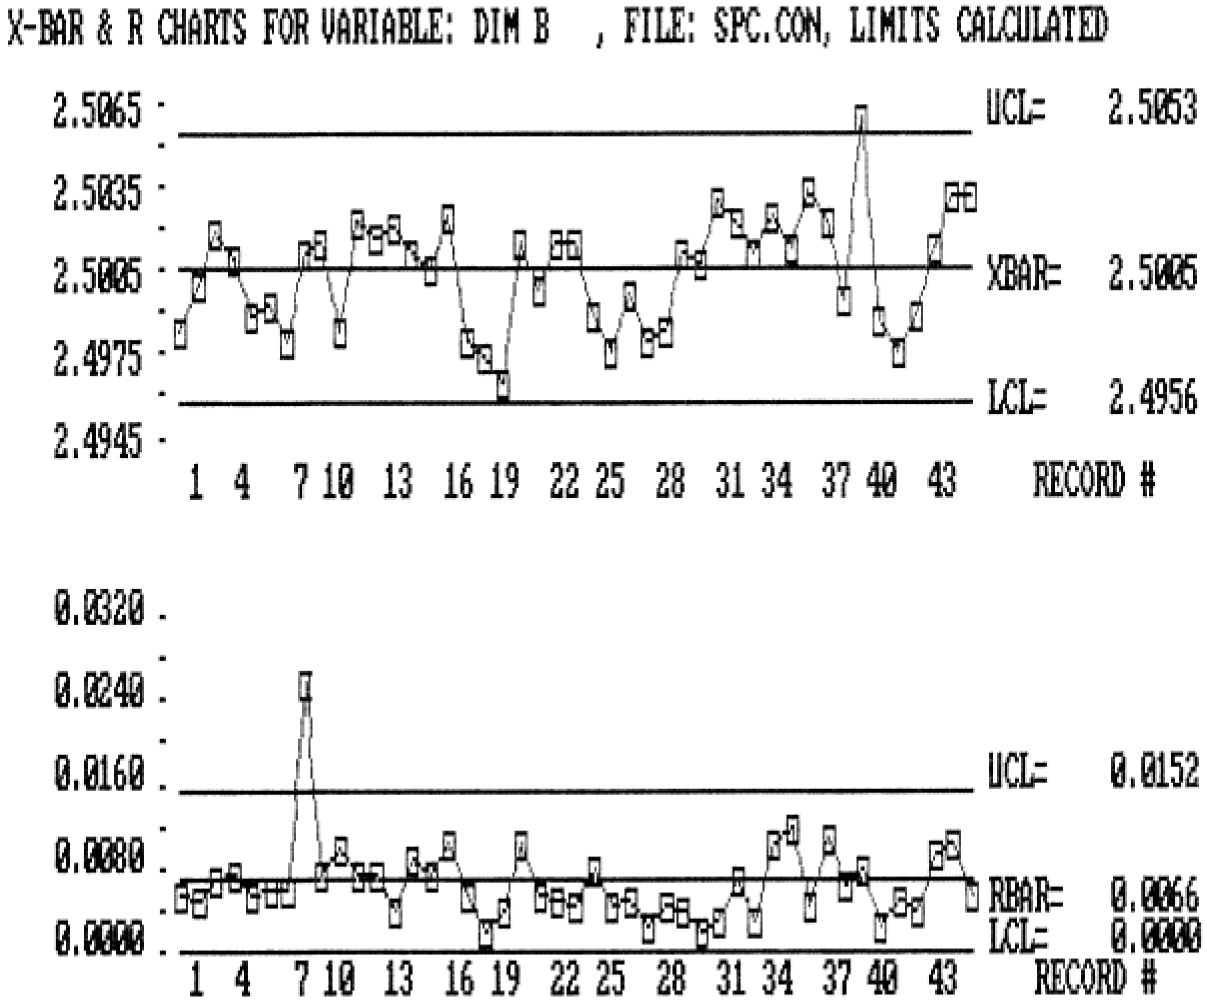

Fig. 5 An example control chart with average of groups of measurements (*X* values) plotted above and ranges within the groups (*R*) plotted below. Control limits have been calculated and placed on the chart by the computer.

Statistical Summary Report. The second type of analysis shows the capability of the process, that is, how the range of natural variation (as measured by a specified multiple of the standard deviation) compares with the tolerance range specified for a given dimension. An example of a useful report of this type is shown in Fig. 6. This information is of great interest both to the customer and the process engineer because it indicates whether or not the process being used to produce the part can hold the dimensions within the required tolerance limits. The user must be aware that different methods of capability analysis are used by different casting buyers, so the software should be flexible enough to accommodate the various methods of calculation that might be required.

68 Parts included in analysis
Actual Sigma calculated

$$\text{Process Capability} = \frac{\text{Blueprint Tolerance}}{6 \times \text{Sigma}}$$

Fig. 6 An example statistical summary report showing the mean of measured observations, the blueprint specification for the mean, difference between specified and measured means, the tolerance, the standard deviation of the measured dimensions, and the capability of the process. These calculations are performed for all measured dimensions on the part.

Histograms. An alternative method of assessing capability involves the use of a histogram, or frequency plot. This is a graph that plots the number of occurrences within successive, equally spaced ranges of a given measured dimension. Figure 7 shows an example output report of this type. A graph such as this, which has superimposed upon it the tolerance limits for the dimension being analyzed, allows a quick, qualitative evaluation of the variation and capability of the process. It also allows the normality of the process to be judged through comparison with the expected bell-shaped curve of a normal process.

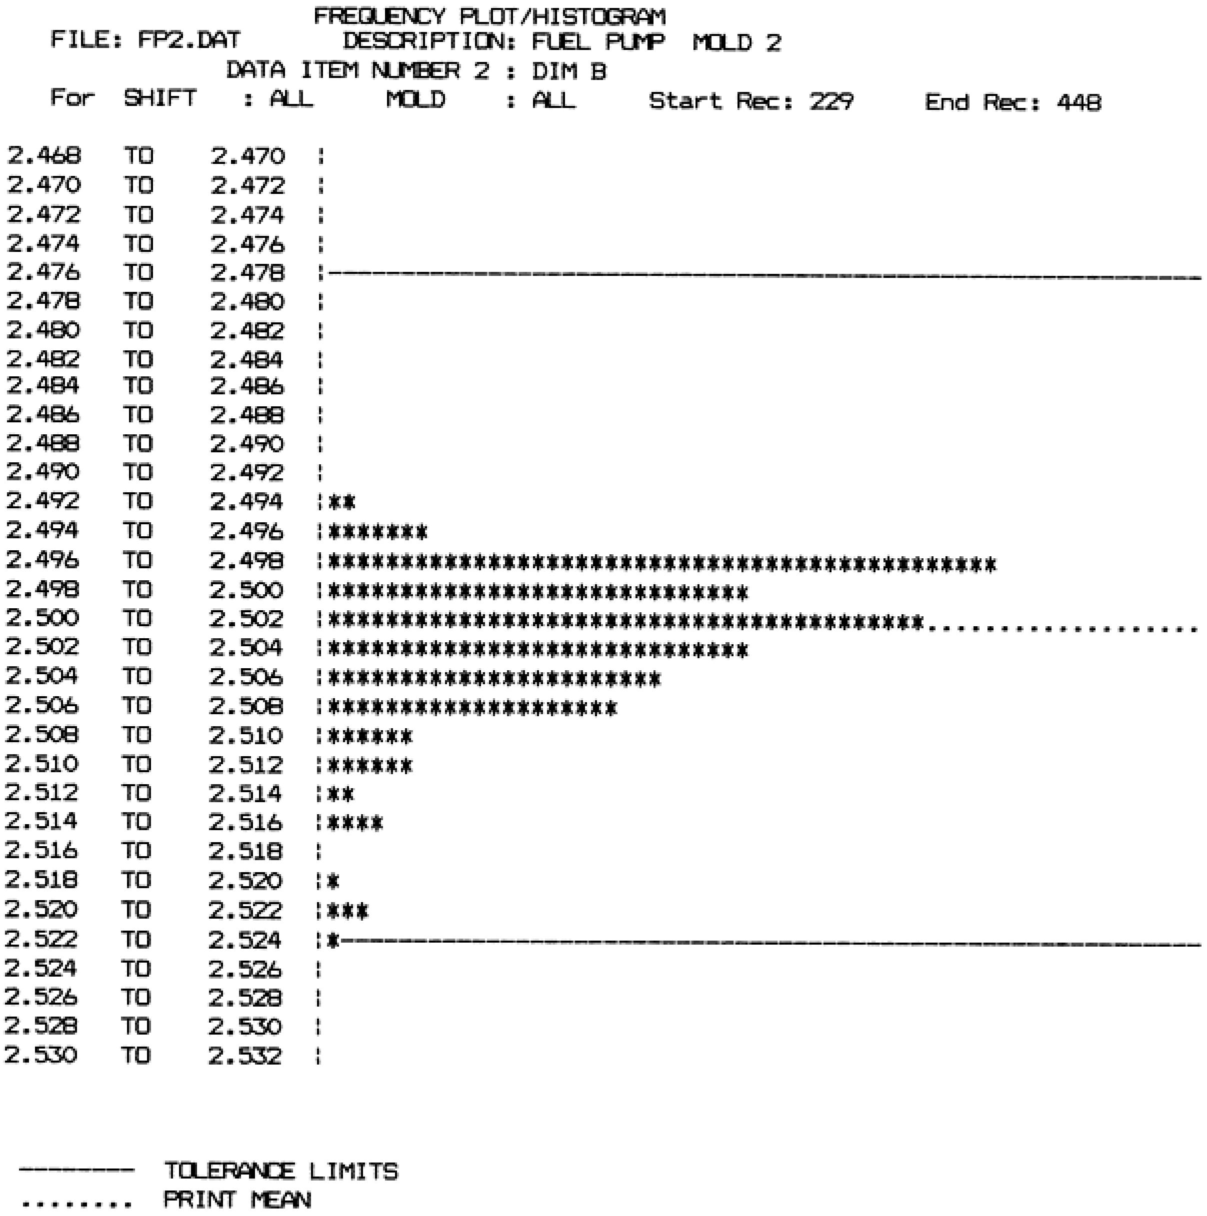

Fig. 7 A frequency plot for one measured dimension showing the distribution of the measurements.

Other Applications for Computer-Aided Inspection

The general sequence described for semi-automatic dimensional inspection can be applied to a number of other inspection criteria. Examples would include pressure testing or defect detection by electronic vision systems. The statistical analysis of scrap by defect types is also very helpful in identifying problem areas. In some cases, direct data input to a computer may not be feasible, but the benefits of entering data manually into a statistical analysis program should not be overlooked. The computer allows rapid analysis of large amounts of data so that statistically significant trends can be detected and proper attention paid to appropriate areas for improvement. The benefits and costs of each anticipated application of automation to a particular situation, as well as the feasibility of applying state-of-the-art equipment, need to be studied as thoroughly as possible prior to implementation.

Coating of Castings

Revised by Charles F. Walton, Consultant

Introduction

CAST COMPONENTS sometimes require special surface characteristics, such as resistance to deterioration or an appealing appearance. Coatings can extend casting life when resistance to corrosion, wear, and erosion is required. This article will discuss cleaning and coating practices for cast iron components. Similar information on nonferrous casting alloys is available in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Cleaning

Cleaning of the surface is the most important prerequisite of any coating process. Suitable levels of cleanliness and surface roughness are established by various mechanical and chemical methods. Foundries deliver castings that have been shot or grit blasted (see the article "Blast Cleaning of Castings" in this Volume). Supplementary nonmechanical cleaning may be needed to reach interior passages or to remove heat-treating scale or machining oil.

The choice of cleaning process depends not only on the types of soils to be removed but also on the characteristics of the coating to be applied. The cleaning process must leave the surface in a condition that is compatible with the coating process. For example, if a casting is to be treated with phosphate and then painted, the cleaning process must remove all oils and oxide scale because these inhibit good phosphating.

If castings are heat treated before they are coated, the choice of heat treatment conditions can influence the properties of the coating, particularly a metallic or conversion coating. In most cases, heat treatment should be done in an atmosphere that is not oxidizing. Oxides and silicates formed during heat treating must be removed before most coating processes.

Molten salt baths are excellent for cleaning complex interior passages in castings. In one electrolytic, molten salt cleaning process, the electrode potential is changed so that the salt bath is alternately oxidizing and reducing. Scale and graphite are easily removed with reducing and oxidizing baths, respectively. Molten salt baths are fast compared to other nonmechanical methods, but castings may crack if they are still hot when salt residues are rinsed off with water.

Pickling in an acid bath is usually done prior to hot dip coating or electroplating. Overpickling should be avoided because a graphite smudge can be formed on the surface. Cast iron contains silicon; therefore, a film of silica can form on the surface as a result of heavy pickling. This can be avoided by adding hydrofluoric acid to the pickling bath. Special safety and environmental protection regulations must be met when using pickling.

Chemical cleaning is different from pickling because, in chemical cleaning, the cleaners attack only the surface contaminants, not the iron substrate. Many chemical cleaners are proprietary formulations, but in general they are alkaline solutions, organic solvents, or emulsifiers. Alkaline cleaners must penetrate contaminants and wet the surface in order to be effective.

Organic solvents that were commonly used in the past include naphtha, benzene, methanol, toluene, and carbon tetrachloride. These have been largely replaced by chlorinated solvents, such as those used for vapor degreasing. Solvents effectively remove lubricants, cutting oils, and coolants, but are ineffective against such inorganic compounds as oxides or salts. Emulsion cleaners are solvents combined with surfactants; they disperse contaminants and solids by emulsification. Emulsion cleaners are most effective against heavy oils, greases, slushes, and solids entrained in hydrocarbon films. They are relatively ineffective against adherent solids such as oxide scale.

After wet cleaning, short-term rust prevention is accomplished by the use of an alkaline rinse. This can be followed by mineral oils, solvents combined with inhibitors and film formers, emulsions of petroleum-base coatings and water, and waxes.

Electroplating

Table 1 lists the common electroplated metals. Other metals--for example, gold, silver, and alloys such as brass and bronze--are used for special decorative effects.

Table 1 Properties and characteristics of conventional electroplated metal coatings

Metal	**Coating hardness**	**Appearance**	**Thickness**		Characteristics and uses
			µm	**mil**	
Cadmium	30-50 HV	Bright white	3-10	0.15-0.5	**Pleasing appearance for indoor applications; less likely to darken than zinc; anodic to ferrous substrate**
Chromium	900-1100 HV	White--can be varied	0.2-1[(a)] 1-300[(b)]	0.01-0.06[(a)] 0.05-12.0[(b)]	**Excellent resistance to wear, abrasion, and corrosion; low friction and high reflectance**
Cobalt	250-300 HK	Gray	2-25	0.1-1.0	**High hardness and reflectance**
Copper	41-220 HV	Bright pink	4-50	0.2-2.0	**High electrical and thermal conductivities; used as undercoat for other electroplates**
Lead	5 HB	Gray	12-200[(c)] 1300[(d)]	0.5-8.0[(c)] 50[(d)]	**Resistant to many acids and hot corrosive gases**
Nickel	140-500 HV	White	2-40[(a)] 130-500[(c)]	0.1-1.5[(a)] 5-20[(c)]	**Resistant to many chemicals and corrosive atmospheres; often used in conjunction with copper and chromium; can be applied by electroless plating**
Rhodium	400-800 HB	Bright white	0.03-25	0.001-1.0	**High electrical conductance; brilliant white appearance is tarnish and corrosion resistant.**
Tin	5 HB	Bright white	4-25	0.015-1.0	**Corrosion resistant; hygienic applications for food and dairy equipment; good solderability**
Zinc	**40-50 HB**	**Matte gray**	**2-13[(a)] 12-50[(d)]**	**0.1-0.5[(a)] 0.5-**	**Easily applied; high corrosion resistance; anodic to ferrous substrate**

(a) Decorative.

(b) Hard.

(c) Wear applications.

(d) Corrosion applications

Iron castings are electroplated to impart corrosion resistance or to provide a pleasing appearance. Typical applications include many different types of interior hardware, machine parts such as printing cylinders, decorative trim, and casings. Iron castings are also electroplated to enhance their wear resistance; for example, hard chromium plating is applied to the wear surfaces of piston rings. Areas not requiring a plated surface can be masked or stopped off to prevent coverage. Plating can be applied as a very thin layer for applications requiring only a pleasing appearance or mild corrosion resistance; thicker plating can be applied for more wear resistance, longer corrosion resistance, or to replace lost metal (Table 1).

Electrodeposition is done by making clean iron castings cathodic in an aqueous solution containing a salt of the coating metal and then passing a direct electrical current through the solution. The effective metal content in the plating bath can be replenished by using anodes made of the coating metal to complete the electrical circuit. Variations in the properties of the deposited coating are influenced by the composition, temperature, pH, and agitation of the bath and by current density. In addition, further variations in the coating can result from the design of the casting, the distance of the casting from the anode, and the preparation of the surface before plating.

Nickel is unique among plated coatings because it can be applied without using an impressed electrical current. Table 2 lists non-electrolytic methods. The high-temperature treatments produce partly diffused coatings containing both nickel and phosphorus. Because no impressed electrical current is involved, the thickness of an electroless nickel plate is exceptionally uniform regardless of the shape of the casting. Preheating large castings prior to immersion prevents a delay in the start of nickel deposition.

Table 2 Nonelectrolytic nickel plating methods and solution constituents

Method	**Solution constituents**	**Temperature**		**Plating rate**		Special considerations
		°C	**°F**	**µm/h**	**mil/h**	
Immersion	Nickel chloride, sodium hypophosphite	70	160	1.2	0.05	**Porous coating with moderate adhesion can be improved with postheating at 650 °C (1200 °F)**
High-temperature chemical reduction	Slurry of nickel oxide and ammonium phosphite	870-955	1600-1750	. . .	. . .	**Selective coverage by reduction of mixture at high temperature**
Electroless acid	Nickel chloride, sodium hypophosphite, sodium citrate	95	200	12	0.5	**Postplating treatment not necessary for iron castings**
Alkaline	**Nickel chloride, sodium hypophosphite, ammonium**	**95**	**200**	**8**	**0.3**	**Solutions are more difficult to maintain than acid baths**

Electroless nickel is used not only for its uniformity in coating thickness but also for its ability to be heat treated to increase its hardness. Typically, an as-plated hardness of 49 to 50 HRC can be increased to 67 to 68 HRC by proper heat treatment. More detailed information on electroplating is available in the Section "Plating and Electropolishing" in *Surface Engineering*, Volume 5 of the *ASM Handbook* and in the articles "Electroplated Coatings" and "Electroplated Hard Chromium" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Hot Dip Coatings

Hot dip coating consists of immersing the casting in a bath of molten metal. A flux-coated and/or chemically cleaned surface is necessary to achieve satisfactory results. Aluminum, tin, zinc, and their alloys can be applied from a molten bath. Hot dip coatings are preferred because they are thicker than electroplates and because an alloy layer is formed between the coating metal and the iron. This provides additional durability and adhesion. Castings of complex shape are easily coated by these processes, although air may become trapped in blind holes unless the castings are rotated.

Hot dip zinc coating (galvanizing) is widely used on iron castings, particularly pipe, valves, and fittings. The uniform and adherent coating provides a barrier against corrosive attack and will further protect an iron casting by acting as a sacrificial anode or by undergoing preferential corrosion. Successful galvanizing depends on surface preparation. Pickling followed by dipping in a bath of zinc ammonium chloride or other flux is done prior to dipping in molten zinc. Excess zinc may be drained or centrifuged from the castings before quenching. Quenching improves the brightness of the coating. Iron castings of any type and any composition can be hot dip galvanized.

Hot dip tin coating (hot tinning) provides a protective, decorative, and nontoxic coating for food equipment, a bonding layer for babbitted bearings, or a precoated surface of soldering. Surface preparation is particularly important, and when maximum adherence is desired, such as when tinning is used to prepare a casting for the application of babbitt, electrolytic cleaning in a molten salt is preferred.

For the hot dip lead coating of iron castings, lead-base alloys are preferred over pure lead; with pure lead, bonding is mechanical rather than metallurgical. Tin is the element most widely used to enhance bonding. Lead coatings are noted for their resistance to fumes from sulfuric and sulfurous acids.

The aluminum coating (aluminizing) of iron castings imparts resistance to corrosion and heat. The coating oxidizes rapidly, thus passivating the surface. The resultant aluminum oxide is refractory in nature; it seals the surface and resists degradation at high temperatures. An aluminized surface has limited resistance to sulfur fumes, organic acids, salts, and compounds of nitrate-phosphate chemicals. More detailed information on hot dip coating (continuous and batch processes) is available in the articles "Hot Dip Coatings" and "Corrosion of Zinc" in *Corrosion,* Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Hardfacing

Hardfacing can be used when a casting requires an unusually hard and wear-resistant surface and when it is impractical to produce a hard surface in the casting process or by selective heat treatment. Frequently, hardfacing is used to repair worn castings by building up an overlay of new material.

Hardfacing is basically a welding operation in which an alloy is fused to the base metal. Both gas and arc methods are used. Ferrous alloys can be either austenitic or hardenable types. Metallic carbides are the chief intermetallic materials used for hardfacing. Carbides are not melted or fused into the surface layer, but are bonded in place by an enveloping metal such as cobalt. The articles "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in *Welding, Brazing, and Soldering,* Volume 6, and "Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering" in *Powder Metal Technologies and Applications,* Volume 7, *ASM Handbook* contain detailed information on hardfacing materials, hardfacing alloy selection, and hardfacing process selection.

Thermal Sprayed Metals and Ceramics

Thermal spraying originally consisted of propelling small molten globules of metal through a flame onto the workpiece. Technological improvements in the process have permitted the development of methods for applying both metallic and nonmetallic materials. Nonmetallics include ceramics, refractories, and carbides.

The thermal spraying of low-carbon iron or steel can be used to build up worn or mismachined surfaces. Nickel combined with other elements can be thermal sprayed to form a hardfaced surface. Zinc, aluminum, and lead can impart general corrosion resistance and can be deposited at very high rates. Babbitt alloys can be thermal sprayed onto bearings. Copper and bronzes are used for electrical and decorative purposes. Thermal barriers in the form of oxides or silicides are generally applied by plasma methods to provide either heat shielding or resistance to attack by molten metals. Wear resistance is enhanced by the application of carbides or borides.

Thermal spraying uses oxyacetylene, oxyhydrogen, detonation plasma, and electric arc techniques to impact molten or semimolten particles onto a substrate casting and to build up the desired thickness. The sprayed coating resembles the

source material in composition, but its physical and mechanical properties are different from those of the source material--more closely resembling the properties of sintered metals or refractories. Bonding of the coating to the casting surface occurs principally by mechanical adhesion and only partly by metallurgical bonding. Rough machining, arc spattering, or coarse abrasive blasting prior to thermal spraying improves the mechanical bonding. Selection of the appropriate method of application depends on the form of the source material (wire, rod, or powder), the stability of the coating material at the application temperature, and the temperature required to achieve satisfactory adhesion. Temperatures within the nozzle range from 2760 °C (5000 °F) in the oxyacetylene process to 16,500 °C (30,000 °F) in plasma spraying. More detailed information is available in the article "Thermal Spray Coatings" in *Surface Engineering*, Volume 5 of the *ASM Handbook.*

Diffusion Coatings

Diffusion coatings can be formed on iron castings by heating the castings in contact with a coating medium. The forms of coating materials are powdered metals, volatilized metal or metal salt, fused baths of metal salts, or a gas. Various types of diffusion coatings and their uses are summarized in Table 3. In some of the processes--nitriding and carbonitriding (case hardening), for example--the coating material becomes an integral constituent of the surface layer and is not visible on the surface of the casting. Diffusion coating and case-hardening processes are discussed in "Diffusion Coatings" in *Surface Engineering,* Volume 5, and "Carbonitriding" in *Heat Treating,* Volume 4 of the *ASM Handbook.*

Table 3 Types of diffusion coatings and their characteristics

Type	**Coating structure**	**Properties**	Uses
Calorized	Metallic aluminum introduced into surface layer, forming aluminum-iron alloy	High-temperature oxidation resistance	**Chemical processes, steam superheaters, and heat transfer**
Chromized	Chromium carbide case formed on surface	High hardness and wear resistance	**Combustion and mechanical equipment**
Cyanided or carbonitrided	Carbon-nitrogen compound formed by diffusion into surface	Wear resistance for surfaces combined with core toughness	**Gears, cams, pawls, and shafts**
Nickel-phosphorus	Ammonium phosphate and nickel oxide products reduced and diffused	Corrosion resistance comparable to austenitic irons; poor wear resistance	**Chemical process pipe and fittings**
Nitrided	Nitrogen introduced into surface by contact of ammonia or other nitrogenous material	Wear and corrosion resistance at elevated temperatures	**Same as for carbonitrided**
Sheradized	**Zinc introduced into surface**	**Corrosion resistance**	**Atmospheric-corrosion resistance**

Conversion Coatings

Chemical reactions at casting surfaces can produce iron-containing compounds that provide wear resistance or an attractive appearance or that serve as excellent bonding agents for subsequent organic coatings. Table 4 details common conversion coatings and their useful properties (chromate and phosphate conversion coatings are discussed in greater detail in *Surface Engineering*, Volume 5, and *Corrosion*, Volume 13, of the *ASM Handbook*). Most of the successful processes are proprietary, and reproducibility of consistently good finishes is one of the important features.

Table 4 Chemical conversion coatings, structures, and characteristics

Type	**Coating structure**	**Properties**	Uses
Chromate	Nonporous film acts as moisture barrier.	High corrosion resistance; inhibits corrosion if surface is broken; can be colored	**Marine applications; can be decorative; nonporous bond layer for paint**
Oxide	Ferric oxide formed from iron	Inhibits formation of ferrous oxide; highly absorbent; some wear resistance	**Decorative blue-black coating; readily absorbs overlays of wax or oil**
Phosphate	**Iron zinc or manganese phosphates are crystalline structures formed on the surface by deposition from chemical solution.**	**Chemically neutral and high adherence to iron surfaces; highly absorbent**	**Excellent for bonding paint to iron; prevents abnormal wear or seizing during break-in**

Gray, ductile, and malleable iron castings all lend themselves readily to phosphating. The ability of a cast iron to accept a phosphate coating is not affected by alloy content, but hinges primarily on two requirements: a clean surface, and a metal temperature approximately equal to that of the phosphating bath. Dry machined surfaces need no further cleaning; cast surfaces can be prepared by blasting or other cleaning methods to remove scale and sand.

Porcelain Enameling

Porcelain enamels are inorganic vitreous coatings that are matured by heat. The inherently good heat transfer, thermal stability, and rigidity of iron at firing temperatures, coupled with the excellent adherence of vitreous ceramic frits as they fuse onto the cast surface, make the combination of porcelain on iron an excellent product. General corrosion resistance or resistance to specific chemicals can be obtained by selecting the proper porcelain enamel. The scratch resistance and hardness of the enamel coating, which allow the surface to resist abrasion, are almost equal in importance to the corrosion resistance.

Four processes are used to apply enamels: dry, wet, thermal spray (or plasma spray), and electrostatic precipitation. The latter two methods are seldom used on iron castings. Preparations for enameling start by blasting with sand, steel shot, or iron grit.

Dry coating methods use formulations that are mainly silica; these formulations generate a surface with the hardness and abrasion resistance of glass. Fluxes and opacifiers are mixed into the silica, and the mixture is then melted, quenched, and ground to make frit. (Frit is the term applied to the basic coating materials.) After application of a bonding ground coat, relatively heavy, smooth coatings (such as those on sinks and bathtubs) can be obtained by multiple firing. Each firing is followed by hot dusting with additional powdered frit, until the desired finish has been achieved.

Wet methods produce thinner coatings. The powdered frit is suspended in a solution of electrolytes and water or in an organic solvent and is applied by spraying or dipping over the ground coat. The sprayed or dipped coating must be dried prior to firing.

Ground coats that wet iron readily, adhere well, and are compatible with the cover coat are essential to the enameling process. Good ground coats promote adhesion between the enamel layer and the substrate, seal and smooth the irregularities of the surface, and prevent oxidation of the iron casting at firing temperatures. Top coats (cover coats) must provide the desired appearance and must be compatible with the ground coat. Formulation of frits requires the judgment and experience of a frit manufacturer to ensure that the coating provides successful results.

Organic Coatings

Organic coatings have a wide variety of properties, but their primary uses require corrosion resistance combined with a pleasing colored appearance. An organic-base film is often resistant to certain environmental substances but not to others, and so must be chosen for a specific set of well-defined service conditions. For example, a vinyl paint might be used on a pump casing that must operate in contact with acidic industrial waters. However, if the same casing is expected to contact

hydrocarbons such as gasoline or solvents, a styrene, epoxy, or phenolic coating would most likely provide superior protection.

The term paint was once commonly used to designate all liquid organic coatings, but it is considered inadequate to describe modern liquid organic coatings, which in general are subdivided into enamels, lacquers, aqueous mixtures, suspensions, bituminous substances, and rubber-base products. Resins dispersed in a vehicle--for example, enamels or lacquers--cure to relatively hard gels by polymerization, oxidation, or solvent evaporation. A comparison of the chemical and environmental resistance of common resins is given in Table 5.

Table 5 Properties of organic coatings on iron castings

Resin	Resistance to chemicals and environment[a]										Application method				Curing method		Typical applications

Enamels consist of milled pigments and other additives dispersed in resins and solvents and are converted from liquids to hard films by oxidation or polymerization. Lacquers are thermoplastic resins dissolved in organic solvents that dry rapidly by evaporation. In aqueous coatings, water is the principal vehicle or reducer. The advantages of water-base paints are nominal cost, nonflammability, true odorlessness, and nontoxicity. The disadvantages are difficulties in wettability, flow, and drying. Rubber-base coatings are noted for their mechanical properties and corrosion resistance rather than their decorative effects. Bituminous paints are black materials in which coal tar is dissolved in a solvent that evaporates. The major uses of bituminous paints are those that require extremely low permeability and high resistance to water. Unusual protection against chemical solutions, or special decorative effects, can be obtained by the use of asphaltic coatings or those produced by japanning, both of which are also considered bituminous coatings.

Fluorocarbon coatings produce an unusual combination of properties. They are tough, stain resistant, and nonsticking, and have a very low coefficient of friction. Fluorocarbon coatings resist all common industrial acids and temperatures to 300 °C (570 °F). Domestic cookware and chemical-processing equipment are two major applications of fluorocarbon coatings on iron castings. Fluorocarbon coatings are sprayed as emulsions of proprietary products onto a primed surface and then fused at temperatures of 385 to 425 °C (725 to 800 °F).

Organic coatings are applied by spraying, dipping, flow coating, fluidized bed coating, electrostatic deposition, and electrophoresis (electrocoating).

Spraying is adaptable to both low-volume and high-volume workloads. It is done by propelling the coating material toward the workpiece by compressed air, hot spraying, hydraulic-airless, and airless-electrostatic methods. Overspraying is most troublesome with compressed air methods and least troublesome with electrostatic methods.

Dipping has been used for centuries; modern refinements include flow coating and electrophoresis. Not all shapes can be painted by dipping. Pockets can exclude paint from some surfaces. The shape of the casting should allow easy draining after dipping. The coating should be selected to inhibit sagging or the formation of droplets on edges. The dipping process is easily automated and can be very efficient in use of materials. A thorough review of organic coatings and their applications, advantages, and limitations is available in the article "Organic Coatings and Linings" in *Corrosion,* Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Fused Dry-Resin Coatings

Dry-resin polymers can be applied (by fusion bonding) to iron castings for many of the same applications for which liquid organic coatings are used. Generally, the fused coatings are thick and can be applied very rapidly--often in minutes; in contrast, several hours is required for the drying and curing of a liquid organic coating.

The fusion bonding of polymers on iron castings can be readily accomplished by the application of dry solvent-free powder by fluidized bed coating or electrostatic deposition. The advantages of the process include the use of resins that are insoluble in ordinary solvents, the elimination of carrier solvents, and the ability to combine various plastics in the coating for maximum effectiveness. Sandblasted castings are excellent bases for this process. The plastic films can be easily machined, which contributes to flexibility in manufacturing. Two disadvantages are that thin films are not easily applied and that finding a suitable holding point on a part to be coated in a fluidized bed may be difficult. The six basic types of plastic fusion-bonded finishes, as well as a comparison of their characteristics, are given in Table 6.

Table 6 Relative effectiveness of fusion-bonding resin coatings

	Effectiveness[a]

(a) E. Excellent; VG, very good; G, good F, fair; P, poor.

(b) Ranges from excellent to poor depending on composition

In a fluidized bed, castings heated to 175 to 310 °C (350 to 590 °F) are placed in a chamber containing resin powder suspended by upward-moving air. The dry resin floats around the casting, adhering to all the surfaces regardless of the complexity of the shape. Heating fuses the coating into a continuous film. This method produces a uniform coating that covers sharp corners, edges, and projections and that can be applied in a wide range of thicknesses (up to 1.5 mm, or 0.06 in.) in a single application.

In electrostatic deposition, the powdered resin is conveyed to a gun, in which it is given an electrostatic charge. The casting has the opposite charge. The charged powder is attracted to the surface, where it is deposited evenly. The electrostatic process is especially useful for applying thinner coatings because the residual charge on the workpiece is discharged by the powder, or leaks off, thus limiting the amount of powder that can be deposited. Preheating of the casting permits thicker coatings because the initial powder layer fuses as it is applied. Curing is done by reheating the casting to fuse the resin coating. Primers may be needed for some types of polymers (such as butyrates and vinyls) in order to achieve adequate bonding.

Foundry Automation

Ronald L. Lewis, and Yeou-Li Chu, The Ohio State University

Introduction

AUTOMATION in the foundry is an integrated technology concerned with the application of both complex hardware (robots, computers, and electronic controllers) and software (management information software, statistical process control, and material process planning techniques) to control various foundry production activities. Automation applications in the foundry can be divided into the following categories:

- Foundry robotic applications
- Cell applications
- Automatic pouring systems
- Automatic sorting and inspection systems
- Automatic storage and retrieval systems
- Computer-aided design and manufacture

Each of these will be briefly reviewed in the following sections.

Foundry Robotic Applications

A robot is a programmable, multifunctional manipulator designed to move material, parts, tools, or specialized devices through variable programmed motions for the performance of a variety of tasks (Ref 1, 2). Depending on the sensory requirement of the task to be performed, robots can be divided into different classes. One classification scheme is given below (Ref 3):

- *Level 0:* This robot registers no information from the surroundings in which it operates. An example of this level is the pick-and-place device. It is merely capable of being fed movements that are repeated indefinitely. These devices are limited to assembly tasks involving smooth parts. Foundry applications include spraying mold wash and extracting castings from a die casting machine
- *Level 1:* Capable of monitoring contact between two surfaces through force and tactile sensors, these robots provide feedback to allow the mating of pieces without jamming. However, they are restricted to what they feel. They must be taught the location of the parts to be assembled, and the design of the parts cannot change during an assembly run. An example of such a foundry application would be robots attached to coremaking machines
- *Level 2:* Still in the research stage, these robots incorporate visual and nonvisual imaging sensors. Thus, they can select pieces from a moving conveyor line and then inspect and orient each workpiece for assembly. Examples would include adaptively controlled grinding and torch cutting operations

Different foundry applications will dictate different levels of sophistication and cost. Robots may range in price from \$5000 for a simple pick-and-place unit to over \$200,000 for a large, highly programmable and flexible multiaxis robot (1988 dollars). In addition to this capital investment, the foundry must be prepared to incur other costs, such as maintenance and education. Therefore, a number of benefits must be achieved to offset these costs and to provide a beneficial cost position. These benefits include (Ref 3, 4, 5, 6, 7, 8, 9, 10):

- *Increased productivity:* Metalcasters report productivity increases of 10 to 300% (Ref 10) because robots do not require coffee breaks, lunch periods, and so on
- *Reduced costs:* Direct labor costs and labor overhead costs such as parking spaces, pensions, health care, wash rooms, and so on, are saved
- *Reduced injuries and illnesses:* Robots can replace a foundry employee working in dangerous and/or hazardous conditions
- *Improved casting quality:* Properly installed and correctly programmed, a robot can perform the same production function repeatedly, rapidly, and consistently without the variations inherent in human handcraft
- *High-speed precision:* Robots can move and position grippers and attach tools at higher speeds and

accuracies than any human operator. Repeatability accuracies for some robot applications approach 0.013 mm (0.0005 in.), but because of the nature of most foundry applications, these higher accuracies are not achieved. Movement speeds of 1270 mm/s (50 in./s) are also possible

- *Performance flexibility:* Unlike hard automation, programmable robots can be retaught for varied, dissimilar tasks
- *High uptime:* Maximizing the use of capital equipment, robots can achieve uptime performance levels as high as 98% in long-run high-production situations
- *Inflation resistance:* The hourly rate for a robot installed today will be the same in 5 years, with no slowdowns or strikes
- *Round-the-clock output:* Robots can work two or three shifts a day, seven days a week, given sufficient parts, materials, and maintenance support
- *Improved worker morale:* Robots have been shown to improve morale, especially when they are installed to perform unpopular foundry tasks

Robotic applications in the foundry industry include cleaning, riser cutting, pick and place, mold venting, and mold spraying.

Cleaning Operations

Cleaning (fettling) operations are traditionally a very labor intensive component of the cost of a casting, often exceeding 60% of the total casting cost (Ref 11). A very high percentage, some estimate over 90%, of all cleaning operations are still performed manually (Ref 12). A number of robotic installations have been completed both in Europe and in the United States. Foundry technical associations and universities such as BCIRA (Ref 13), the Steel Castings Research and Trade Association (Ref 14), Svenska Gjuteriforeningen (Ref 15), the Fraunhofer-Institute in Stuttgart (Ref 16), the University of Aachen, the University of Leuven, and the University of Rhode Island have been conducting research in robotic foundry applications.

Cleaning operations can be divided into two categories: fixed and variable (Ref 17). Fixed grinding is the removal of the material that is present on every casting in a fixed position (that is, feeder pads, flash, gates, and so on). Variable cleaning can occur anywhere on the casting and usually results from defects in the mold or cores. To date, there are no applications of automated variable cleaning. In addition, if an automatic cleaning operation is implemented, some form of inspection is necessary to detect variable cleaning requirements and to ensure that they do not interfere with the automatic cleaning operation.

For high-volume production, automatic fixed-stop machines have been specifically designed to grind castings. Many were designed to allow for the simultaneous grinding of many casting faces. Other machines are rotary in design with multiple heads. Through the use of template-driven machines, a complex casting periphery can be ground. Unfortunately, all of these systems, although automated, are not usually programmable; therefore, they cannot be easily adjusted for widely varying casting shapes or geometries. In addition, they cannot adapt to significant differences in casting irregularities.

Truly programmable cleaning operations are normally conducted by robots. Figure 1 shows a successful robotic installation. The cell consists of a robot and four specially designed grinding wheels. The wheels are hydraulically driven from a central unit. Wheel wear compensation is automatic such that the working point of the wheel is at the exact same location from cycle to cycle. Before entering the cell, castings are introduced to a dedicated press, where the main riser is removed and specific contour locations are stamped that will serve as reference areas for positioning. The casting is picked up by the robot and moved to each grinding machine. The system is now operating three shifts a day with an 89% uptime. The casting finish weight is 18 kg (40 lb). The complete cycle time is 3 min per casting. The average production rate, sampled over a 4-month period, is over 400 castings per day.

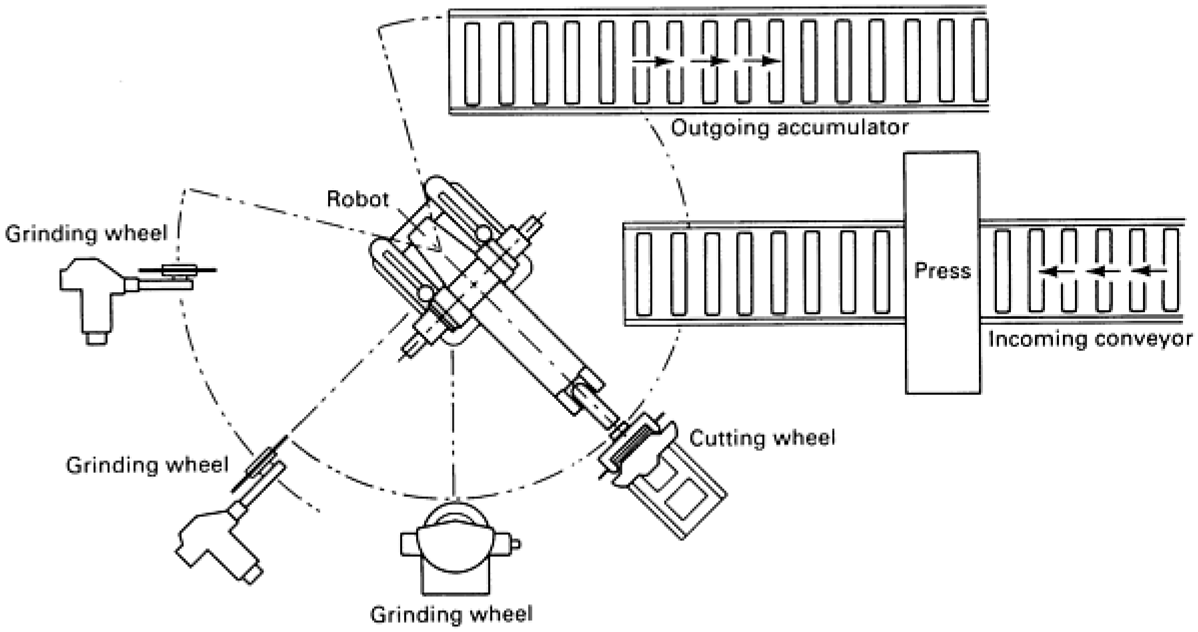

Fig. 1 Schematic of a first-generation robotic system designed to perform fettling operations at a rate of one completely machined casting every 3 min

Depending on casting size, the robot can either hold the casting and move it to the grinding machine or it can hold the grinding tools and apply them to the casting. The advantages of using a robot to manipulate a casting include the following (Ref 17):

- The robot can pick up the casting from a fixed point that can be magazine fed or from several predetermined positions if the castings are palletized
- The robot can pick up castings within the limits of its capacity that would in many cases be too heavy for a manual operation
- The robot can move the casting to a succession of different tools to perform the cleaning operation to the required standard in the minimum amount of time by using the most efficient tool available at each operation. These sequential operations can be carried out without having to stop the cycle to change tools
- The robot can put the casting down on a fixture and regrip it to allow access to other surfaces of the casting. For example, the robot can turn the casting around or completely over
- Upon completion of cleaning, the robot can place the casting in a fixture, drop it in a bin, or place it on any predetermined position on a pallet

When the casting weight is high or when a variety of grinding wheels are necessary, it is more feasible to allow the robot to handle the tool rather than the casting. Industrial manipulators, although not programmable, are useful for this application (Ref 18). Tool change downtime is obviously very important with such a system.

A number of problems are inherent in any system, regardless of the type used. These problems include the following (Ref 17):

- Grinding develops varying load conditions, which cause inaccuracies in robot positioning. This can be overcome by either an adaptive control system or by a template-driven system such as that shown in Fig. 2
- Imprecision in casting geometries creates inaccuracies in location
- Corrections must be made for wheel wear; simple light beam sensors are often used to sense the location

of the edge of the wheel

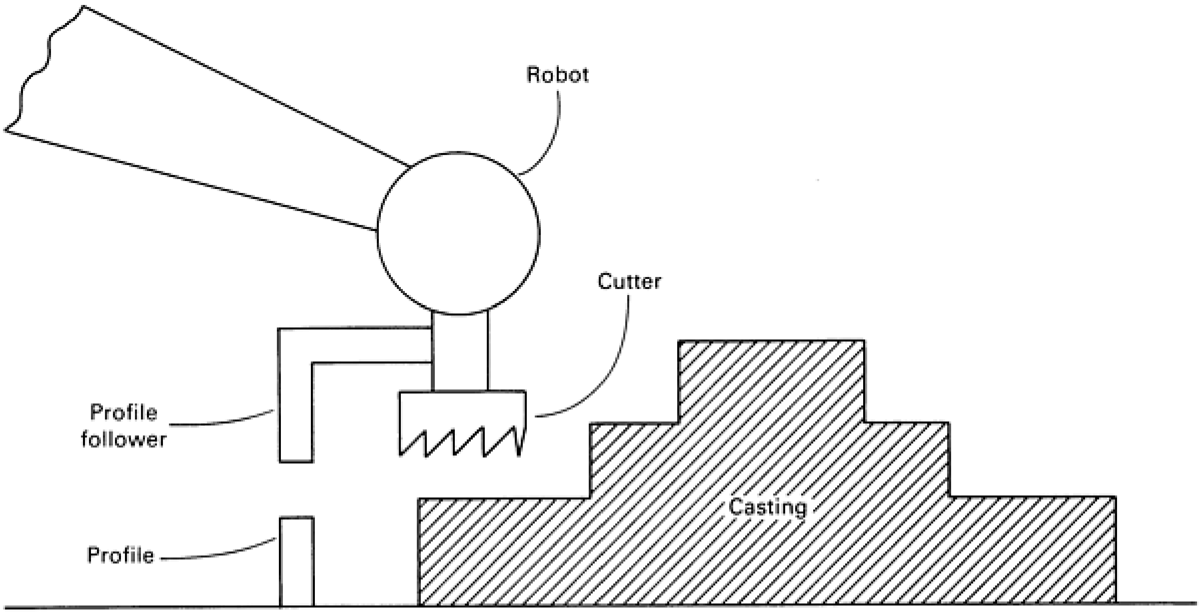

Fig. 2 Guidance template used to control the movement of the robotic arm

Riser Cutting

For the reasons previously outlined, robotic flame cutting for riser and gate removal is now possible. This is particularly important for heavy section steel castings, where risers cannot be removed economically by grinding, impact, and so on. Unlike cleaning, however, the torch must be held by the robot. As in cleaning, such systems range from semiautomatic to fully programmable robotized systems. Installations can use both conventional and gantry-style robots (Ref 19, 20). Steel thicknesses in excess of 610 mm (24 in.) have been successfully cut. To perform the flame cutting operation, the operator, using the control panel, moves the torch into the general position of the riser. The unit is preprogrammed for six riser contact sizes. The operator then selects the proper size, and the cut is executed.

A more automatic system uses a six-axis robot for complete automation of the cutting operation (Ref 19). Specially designed locating blocks or pads are cast into each casting. Contact location principles are utilized to provide alignment between the robot and the casting. The robot is programmed using a teach pendant device. In addition to position and path, the operator programming the robot must also define the travel speed between each point, preheat delay, and cutting oxygen pressure for each cut. Results indicate a savings of 120 to 180%, depending on the casting to be cut (Ref 19, 20, 21).

The following factors must be taken into account when considering an installation or application (Ref 21):

- *Fixturing:* Distortion of gate position due to rough handling, mold inaccuracy, and so on, all lead to errors in position. Some means of sensing the positions of the gates and risers is necessary
- *Feedback system:* Because of variations in thickness and other defects, such as flash and drops on the casting, an adaptive control system that accounts for this would be very beneficial (Ref 22)
- *Automatic torch ignition:* This provides an added measure of safety and convenience
- *Preheat sensing:* One system is equipped with a fiber optic lens that sights through the oxygen orifice (Ref 19). An infrared sensing measurement is made to the computer controlling the robot. If the signal indicates kindling temperature, oxygen is employed and the cut is continued

Pick and Place Operations

The most common application of robots in any manufacturing environment consists of pick-and-place tasks. This is also true in the foundry industry. Some applications are given below:

- The first application of robotics in the foundry industry was in the die casting process (Ref 21, 23, 24, 25). Robots were used for such operations as extracting the casting from the die and loading and unloading the casting to firm presses
- Most attribute the second application of robotics in the foundry to investment casting (Ref 21, 26). In this application, robots are used to dip the pattern assembly into the ceramic slurry to obtain a precise and uniform distribution of the coating. This process has been quite successful because it has greatly increased the consistency as compared to manual dipping
- More recently, robots have been used in the evaporative foam process. Here robots have been used to remove the expandable polystyrene patterns from the mold and then assemble them into a complete pattern, to position the patterns into flasks, and to remove them after pouring. As in investment casting, robots have also been used to dip the castings into mold washes
- Core handling applications can also be found, especially for shell core handling

Mold Venting

To produce sound, high-quality castings, one of the most important manufacturing steps is to vent the mold properly. In green sand molding, this is accomplished either by pressing a metal pin into the mold or by drilling through the mold in precise locations.

A robot can be programmed by a teach pendant device to perform this operation. The program is then stored and retrieved when the pattern is produced again. The venting function requires a robot capable of only an *X-Y* positioning and an up-and-down motion (Ref 27). Off-line programming functions for the robot have even been incorporated into this operation.

Mold Spraying

One of the most common applications of robotics in manufacturing is paint spraying. Similarly, in sand molding, robots have been used to spray molds and cores with a wash before drying with gas torch flames. One application is shown in Fig. 3.

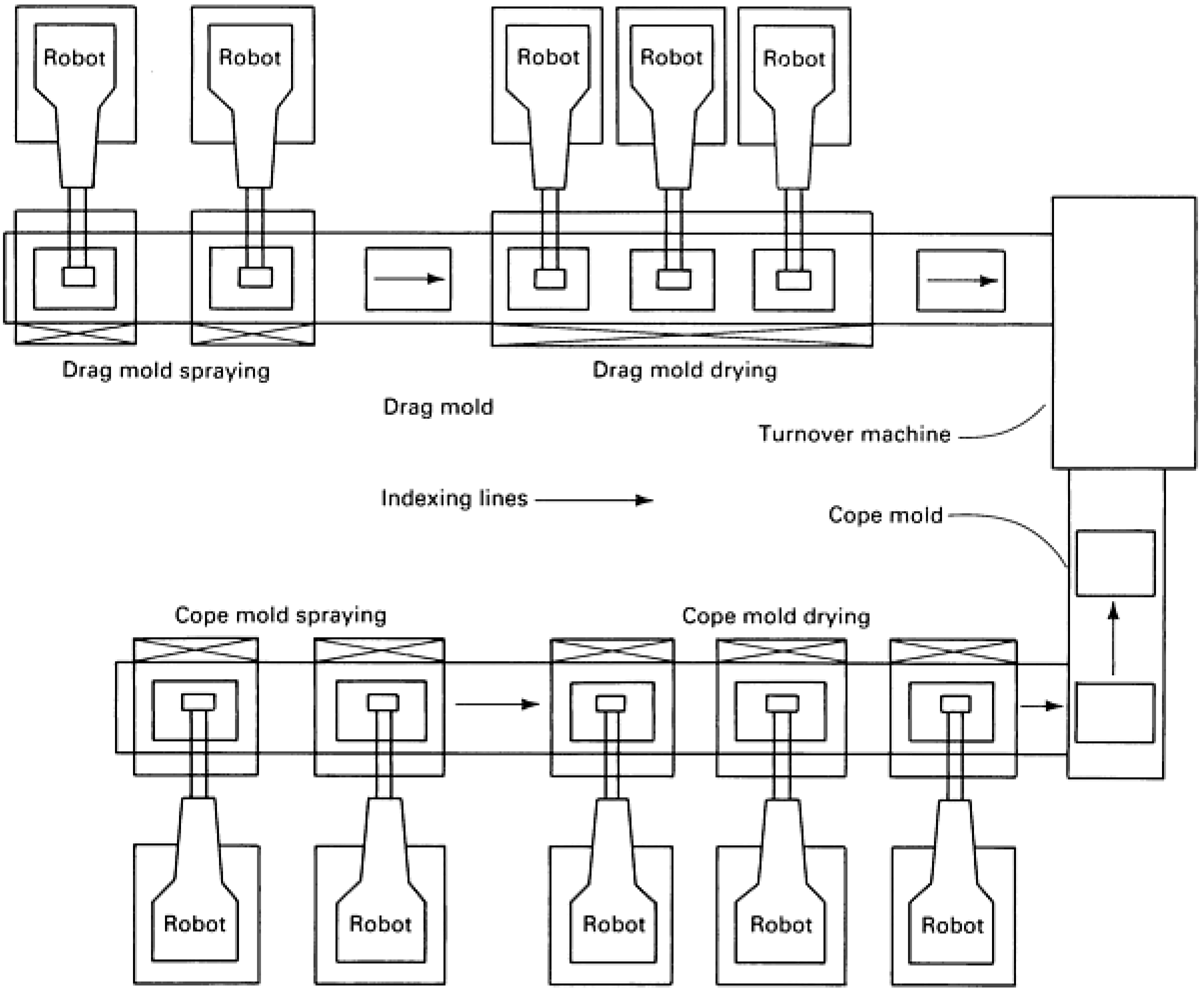

Fig. 3 Robots stationed along two indexing lines to spray a coating on each cope and drag, followed by drying of the foundry mold components prior to assembly in the turnover machine

One advantage of such a system is the consistency of spray and the reduction of overspraying. Robotic-controlled drying has been found to reduce fuel consumption by 67%. In addition, after each spray of the mold wash, the spray gun can be cleaned for the next mold, thus eliminating the downtime that would have been spent to fix clogged spray heads.

Another application of robotic spraying systems is found in die casting (Ref 24, 28, 29, 30). Robots are used to spray both water and die lubricants on the die during each cycle.

Cell Applications

Many traditional manufacturing processes use cell concepts to improve productivity, control, and quality (Ref 31). Figure 4 shows a die casting cell. Such cells incorporate many individual automation concepts and techniques into an integral production system (Ref 32, 33). One important feature of cells is that they are usually under the supervision of a computer control. This concept of cell automation is being used in the foundry industry. Examples can be found in both the die casting and the evaporative foam processing areas (Ref 7, 21, 29, 30). The die casting cell consists of a number of components, including the following:

- *Die casting machine:* This may consist of either a vertical or a horizontal system
- *Furnace:* This unit provides a continuous supply of liquid metal that must be maintained at the proper temperature
- *Trim press:* The die casting cell often has a trim press that automatically removes most of the flash and the gating system
- *Robots:* These are often used for three separate tasks within the die casting cell. First, they are used to remove the casting from the machine and to load the casting parts into a trim press, cooling tower, quench tank, or pallet. Second, robotic ladling systems handle the liquid metal. Finally, robots are used to spray lubricants on the die surface itself
- *Computer control system:* All of the above systems must be integrated with each other to form a

complete die casting cell. Many die casting process variables are controlled and/or monitored by computer controls. This computer control allows the die casting machine to regulate the die casting process more precisely, thus producing higher-quality and more consistent castings

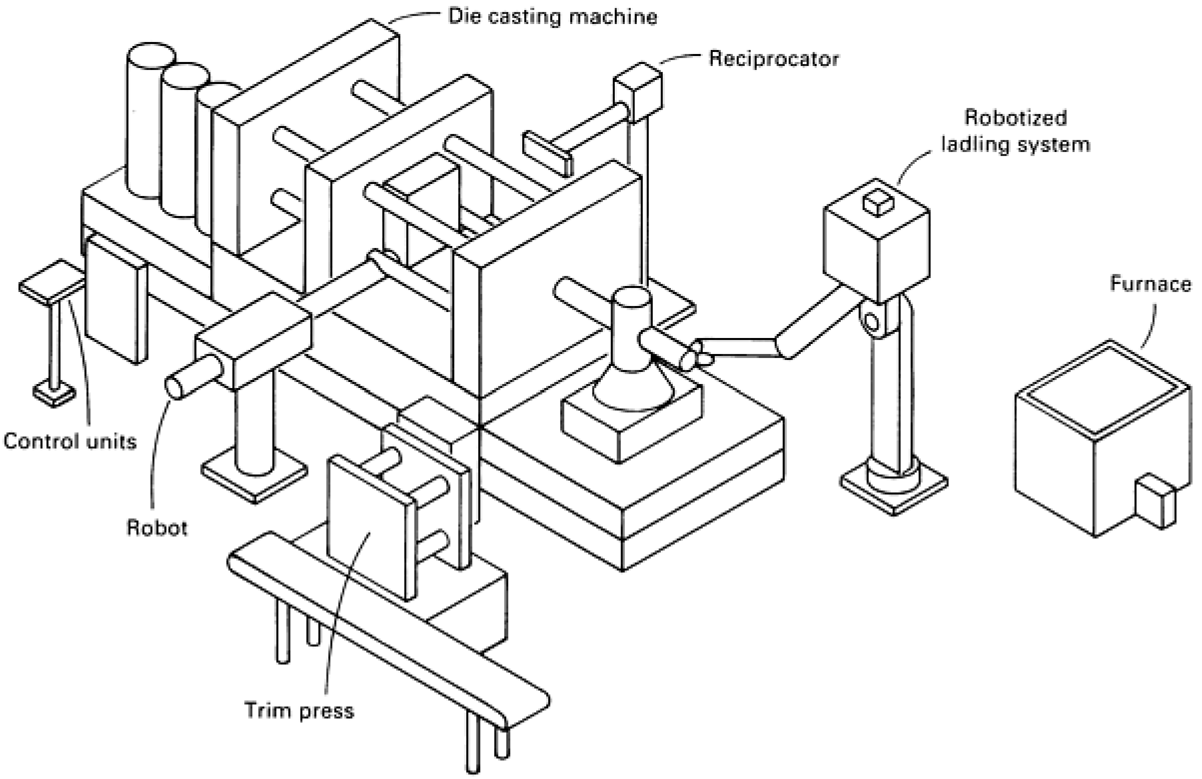

Fig. 4 A typical highly automated cell used in a die casting operation. It includes a die casting machine, a furnace, a trim press, two robots, and a computer control system to coordinate the movement of each cell component.

The results of implementing such cells are significant. A savings of $120,000 of direct labor (1986 dollars) cost per year per cell for a three-shift operation has been realized over manual operations (Ref 29). The hourly production of parts has been found to increase by 48.7% (Ref 23).

A totally automatic computer-integrated manufacturing (CIM) system for the Replicast process is currently under development (Ref 33). The proposed layout is shown in Fig. 5. As can be seen, the system is totally automated. The proposed system will use existing technology in each subportion of the cell. The integration of these techniques is the problem. The products to be produced are steel valve castings. The expected production level is 18 Mg (20 tons) of finished steel castings per week. The loop conveyor system consists of 72 flasks; the proposed cycle time is 165 to 190 min per flask.

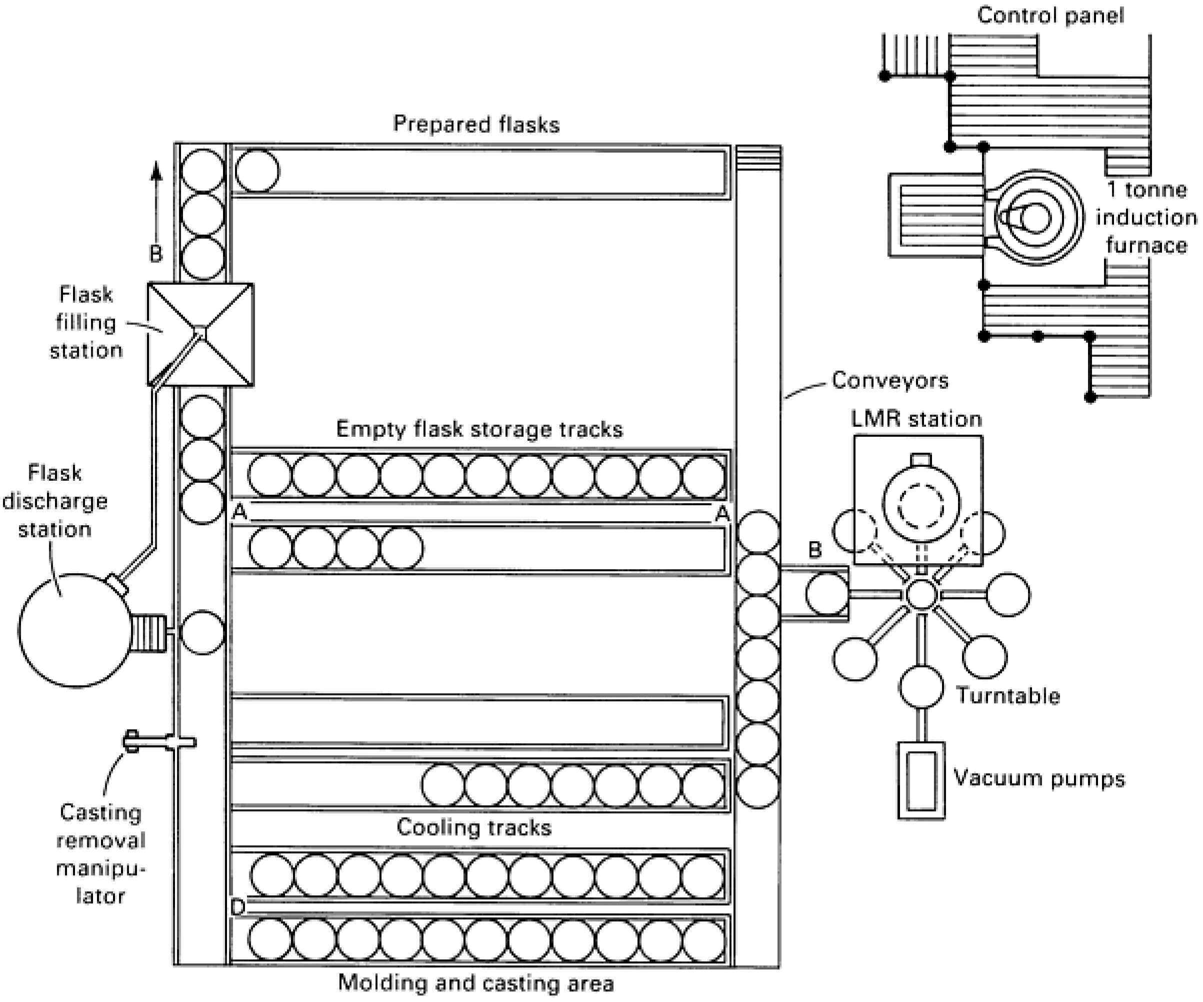

Fig. 5 Schematic of a layout for a CIM system that uses the Replicast ceramic shell process to produce steel valve castings. The loop conveyor system consists of four separate tracks (B-B in a U-shaped configuration along the perimeter of the system and A-A, C-C, and D-D enclosed in a ladder array within B-B) that contain 3 sets of 24 flasks each for a total of 72 flasks. Each track performs the following function in the production routing. A-A is the storage area for empty flasks. B-B transfers empty flasks to the flask filling station, where the thin ceramic shell is placed in the flask with its pouring cup at the center and the flasks vibrated to compact the sand that supports the shell; conveys flasks to liquid-metal refining (LMR) station turntable, where the molten metal is then poured into the mold (either under atmospheric pressure or a vacuum). C-C and D-D are cooling stations where the molten metal solidifies. B-B conveys flasks to a device that separates the casting from the mold and then transports the flasks to a discharge station, where the sand is dumped into hopper to be screened, cooled, and classified. Empty flasks in A-A await reuse to repeat the cycle of operations described.

A second proposed prototype casting cell is shown in Fig. 6. The proposed system uses well-established techniques for the automatic transport of expanded polystyrene type patterns, ceramic shells, and flasks. The system requires two to three robots, depending on the level of automation required. The first would be used to produce the molding material, while the second would position the pattern into the flask and then remove the casting. Robotic-controlled flame cutting stations and automatic cleaning facilities could also be installed.

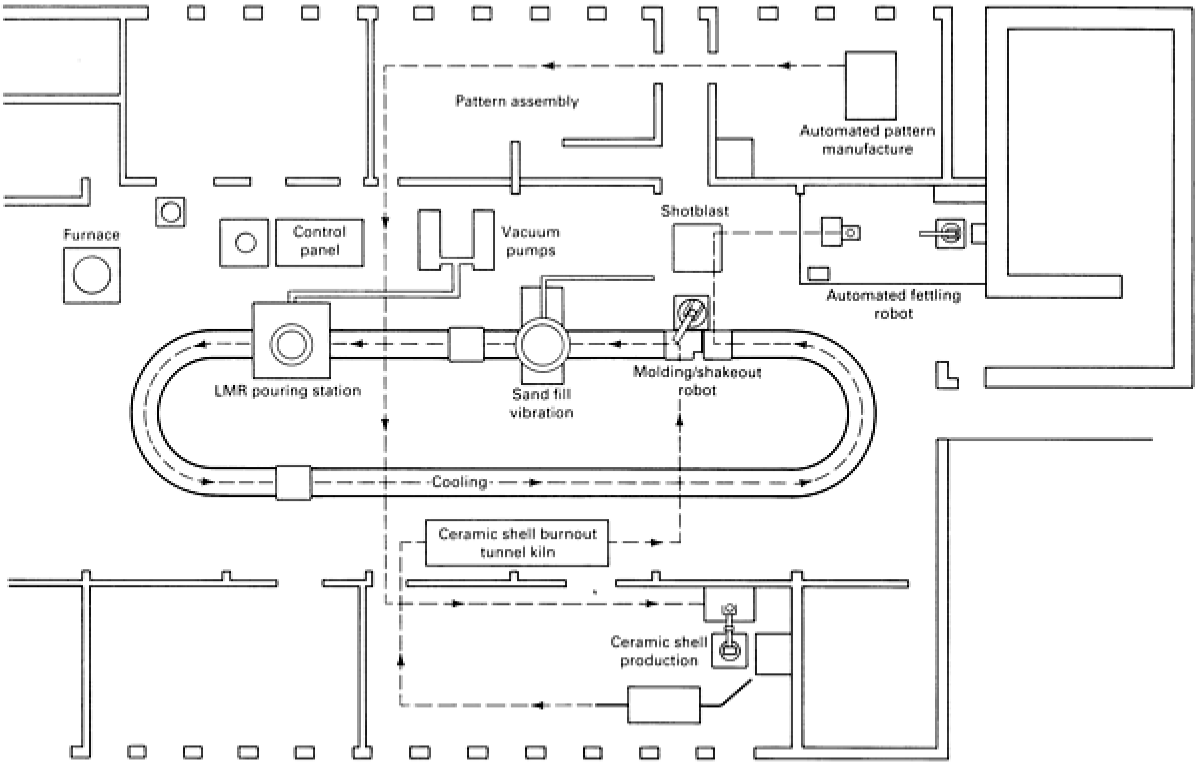

Fig. 6 Schematic of an integrated casting system that incorporates existing installations and technology to demonstrate the operation of a totally automated system. Up to three robots could be employed. The first is used to produce the ceramic shells widely used in investment casting operations; the second, to position shells in molding flasks and to remove castings from the mold after the molten metal has been poured; and the third, to flame cut or abrasive cut the casting in an automated fettling cell.

Automatic Pouring Systems

The pouring control system for any automatic foundry cell is critical for achieving maximum yield per run or shift while still maintaining high quality standards in the castings produced (Ref 35). A number of automatic pouring systems are available; some are discussed below. Additional information can be found in the article "Automatic Pouring Systems" in this Volume.

Robotic System. The die casting industry uses an automatic pouring ladle with robot-like movements that is controlled by a programmable controller. The cycle begins at the holding furnace, the ladle dips precise amounts of molten aluminum from a dipwell, carries it to a position directly over the mold without spillage within 3 to 6 s, and pours it quickly into the mold.

A simple adjustment on the controller determines the amount of liquid metal dipped by the ladle. A sensor detects the level of the liquid-metal surface to ensure accurate shot repeatability throughout the metal-level height range.

Bottom-Pour System. The automatic system combines microprocessor control, fiber optics, and infrared sensing to control bottom-pour ladles. A pulsed infrared beam is bounced off the mold surface to direct and control the hydraulic alignment of the mold with the ladle stopper. Two fiber optic cables sense the leading and trailing edges of the pouring cup. This reduces metal loss due to spillage and results in higher-quality castings. The microprocessor controls the time the stopper is open by computing the diminishing height of metal during the pouring process (Ref 36).

Laser Level Measurement. It is feasible to combine a laser light source with a solid-state electronic camera and a process control computer to control the amount of molten iron dispersed into special pouring ladles. This control has been installed on holding furnaces that supply predetermined quantities of molten iron to rotary mechanical pouring machines. Figure 7 shows a basic schematic of the system.

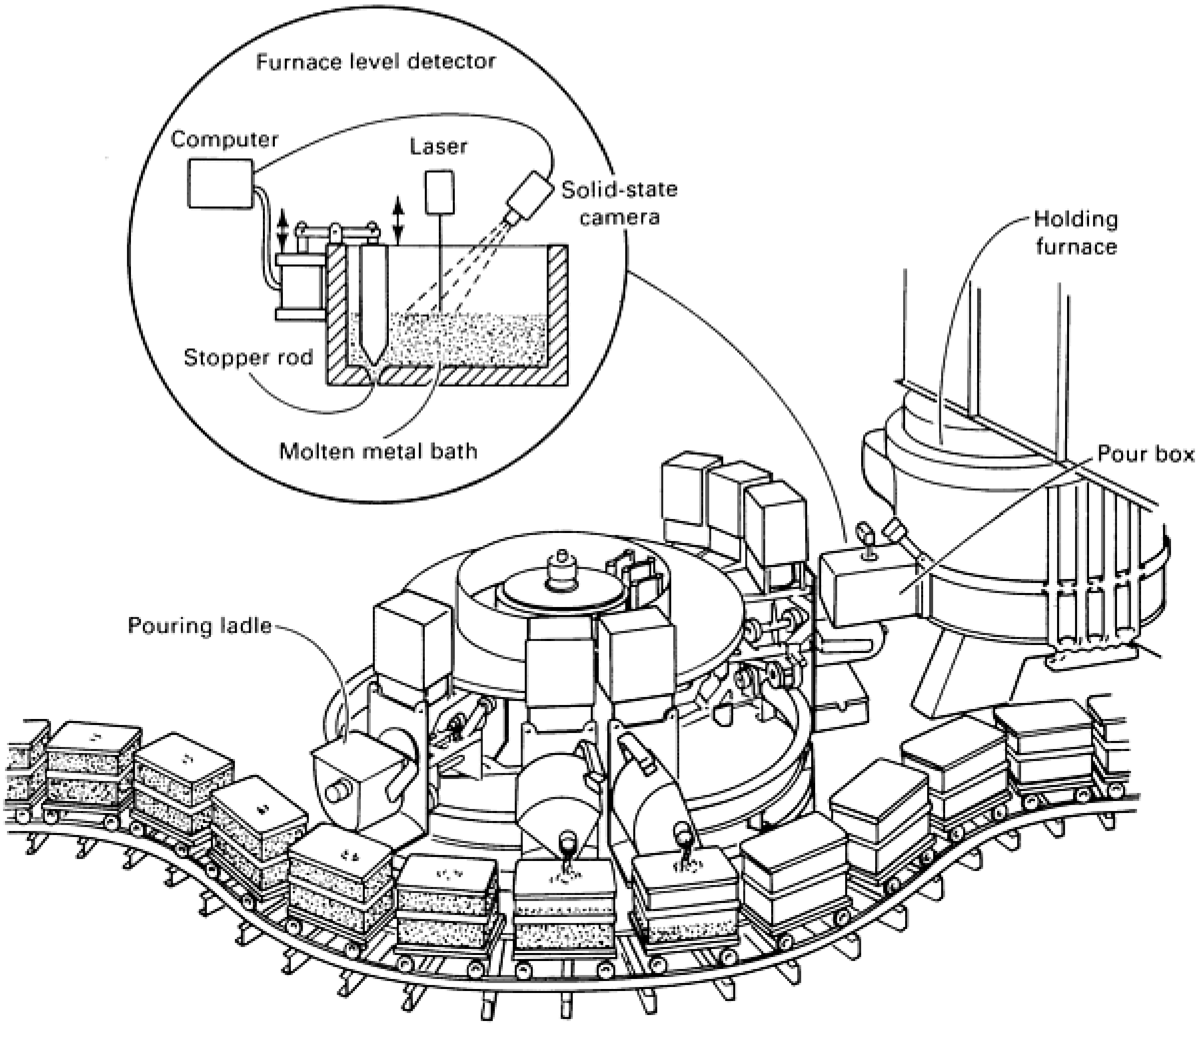

Fig. 7 Laser light source and a solid-state electronic camera interfaced with a process control computer to monitor the furnace level in a state-of-the-art rotary mechanical pourer

The laser beam controls the rate at which each ladle is filled based on the heat of metal in the holding furnace. The laser beam is focused on the surface of the molten iron. A video camera picks up the laser beam reflection and transmits the information to a process control computer. Decisions are then made as to the amount of metal poured. It is estimated that 5 to 14 kg (10 to 30 lb) per mold of iron is saved by this system. Payback is estimated to be 1 to 3 months.

Automatic Storage and Retrieval Systems

The storage of cores and patterns is another aspect of foundry operations that will lend itself to automated material handling technology. Automatic storage and retrieval in high-rise narrow-aisle rack space has had wide acceptance in almost every warehousing environment. In recent years, its use as a temporary storage method for workpieces in process and process equipment has brought this technology from the warehouse into the manufacturing plant itself--sometimes right to machine-side. An example of such a system is shown in Fig. 8.

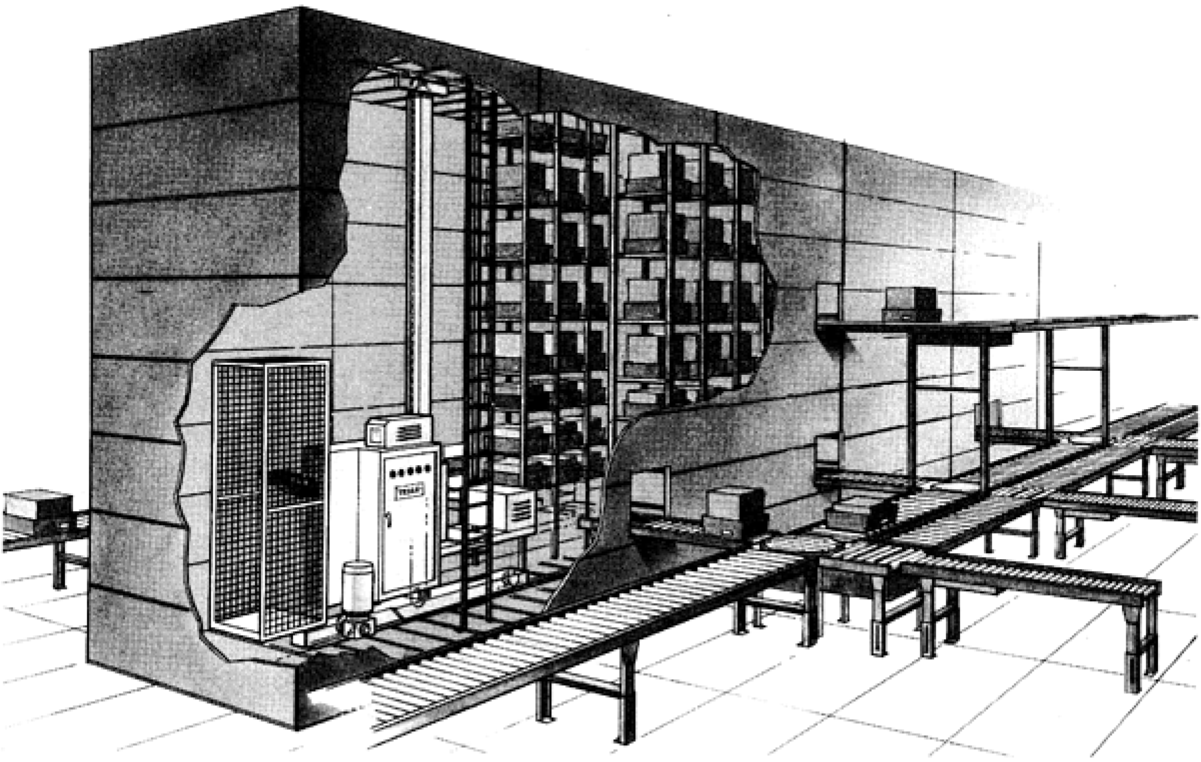

Fig. 8 Components of a typical in-plant automatic storage/retrieval system

This type of automatic storage and retrieval (AR/RS) system can be used to solve the typical problems involved in securing temporary storage for, or simply locating, cores and/or patterns. Computerized AS/RS systems make maximum use of the plant (square footage set aside for storage by storing at heights impossible or dangerous to reach by fork truck). The computer provides a real time, accurate inventory of all stored materials and the exact location of each storage container.

Automatic guided vehicles (AGV) represent still another recent material handling development that has a place in foundry applications, especially in die casting shops. The battery-operated, driverless vehicle follows a wire guidepath imbedded just below the surface of the plant or warehouse floor. The wire carries a low-voltage signal that is picked up by sensors mounted beneath the vehicle. These sensors, in turn, energize small servo motors that steer the vehicle and keep it on track. Guidepath design ranges from simple loops to very complex multipath, multivehicle systems. An AGV that transports palletized workpieces within a flexible manufacturing cell is illustrated in Fig. 9. Such a system could be used for the transportation of dies, molds, and/or patterns in a foundry (Ref 31).

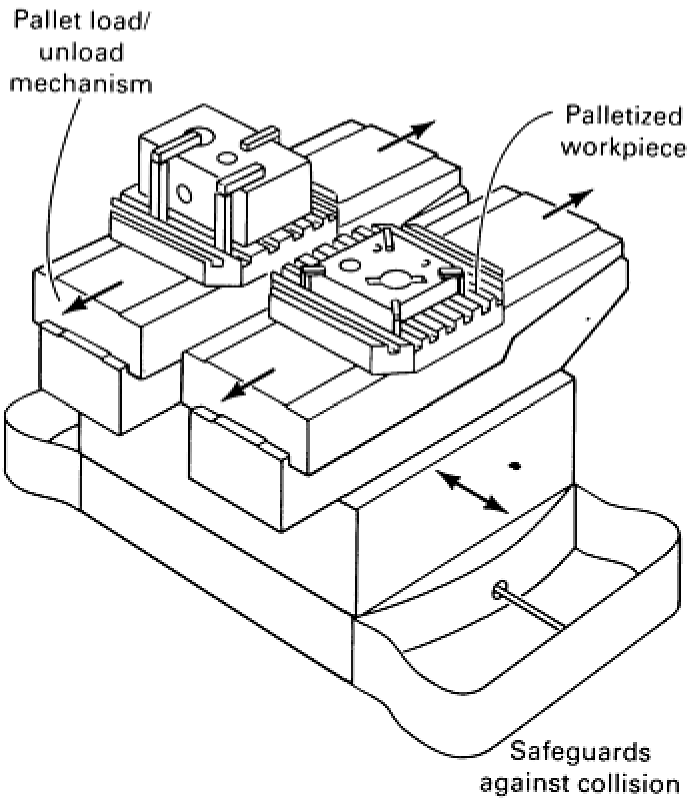

Fig. 9 An AGV being used to transport palletized workpieces within a flexible manufacturing cell

These vehicles interface easily with an AS/RS system. If a central computer is being used to direct the flow of materials and to store and record inventory, the system can become highly automated.

The AGV is best suited to intermediate use where transport must be made on a regular basis but not continuously. This would describe the situation in most die casting shops, where dies must be transported from the point of manufacture to storage or point of use.

Automatic Sorting and Inspection

For the complete automation of foundry operations, methods must be developed that can automatically sense and sort castings. One such computer-aided vision system is described in Ref 37. This system is illustrated in Fig. 10.

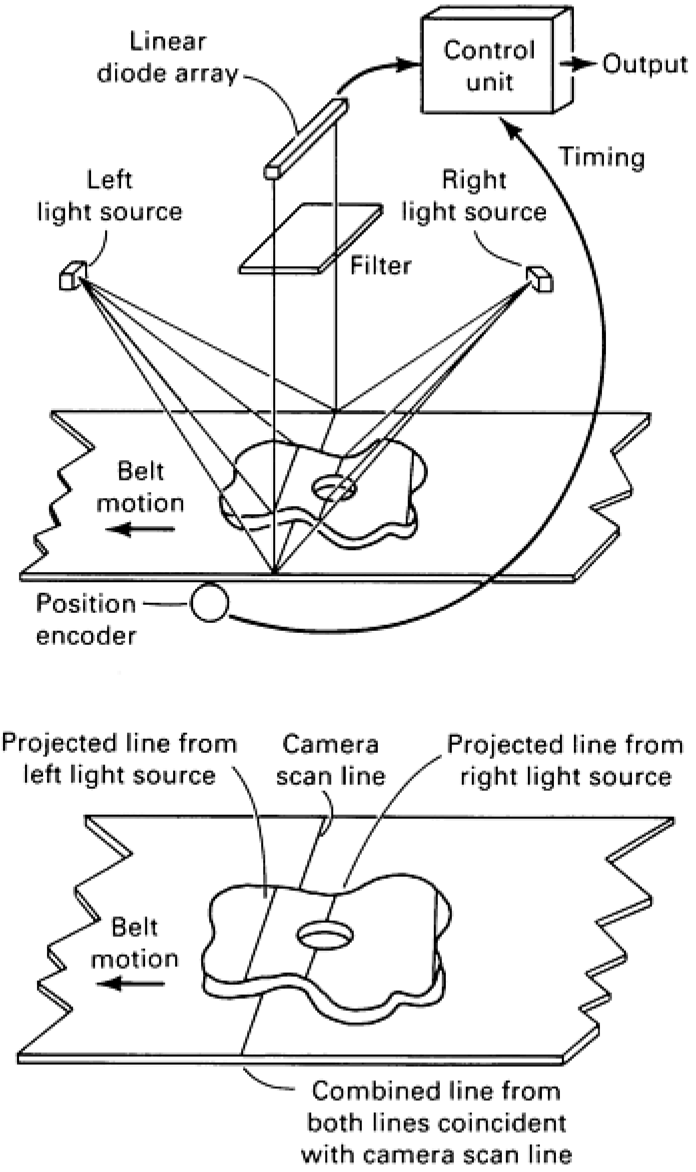

Fig. 10 Schematic of a computer-aided vision system capable of sorting 200 different objects at a rate of 10,000 pieces per hour

When the linear photo sensor array is scanned, bright segments correspond to the unobstructed belt, while dark segments correspond to the part. The vision camera compares the acquired image to its memory of various parts. The part location is maintained by a position encoder. After the casting is identified, it is placed into the appropriate container by pneumatic kikers. The sorting unit has the capability of sorting 200 different objects at a rate of 10,000 pieces per hour.

Computer-assisted coordinate-measuring machines are being installed in foundry pattern shops to measure both pattern and casting dimensions. These machines can perform a variety of dimensional checks ranging from basic geometric measurement to parallel and plane projection. The operator simply identifies critical part locations so that the machine can establish a working plane. The coordinate-measuring machine can perform in a few minutes the tedious checks that take 2 to 4 h to be done manually.

Computer-aided design and manufacture (CAD/CAM) offers a way to link the interrelated activities at the various manufacturing facilities, each using information as required from the data base and contributing new information as it is generated. The process begins with a part description, usually an illustration. From this, the designs for the casting, pattern, and mold are developed. At each step, the design information from previous steps is available for the geometric modeling of additional features. The CAD system automates some design tasks. Commonly used components are stored in the data base and recalled as necessary. The pattern design can be replicated and positioned to form the basis for the mold design. Special design calculations can be programmed. As an example, shrinkage allowances and draft angles are automatically calculated (Ref 38, 39, 40, 41, 42).

One advantage of developing a computer-aided design of the casting is that relevant data are available for creating foundry tooling. Drawings and material lists can be generated from the CAD system. Where computer numerical control (CNC) machining is to be used, cutter paths will be generated and downloaded directly to machine tools. Future foundry automation would use information on mold and casting geometry for automatic pouring, robotic handling, and verification of manufactured items as required (whether patterns, castings, or machined parts). Again, from an integrated data base, dimensional information is available and can be transferred to the shop floor by the CAM system to generate templates, drawings, checklists, or coordinate-measuring machine programs.

A true marriage of computer-aided design and manufacture will reduce casting implementation time by 40 to 50% (Ref 43, 44). Many pattern shops currently use computer numerical control to produce patterns. This method is proving to be a more accurate and faster approach to building patterns than the cast-to-size or trace machining methods (Ref 45). With the CNC approach, the mathematically defined surface model designed on a three-dimensional CAD system is expanded to include shrinkage requirements. The numerical control (NC) programmer develops tool paths from the surface model geometry and then test machines the part graphically to verify tool path selection. In addition, accurate predictions of the actual machine cutting times can be obtained. The final step is to feed the electronic data to a CNC machine that cuts the final shape. No craftsman-formed master pattern is required. The electronic part data can be compactly stored without distortion. Part data can be retrieved and revised very quickly compared to manual part programming techniques.

Riser Design

Lee A. Plutshack and Anthony L. Suschil, Foseco, Inc.

Introduction

RISER DESIGN, or risering, deals with the development of suitable reservoirs of feed metal in addition to the desired casting shape so that undesirable shrinkage cavities in the casting are eliminated or moved to locations where they are acceptable for the intended application of the casting. When metals solidify and cool to form a casting, they generally undergo three distinct stages of volume contraction, or shrinkage. (Exceptions to this shrinkage behavior of some graphitic cast irons will be noted later in this article.) These stages, shown schematically in Fig. 1, are:

- Liquid shrinkage: The liquid metal loses volume as it gives up superheat and cools to its solidification temperature
- Solidification shrinkage: The metal freezes, changing from a liquid to a higher-density solid. For pure metals, this contraction will occur at a single temperature, but for alloys it will take place over some temperature range or freezing interval
- Solid shrinkage: The solid casting cools from its solidification temperature to room temperature

The last of these, solid shrinkage (also called patternmaker's shrinkage), is accommodated by making the pattern (and therefore the mold cavity) somewhat larger than the desired dimensions of the final casting. Liquid shrinkage and solidification shrinkage are the concern of risering practice. In the absence of risers, a casting would otherwise solidify as shown in Fig. 2.

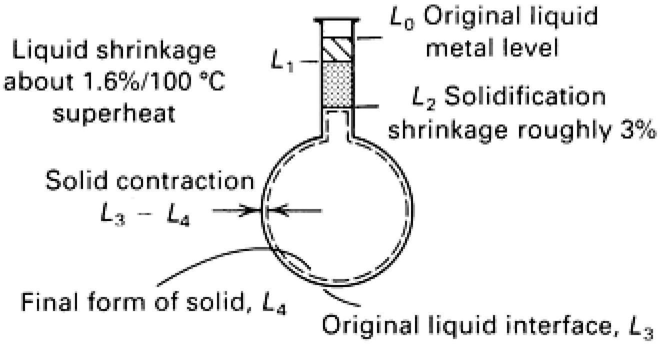

Fig. 1 Schematic of the shrinkage of low-carbon steel. The contribution of each one of the three distinct stages of volume contraction is shown: liquid shrinkage, solidification shrinkage, and solid contraction. Source: Ref 1

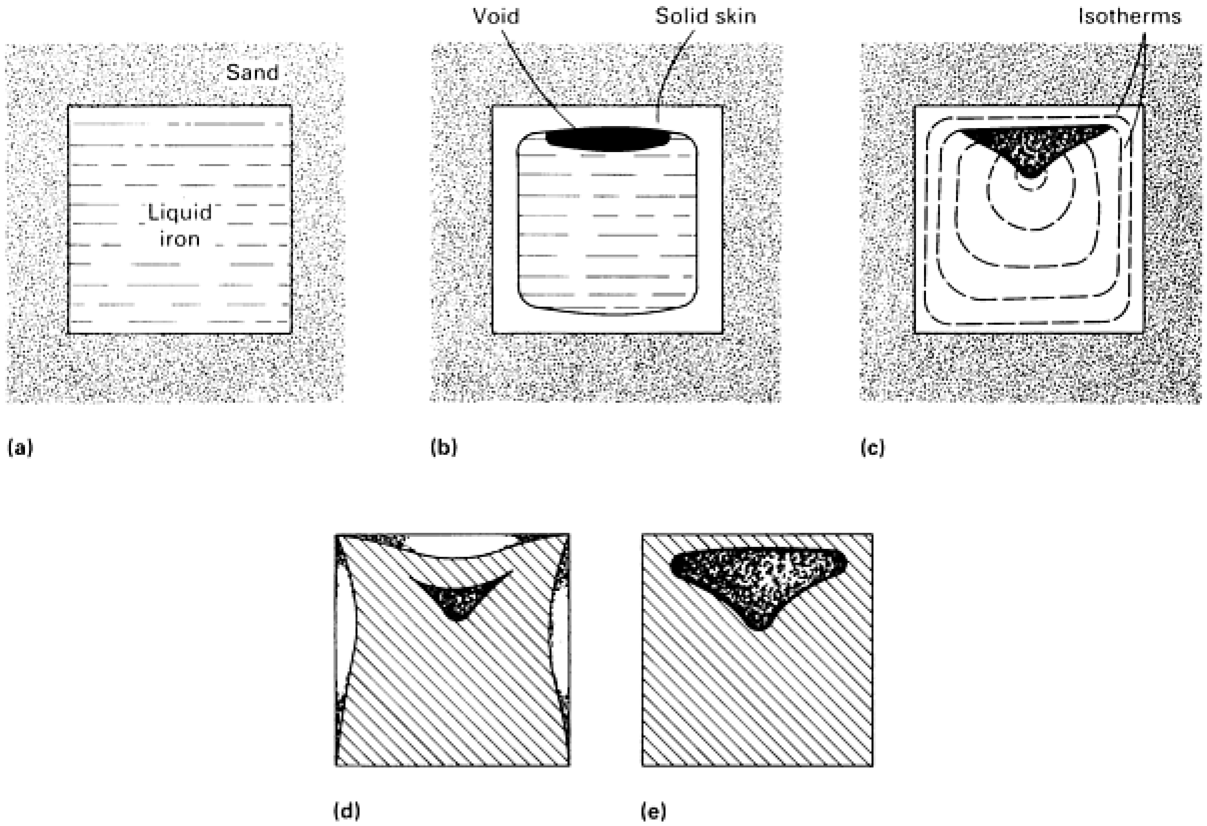

Fig. 2 Schematic of sequence of solidification shrinkage in an iron cube. (a) Initial liquid metal. (b) Solid skin and formation of shrinkage void. (c) Internal shrinkage. (d) Internal shrinkage plus dishing. (e) Surface puncture

Visible signs of shrinkage-induced casting defects include internal shrinkage voids, surface deformation or dishing, and surface puncture: These defects will vary with different alloys; for example, internal shrinkage may be more dispersed, or alloys with strong skin-forming behavior may not exhibit surface deformation.

To eliminate these undesirable defects in the casting, a riser will be added to accommodate the liquid shrinkage and to supply liquid feed metal to compensate for the solidification shrinkage within the casting (Fig. 3). Therefore, the shrinkage in the riser/casting system is concentrated in the riser, which will then be removed from the finished casting.

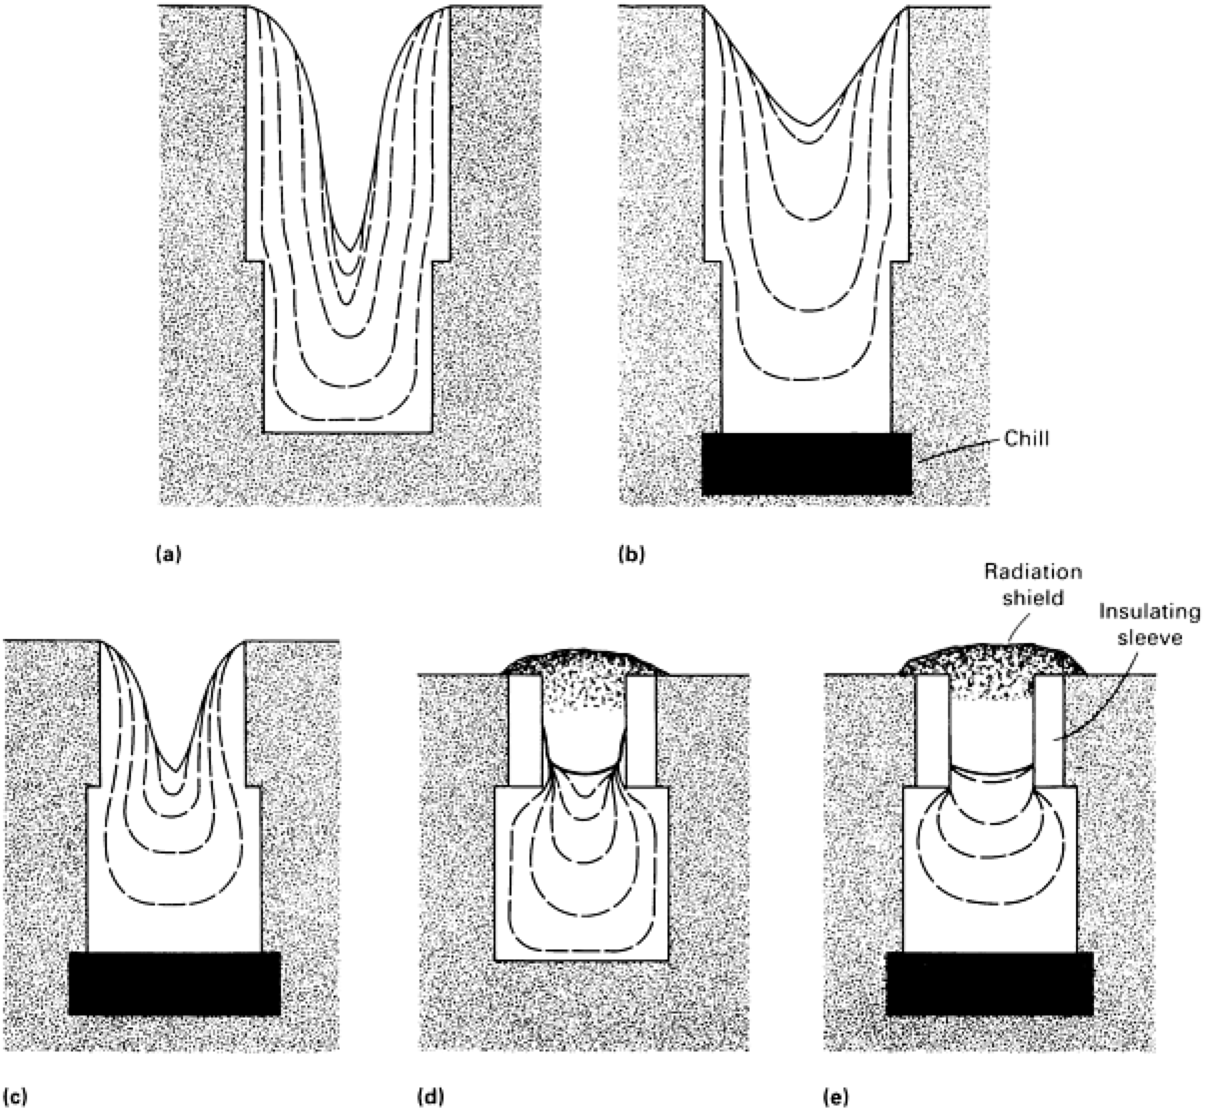

Fig. 3 Methods of controlling shrinkage in an iron cube to reduce riser size. (a) Open-top riser. (b) Open-top riser plus chill. (c) Small open-top riser plus chill. (d) Insulated riser. (e) Insulated riser plus chill

As illustrated in Fig. 3, the riser must often be larger than the casting it feeds, because it must supply feed metal for as long as the casting is solidifying. Various methods are used to reduce the size of the required riser, including chilling the casting (that is, reducing its solidification time) or insulating the riser (that is, extending its solidification time).

Optimum Riser Design

The role of the methods engineer in designing risers can be stated simply as making sure that risers will provide the feed metal:

- In the right amount
- At the right place

- At the right time

To this list can be added several other considerations:

- The riser/casting junction should be designed to minimize riser removal costs
- The number and size of risers should be minimized to increase mold yield and to reduce production costs
- Riser placement must be chosen so as not to exaggerate potential problems in a particular casting design (for example, tendencies toward hot tearing or distortion)

In practice, these considerations are often in conflict, and the final riser design and pattern layout represent a compromise.

Feed Metal Volume

The riser must be adequate to satisfy the liquid and solidification shrinkage requirements of the casting. In addition, the riser itself will be solidifying, so the total shrinkage requirement to be met will be for the riser/casting combination. The total feeding requirement will depend on the specific alloy, the amount of superheat, the casting geometry, and the molding medium.

Liquid shrinkage will depend on the alloy and the amount of superheat. As indicated in Fig. 1, liquid shrinkage for carbon steels is generally considered to be in the range of 1.6 to 1.8%/100 °C (0.9 to 1.0%/100 °F) superheat. For graphitic cast irons, liquid shrinkage has been variously reported in the range of 0.68 to 1.8%/100 °C (0.38 to 1.0%/100 °F) (Ref 2, 3, 4, 5).

Solidification Shrinkage. Table 1 indicates that solidification shrinkage will vary considerably according to the alloy melted and that, within the graphitic cast irons, expansion may occur. This phenomenon is often ascribed to the precipitation of the less dense graphite phase overcoming the contraction associated with the solidification of austenite. Theoretical calculations indicate that such density differences cannot account for the higher reported expansion percentages (Ref 2, 5). Practice shows that, with proper control of metallurgical and mold conditions, expansion phenomena can be used to reduce greatly or eliminate risers (with the liquid shrinkage accommodated by the gating system instead of the riser system) (Ref 5).

Table 1 Solidification contraction for various cast metals

Metal	Percentage of volumetric solidification contraction
Carbon steel	2.5-3
1% carbon steel	4
White iron	4-5.5
Gray iron	Varies from 1.6 contraction to 2.5 expansion
Ductile iron	Varies from 2.7 contraction to 4.5 expansion
Copper	4.9

Cu-30Zn	4.5
Cu-10Al	4
Aluminum	6.6
Al-4.5Cu	6.3
Al-12Si	3.8
Magnesium	4.2
Zinc	6.5

Source: Ref 6

Mold Dilation. Mold wall movement after a mold cavity has been filled with liquid metal can enlarge the casting and thus increase the feed metal requirements. Such mold dilation is a function of the molding medium, the mold filling temperature, and the alloy.

With gray and ductile irons, mold dilation may result partially from expansion pressures within the solidifying casting generated by the precipitation of graphite. In soft green sand molds, such mold dilation may produce an additional 15% feed metal requirement above that needed to satisfy the calculated liquid and solidification shrinkages (Ref 7). In copper-base alloys, it has been suggested that an additional 1% volumetric shrinkage should be expected as a result of mold cavity expansion in green sand molds (Ref 8).

Casting Geometry. The shape of a casting will affect the size of the riser needed to meet its feed requirements for the obvious reason that the longer the casting takes to solidify, the longer the riser must maintain a reservoir of liquid metal. For rangy, thin-section castings (where solidification will be rapid), feed metal requirements may be smaller than what would ordinarily be calculated. This is because a portion of the liquid and solidification shrinkages will be fed by liquid metal entering the mold from the gating system. Table 2 indicates the effect of differences in casting geometry on minimum riser volume requirements for steel castings.

Table 2 Minimum volume requirements for risers on steel castings

Type of casting	Minimum riser volume/casting volume (V_r/V_c), %			
	Insulated risers		Sand risers	
	***H/D* = 1:1**	***H/D* = 2:1**	***H/D* = 1:1**	*H/D* = 2:1
Very chunky (cubes, etc.): dimensions in ratio 1:1.33:2	32	40	140	**198**
Chunky: dimensions in ratio 1:24	26	32	106	**140**

Average: dimensions in ratio 1:3:9	19	22	58	**75**
Fairly rangy: dimensions in ratio 1:10:10	14	16	30	**38**
Rangy: dimensions in ratio 1:15:30	9	10	13	**15**
Very rangy: dimensions in ratio 1:>15:>30	**8**	**8**	**11**	**13**

Source: Ref 9

Riser Location

To determine the correct riser location, the methods engineer must make use of the concept of directional solidification. If shrinkage cavities in the casting are to be avoided, solidification should proceed directionally from those parts of the casting farthest from the riser, through the intermediate portions of the casting, and finally into the riser itself, where the final solidification will occur. Shrinkage at each step of solidification is thus fed by liquid feed metal being drawn out of the riser.

The ability to achieve such directional solidification will depend on:

- The alloy and its mode of solidification
- The mold medium
- The casting design

Two distinct types of castings must be considered: castings with uniform wall thickness and castings with wall sections of varying thickness.

Progressive and Directional Solidification. Figure 4 illustrates the interplay of progressive and directional solidification in a casting. With the mold cavity filled, solidification will generally proceed from the mold wall, where a skin of solid metal will form. As heat is lost to the mold, that skin will grow progressively inward. Two conditions serve to change the rate of this growth. At the casting edge, where the greater surface area allows more rapid transfer of heat to the mold, the solidification rate will be faster. At the riser, where the mass of the riser provides more heat, and where heat transfer to the mold is reduced at the internal angle of the riser/casting junction, the rate of skin formation will be reduced. This combination of edge effect, or end effect, and riser effect provides directional solidification.

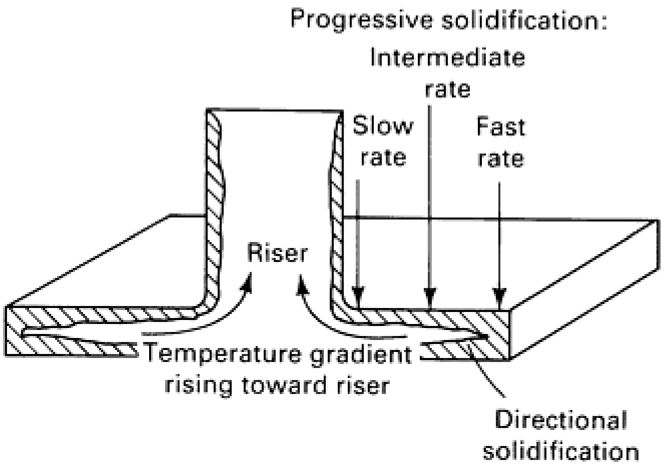

Fig. 4 Directional and progressive solidification in a casting equipped with a riser. Source: Ref 10

If the wedge-shaped pattern of the solidification front begun at the casting edge can be maintained, a channel of liquid feed metal should be available throughout its progress toward the riser. If, however, the parallel advancing walls progressively solidifying in the intermediate zone begin to meet, movement of liquid feed metal will be restricted, and centerline shrinkage will result.

Solidification Mode. The ability to promote and sustain directional solidification will depend greatly on the manner in which an alloy solidifies. Alloys can be classified into three types based on their freezing ranges:

- *Short:* liquidus-to-solidus interval <50 °C (<90 °F)
- *Intermediate:* interval of 50 to 110 °C (90 to 200 °F)
- *Long:* interval > 110 °C (> 200 °F)

This classification is not precise, but the general solidification mode of each type is illustrated in Fig. 5, 6, 7, 8.

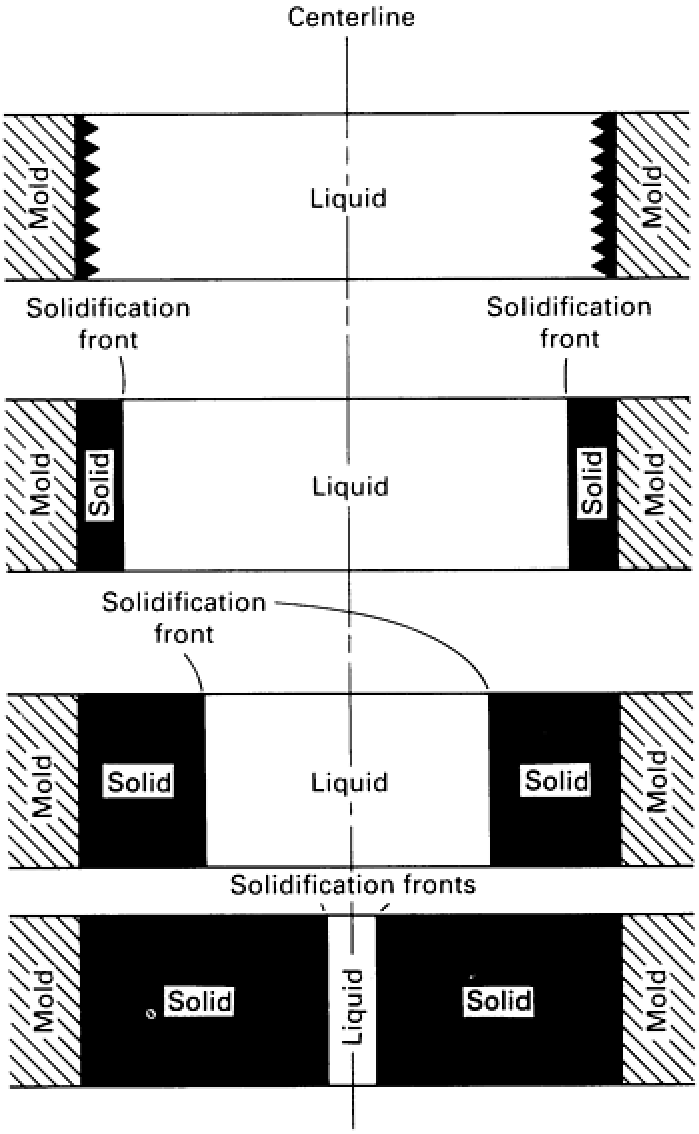

Fig. 5 Schematic of mode of freezing in pure metals. Crystallization begins at the mold wall and advances into the casting interior on a plane solidification front. Source: Ref 11

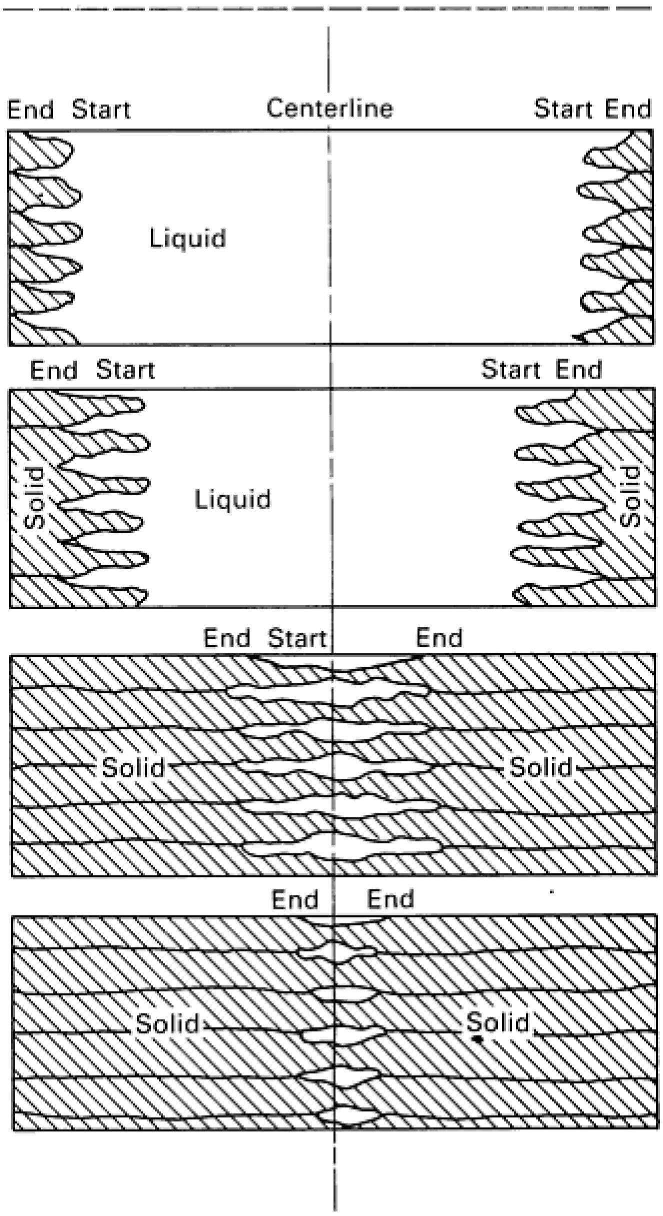

Fig. 6 Diagram of mode of freezing in alloys having a short freezing range

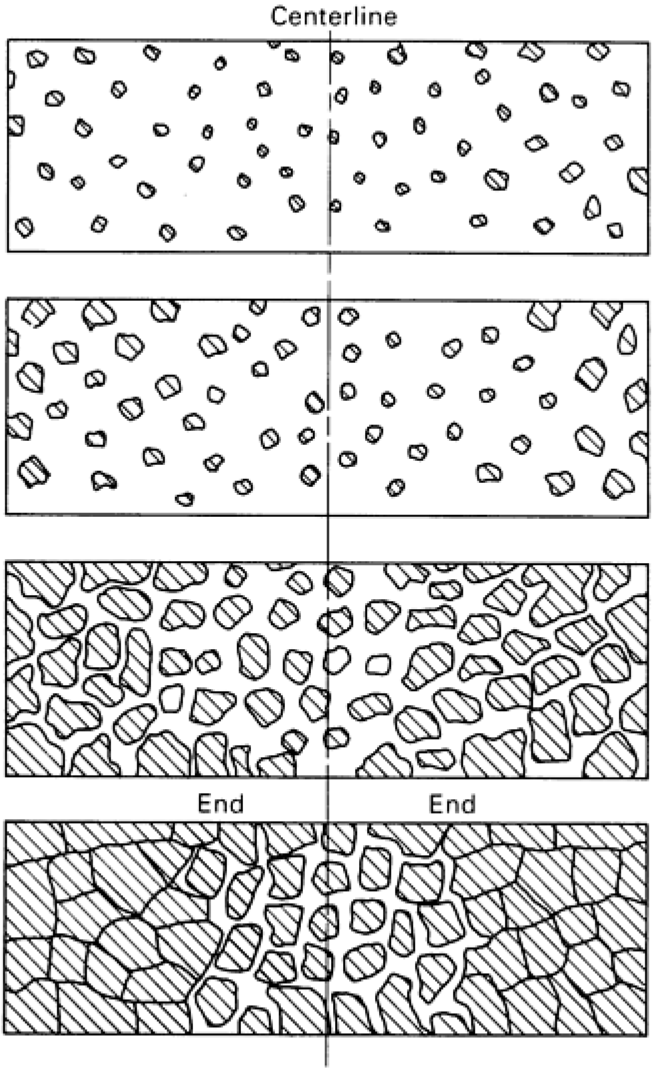

Fig. 7 Schematic of mode of freezing in alloys having a long freezing range

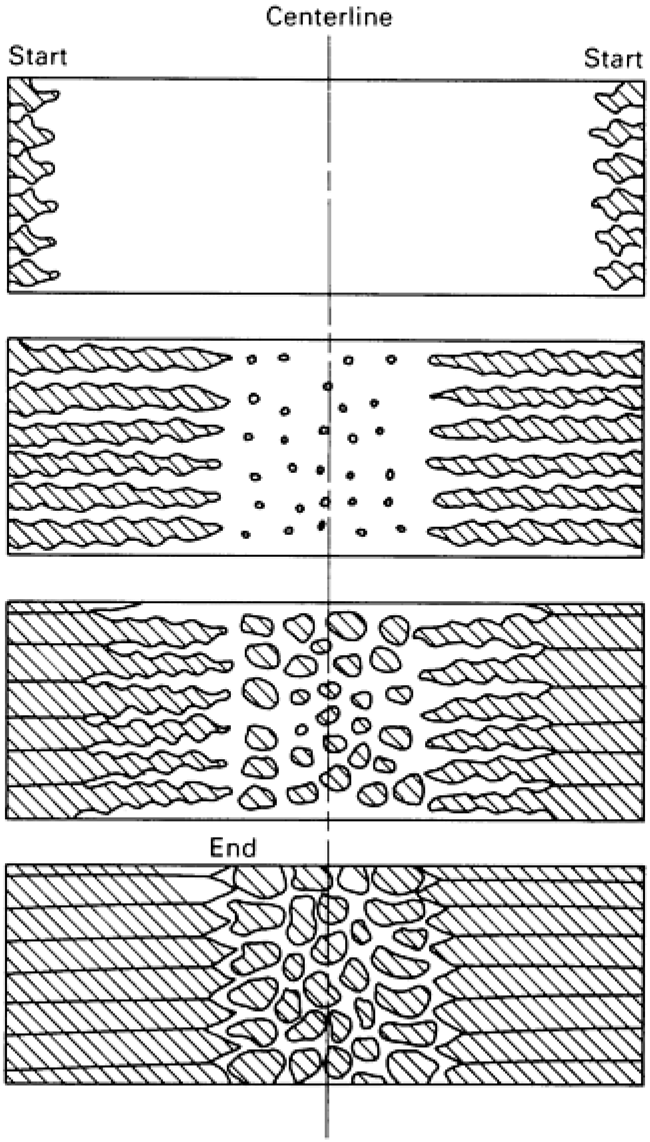

Fig. 8 Schematic of intermediate mode of freezing in alloys having a moderate freezing range

For pure metals (Fig. 5), in which the freezing range approaches zero, the solidifying casting walls progress inward as a plane front. Short freezing range alloys (Fig. 6) will show a strong tendency toward skin formation, and the fronts of the crystals solidifying inward (start of freeze) will not advance much faster than their bases (end of freeze). Such relative, short crystalline growth helps keep liquid feed metal in contact with all the solidifying surfaces. Such strong progressive solidification in these short freezing range alloys promotes the development of directional solidification along any temperature gradients in the solidifying casting. For example, in carbon steel, gradients of only 0.022 to 0.045 °C/mm (1 to 2 °F/in.) in plates and 0.135 to 0.269 °C/mm (6 to 12 °F/in.) in bars are sufficient to produce a shrinkage-free casting section through directional solidification.

For long freezing range alloys (Fig. 7), the development of directional solidification is difficult. Although a thin skin may initially form on the mold walls, solidification does not proceed progressively inward. Rather, it develops throughout the solidifying casting at scattered locations. This mushy or pasty mode of solidification results in the development of numerous small channels of liquid metal late in solidification. Feeding through these channels is restricted, and dispersed shrinkage porosity occurs throughout the casting.

Such solidification is typical of many commercial copper-base alloys, in which the difficulty in feeding caused by shrinkage porosity is aggravated, especially in thick sections, by the high thermal conductivity of the alloys, which helps maintain a nearly uniform temperature throughout the solidifying casting. To promote directional solidification in such alloys may require temperature gradients as high as 1.46 °C/mm (65 °F/in.), which can usually be achieved only by severely chilling one portion of the solidifying casting. Generally, the goal in risering such alloys is not to eliminate shrinkage but to ensure that it is finely dispersed (microporosity).

For alloys with an intermediate freezing range (Fig. 8), the mode of solidification will combine elements of both the skin-forming and mushy solidification modes. Short freezing range alloys may shift to a more intermediate mode of solidification in heavy casting sections, in which heat loss from the casting surface will be slowed as the molding medium heats up. As temperature gradients from the center of the solidifying section to the casting edge are reduced, crystal growth will change from the columnar pattern growing in from the mold walls to an equiaxial pattern dispersed throughout the still-liquid center.

The various solidification modes result in very different typical shrinkage configurations in the casting and riser (Fig. 9 and 10) and present the methods engineer with distinctly different problems to overcome in riser and casting design. Selection of appropriate methods will depend largely on the possibility of promoting directional solidification. Figure 11 illustrates the effects of several mold and metal variables on the development of progressive (and therefore directional) solidification.

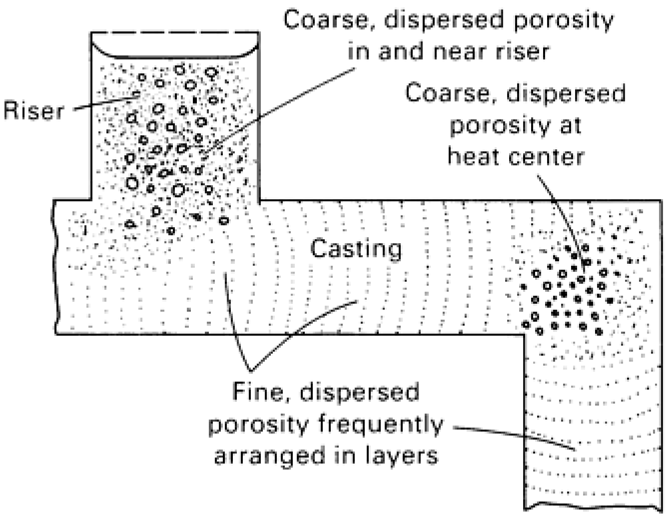

Fig. 9 Forms of shrinkage porosity in the sand castings of alloys that freeze in a pasty manner

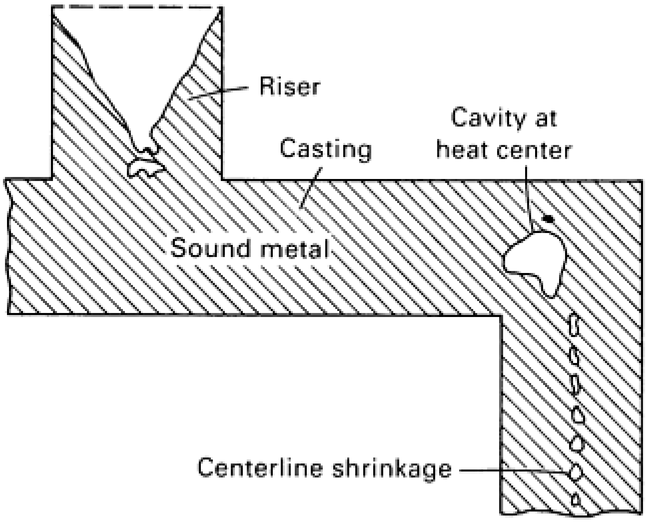

Fig. 10 Shrinkage cavities produced by skin formation in alloys

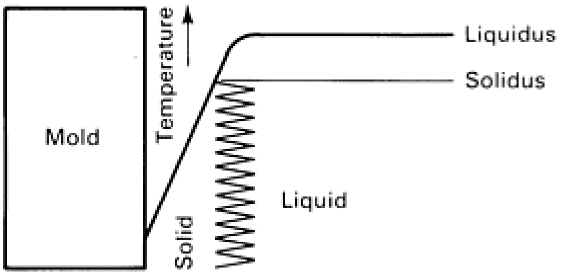
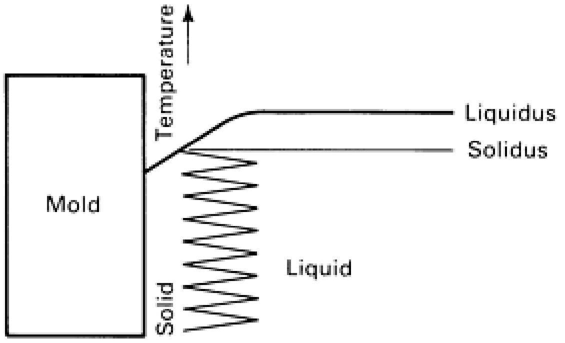
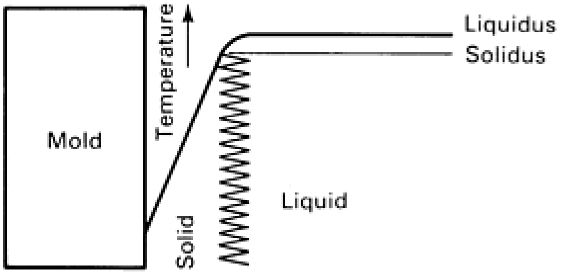


High conductivity and high heat capacity results in steep gradients and high degree of progressive solidification.

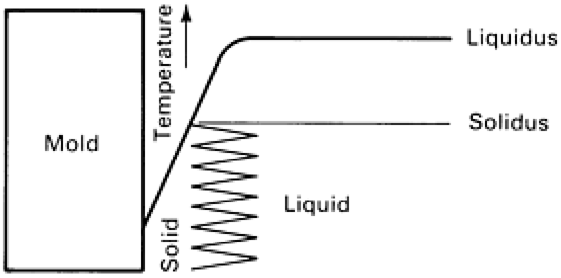


Low conductivity and low heat capacity results in mild gradients and low degree of progressive solidification.

(a)

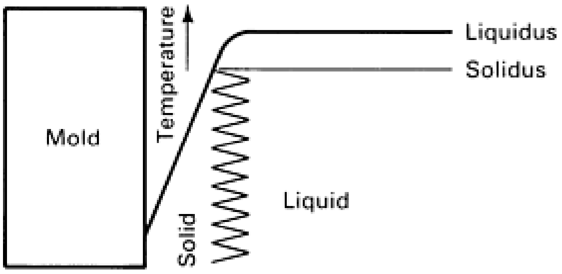


Short range results in high degree of progressive solidification.

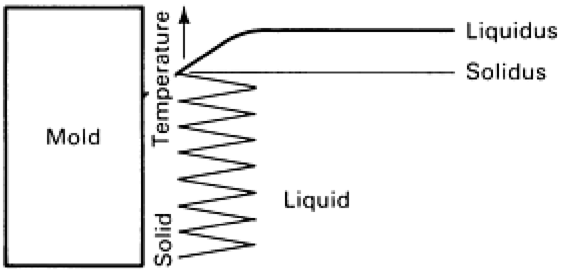


Long range results in low degree of progressive solidification.

(b)

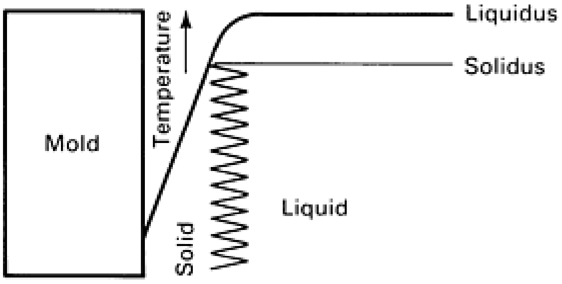


Low conductivity results in steep gradients and high degree of progressive solidification.

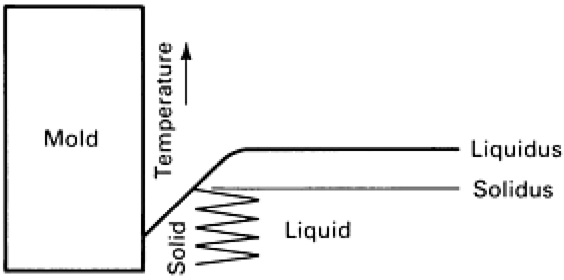


High conductivity results in mild gradients and low degree of progressive solidification.

(c)



High solidification temperature results in steep gradients and high degree of progressive solidification.



Low solidification temperature results in mild gradients and low degree of progressive solidification.

(b) Effect of liquidus-to-solidus range of solidifying metal. (c) Effect of conductivity on solidifying metal. (d) Effect of temperature level on solidification. Source: Ref 12

Castings of Uniform Wall Thickness. The specific alloy and the section configuration will combine to impose a limiting feeding distance over which a casting can solidify free of centerline shrinkage. As shown in Fig. 12, total feeding distance in a section with a cooling edge is the sum of the riser effect and edge effect discussed earlier. Figure 12 illustrates several key points:

- The contribution from the edge effect is generally greater than that from riser effect
- In the absence of cooling edges, feeding distance between risers is dramatically reduced
- If the maximum feeding distance in a section is exceeded, the edge effect will give a sound edge to its usual length, but centerline shrinkage may extend for some variable distance into the area that would ordinarily be expected to be sound because of riser effect

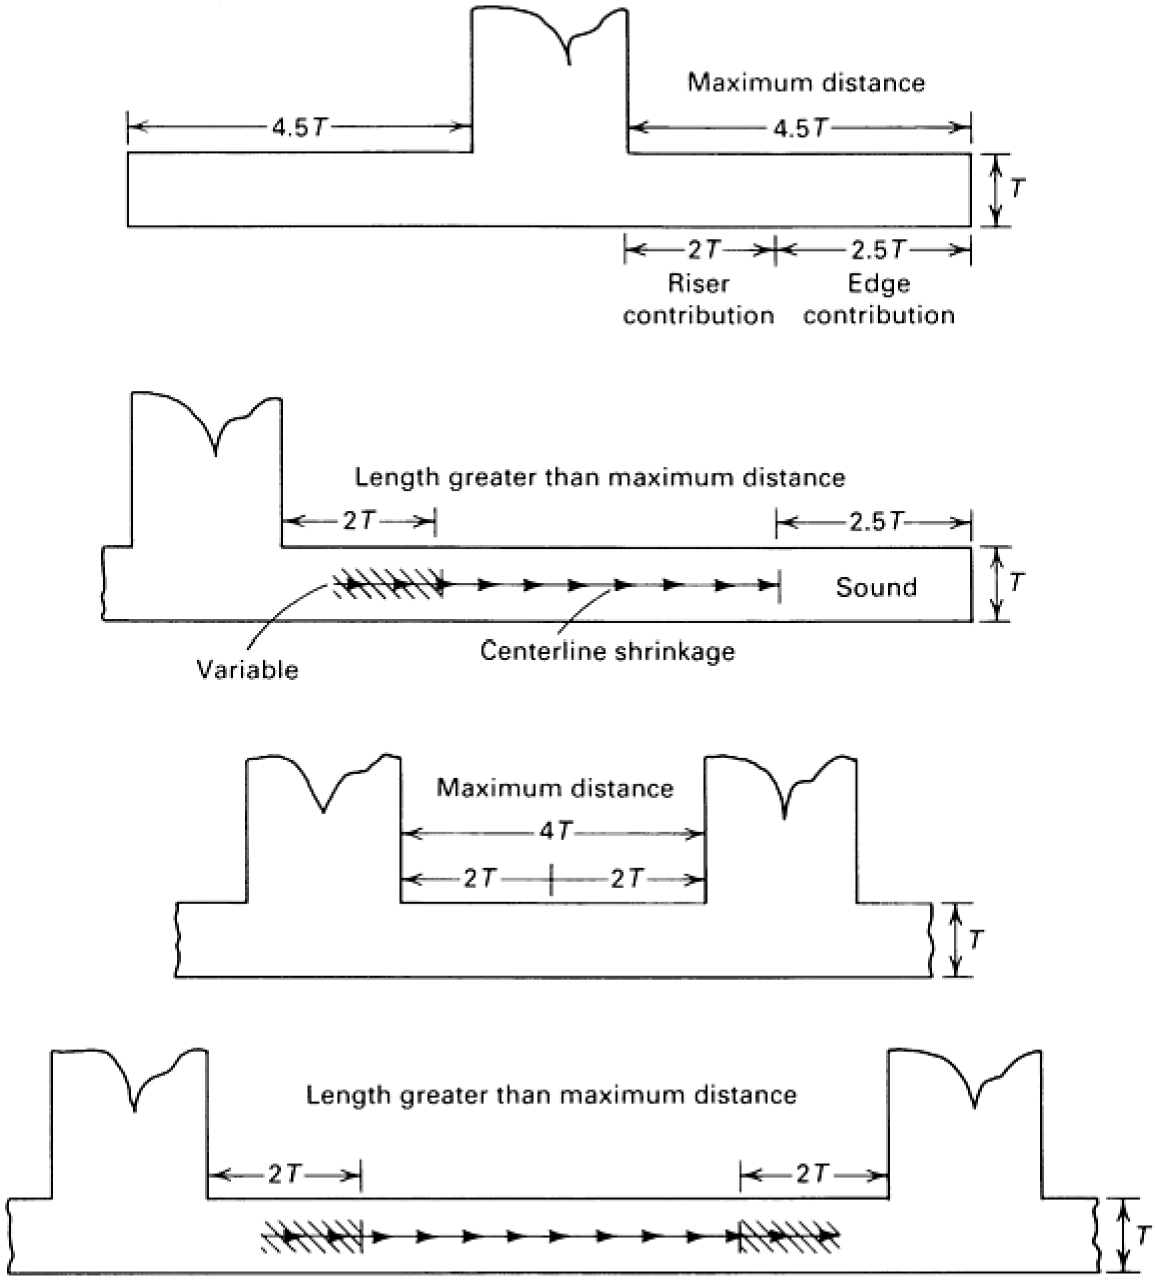

Fig. 12 Feeding distance relationships in steel plates (section width greater than 3*T,* where *T* = thickness). Source: Ref 13

Figure 13 illustrates the same relationships in steel bars. When compared with Fig. 12, Fig. 13 also highlights the fact that bar-shaped sections will have shorter feeding distances than platelike sections of the same thickness.

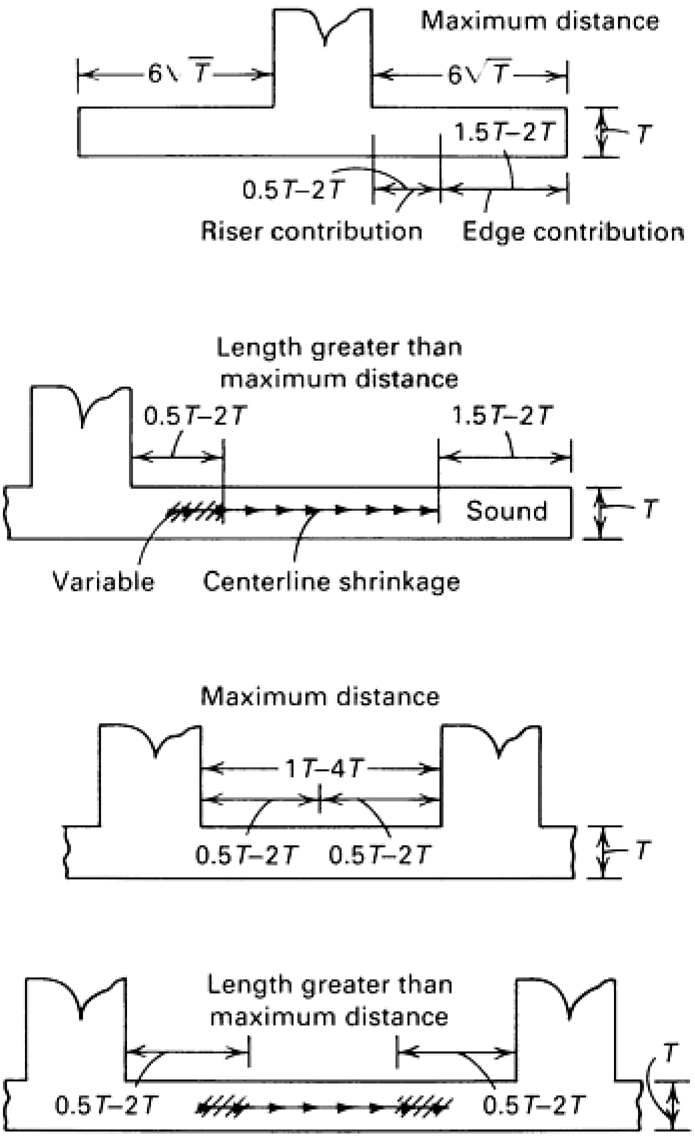

Fig. 13 Feeding distance relationships in steel bars (section width equal to thickness, *T*). Source: Ref 13

Figure 14 shows the use of chills to extend feeding distance. When applied to the edge of a casting section, the chill will withdraw heat rapidly, enhancing the development of directional solidification away from the edge. This will add to the length of the zone that will be sound due to end effect.

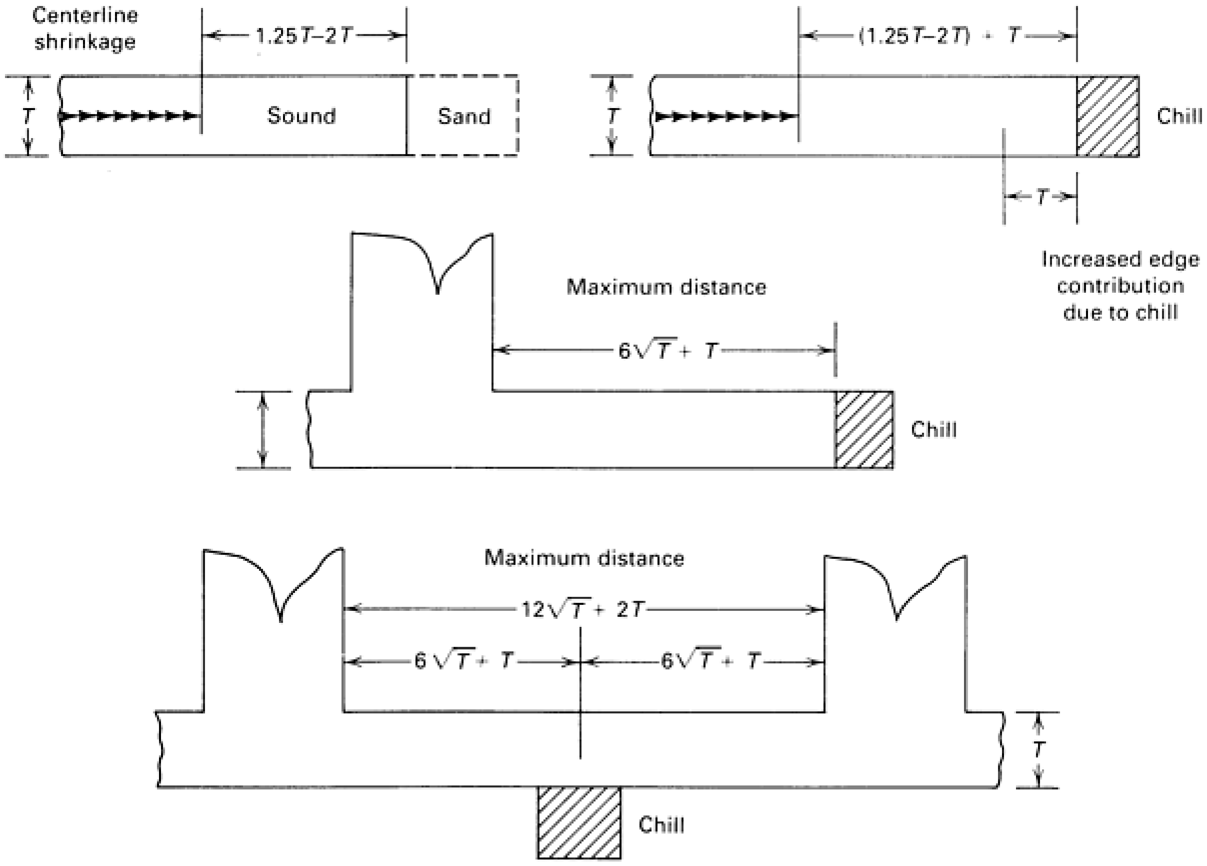

Fig. 14 Effect of chills on feeding distance relationships in steel bars. Source: Ref 13

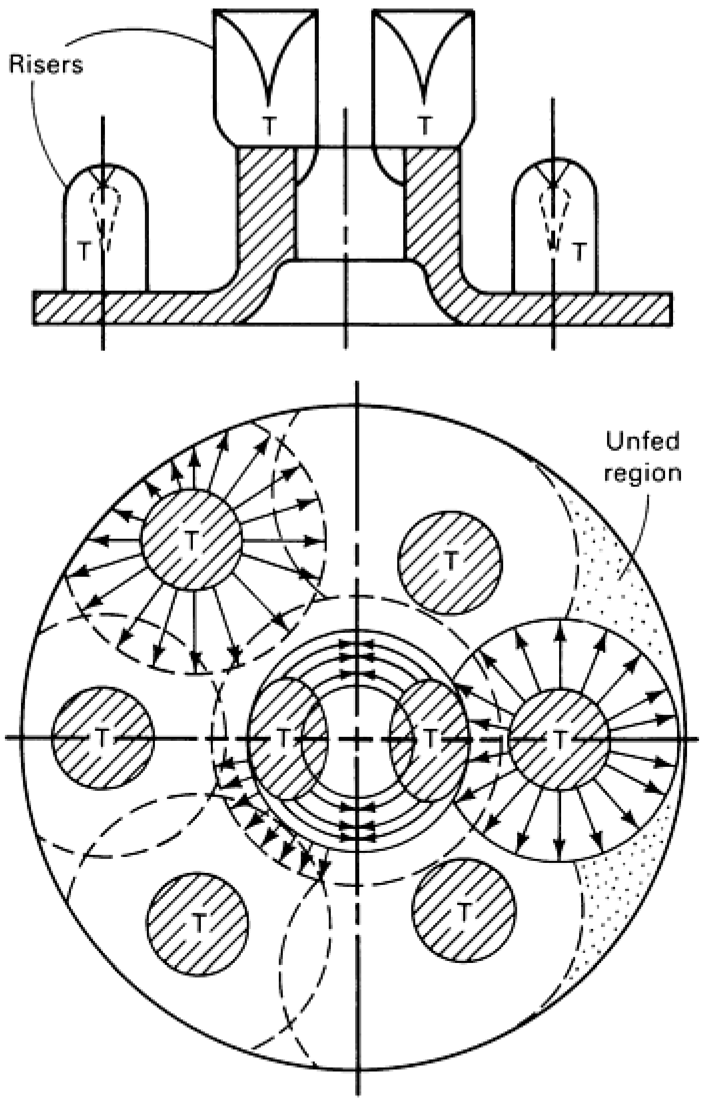
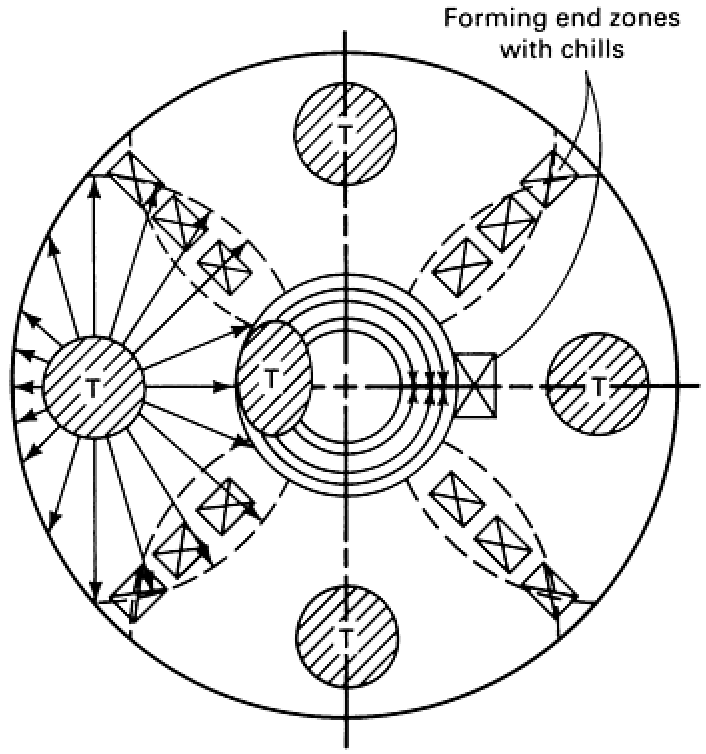
In addition, if a chill is placed between risers in a casting section where there is no natural cooling edge, it can be used to establish an artificial end effect. In this way, the distance between risers can be dramatically increased, thus reducing the number of risers needed to ensure a sound casting.

Such a use of chills is illustrated in Fig. 15. The first attempt at subdividing this casting into feedable sections with riser placement based on the absence of end effect (except at the periphery of the flange) results in the use of eight risers (two on the hub and six on the flange). The overlapping feeding zones of the riser (based on riser effect) cover the feeding requirements of most of the flange, but there still remain unfed regions (in which centerline shrinkage would occur) that would probably require the addition of at least one more riser on the flange.



(a)



(b)

Fig. 15 Use of chills to reduce the number of risers (T) on a steel flange casting. (a) Side and top view of the casting illustrating locations of the eight risers used when the workpiece is divided into feeding areas without considering end effects. (b) Top view of identical casting showing locations of five risers used when the workpiece is divided into feeding areas in which riser effect and end effect considerations are accounted for through the use of chills. Source: Ref 14

The second subdivision of the casting, using chills to establish artificial end effects, reduces the number of risers needed to only five (one on the hub and four on the flange). Such an application of chills, in addition to ensuring a sound casting, can provide economic advantages by simplifying molding and patternmaking procedures, increasing casting yield, and reducing riser removal costs.

It should be reemphasized that feeding distances in sections of uniform thickness depend on alloy characteristics and section configuration (that is, whether barlike or platelike) to determine how far directional solidification can be sustained. If the walls of the progressively solidifying intermediate sections begin to come together, disrupting and constricting the feeding channels through which feed metal can move, centerline shrinkage will occur. Once the feeding distance of a section has been exceeded, the development of centerline shrinkage will not be overcome by increasing the size of the riser.

It should also be noted that the greatest amount of data on feeding distance is available for carbon steel. A variety of nomograms and tables have been widely used for decades (Ref 13, 14, 15, 16). For most other alloys, precise data are not available, so their feeding distances are often characterized by their similarity (or lack of similarity) to carbon steel. One method of making this comparison is by the calculation of centerline feeding resistance (Ref 6). This measurement indicates that some alloys (for example, Monel) will have feeding distances very much like those of carbon steel, and the methods engineer can use feeding distance tables and nomograms established for the latter.

Some alloys, such as 18-8 steel, 12% Cr steel, 99.8% Cu, and 60-40 brass, will have greater feeding distances in similar casting sections, so a multiplier can be applied to steel-base nomograms. In other alloys, such as 88-10-2 bronze, 85-5-5-5 bronze, Al-8Mg, and Al-4.5Cu, the centerline feeding resistance is so great that feeding distance is virtually nonexistent unless severe chilling is used.

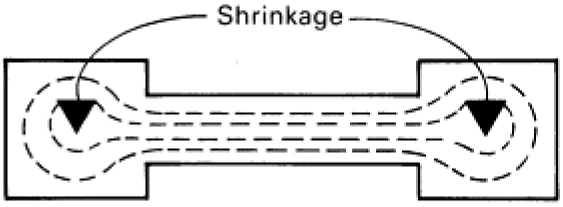
Finally, there are the graphitic cast irons. In these materials, the crystallization of the low-density graphite as flakes or nodules should promote self-feeding behavior in the solidifying casting and allow infinite feeding distances as long as the early liquid feed demand of the casting is satisfied by the gating system or by a riser.

Very large gray and ductile iron castings are often produced to meet radiographic or ultrasonic soundness standards with minimal risering. The key to such practice is a rigid molding medium to minimize mold wall movement.

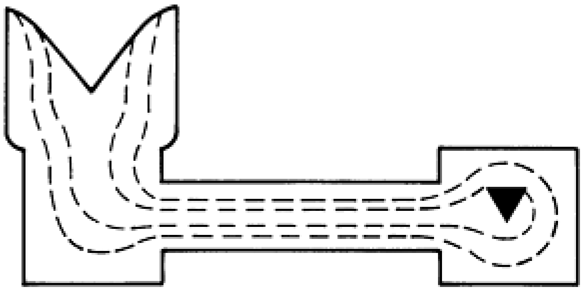
Castings With Sections of Varying Thicknesses. Most commercially produced castings consist of sections of varying thickness and configuration. Thicker, more slowly solidifying sections are separated from each other by thinner, rapidly solidifying sections. The heavier sections will then act as risers, supplying the feed metal demands of the lighter sections.

The selection of a risering method changes from a problem of riser spacing to one of riser placement so that each of the late-solidifying sections has its feed requirements met. Therefore, the methods engineer must divide a casting into sections requiring risers by determining the feeding paths by which solidification will move directionally from early- to late-solidifying sections (Ref 17). These feed paths can often be manipulated by proper application of chilling or insulating materials to minimize risering needs.

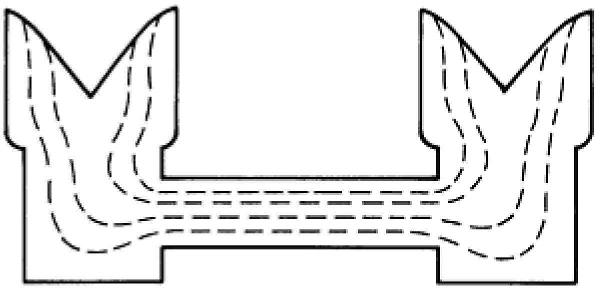
Several methods of risering isolated heavy sections are shown in Fig. 16, using a casting with two heavy sections joined by a thinner connection. In Fig. 16(a), with no risers, shrinkage develops in the two heavy sections. When an adequate riser is applied to one side (Fig. 16b), shrinkage remains unfed in the other heavy section, or hot spot, because the connecting section freezes first.



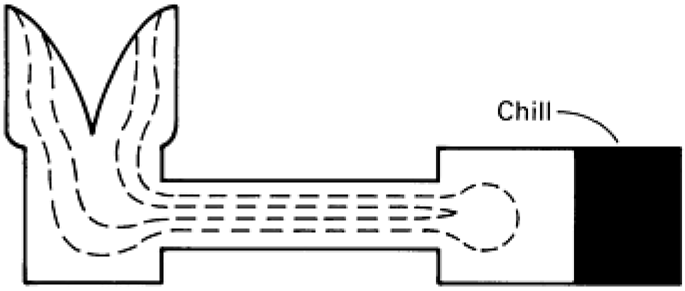
(a)



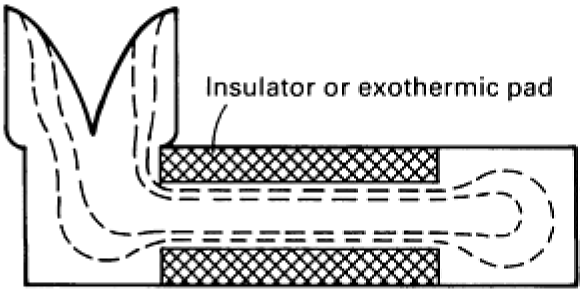
(b)



(c)



(d)



(e)

Fig. 16 Risering of isolated heavy sections joined by a thinner section to minimize shrinkage and number of risers. (a) Workpiece with no risers. (b) Riser added to one side. (c) Risers located on both ends. (d) Chill applied to one end and riser to other end. (e) Riser used on one end and insulator or exothermic pad on opposite end

A simple solution is to use risers on both sides (Fig. 16c). Two feed paths are thus established, running from the center section outward to the two risers.

Two alternative methods are shown by which a single feed path can be generated. In Fig. 16(d), a chill is applied to the isolated section to reduce its solidification time below that of the connection. In Fig. 16(e), the solidification time of the connection is extended by applying an insulating or exothermic pad to the casting walls.

Duration of Liquid Feed Metal Availability

A variety of methods have been devised to calculate the riser size needed to ensure that liquid feed metal will be available for as long as the solidifying casting requires. Several of the most commonly used methods will be discussed briefly.

Shape Factor Method. Drawing on the theoretical work of Caine (Ref 18), researchers at the U.S. Naval Research Laboratory (NRL) devised a method to determine riser size by calculating a shape factor by adding the length and width of a casting section and dividing this sum by the section thickness (Ref 19). The NRL method is illustrated in Fig. 17 with the example of a 508 mm (20 in.) square plate 50 mm (2 in.) thick. According to the earlier discussion of feeding distance, this casting (at least in steel) should be able to be made free of centerline shrinkage with a single top riser in the center of the casting. Figure 12 shows that the feeding distance of this 50 mm (2 in.) plate, with end effect, will be 229 mm (9 in.) from the edge of the riser. If the proposed central riser is at least 50 mm (2 in.) in diameter, the feeding distance requirements should be met.

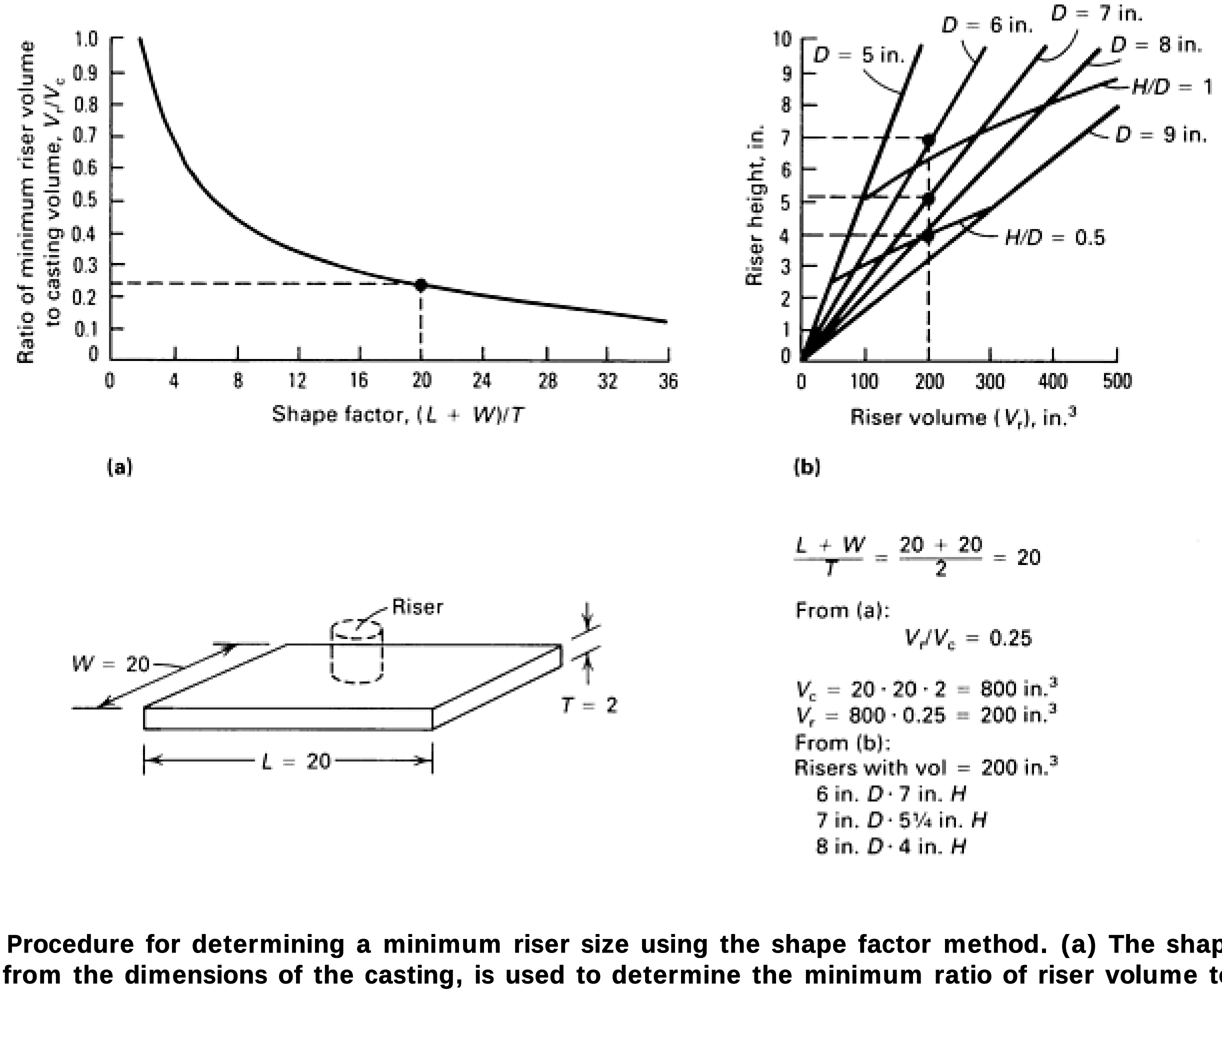


Fig. 17 Procedure for determining a minimum riser size using the shape factor method. (a) The shape factor, derived from the dimensions of the casting, is used to determine the minimum ratio of riser volume to casting

volume. (b) The same dimensions used to obtain the shape factor provide the data for casting volume, V_c, from which riser height and riser diameter can be determined. Dimensions given in inches. Source: Ref 19

Figure 17 shows the calculation of the shape factor and volume of the casting. In Fig. 17(a), one reads up from the shape factor (20) on the *x*-axis to intersect the NRL-developed curve. From this point, one reads across to the *y*-axis to find a minimum riser volume, V_r, needed to feed the casting volume, V_c. Figure 17(a) shows that, for this example, the required V_r/V_c ratio is 0.25; that is, the riser must be designed to contain a minimum of 25% as much metal as is required by the casting itself. To find the appropriate riser size, simple nomograms like the one shown in Fig. 17(b) are used; risers of various height-to-diameter ratios can be found to satisfy the calculated volume requirement. As shown in Fig. 17(b), most such nomograms assume a riser *H*/*D* ratio of around 1:1.

Geometric Method. Originally devised for determining side risers for malleable iron castings, the geometric method takes the typical conical shape of the shrinkage cavity formed in a riser as it simultaneously feeds metal into the casting and solidifies inward from its walls (Fig. 18) and simplifies it to the configuration of a cylindrical pipe (Ref 20). The size of this pipe depends on the weight of the casting section and the shrinkage percentage (both liquid and solidification shrinkages) of the casting alloy. Simple nomograms and tables are available to determine pipe sizes for a given alloy and casting weight and for a variety of ratios for the height of the pipe, H_p, divided by the diameter of the pipe, D_p.

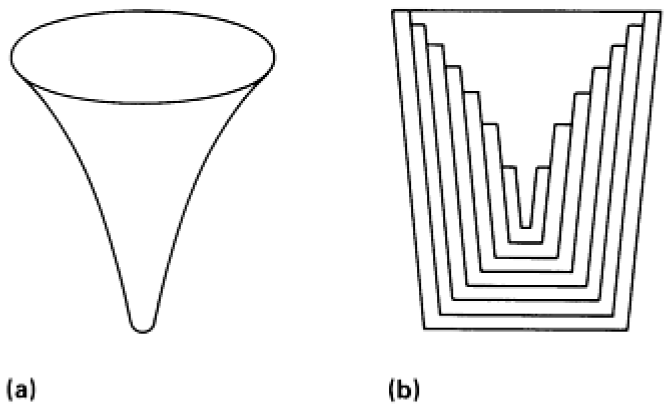

Fig. 18 Formation of the conical type of shrinkage cavity (a) due to the accumulation of solidified layers on the outer walls of the riser (b)

As shown in Fig. 19, the actual riser size is arrived at by surrounding the pipe by a riser wall, *W*, that is expected to solidify at the same rate as the walls of the casting. The calculation of the required wall thickness will thus vary with casting configuration:

- For platelike castings, *W* = casting thickness
- For cube-shaped castings, *W* = 35% of the edge length of the cube
- For round or square bars, *W* = twice the bar diameter or thickness

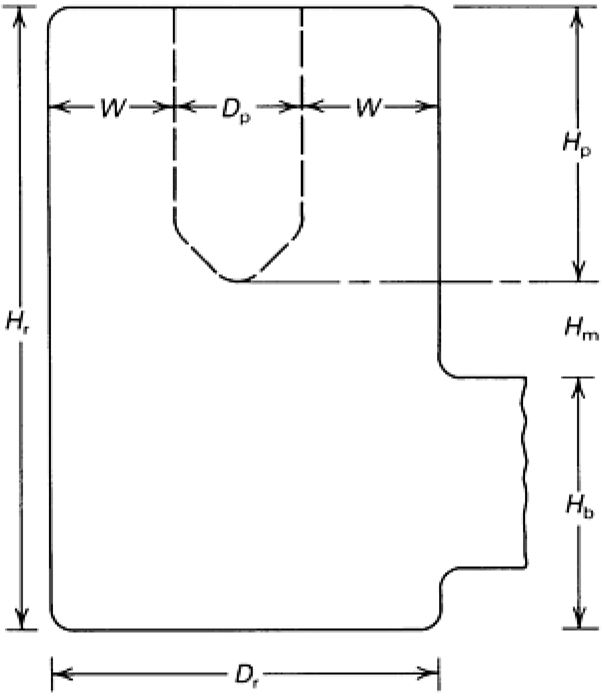

Fig. 19 Cross section of a piping side riser designed by the geometric method

The final riser diameter, D_r, thus equals $D_p + 2W$. The overall riser height, H_r, is determined by adding together:

- The pipe height, H_p
- A middle section, H_m, above the riser connection with the casting (neck) to provide a safety margin
- A base section, H_b, including the depth of the riser neck

Casting yield is usually maximized by choosing a ratio for H_p/D_p of 2.5:1, generally resulting in a riser with an H/D ratio (above the neck) of about 1:1.

Design rules for the geometric method have been further developed to design tapered risers, as shown in Fig. 20. This design not only improves casting yield but also promotes the development of definite piping behavior in the riser, ensuring that metal will feed out from riser to casting.

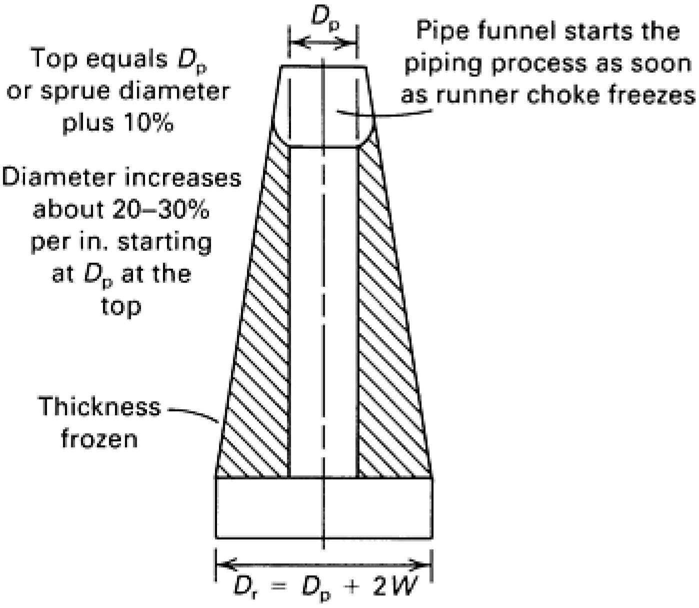

Fig. 20 Example of a design system for tapered tall risers. Source: Ref 21

The modulus method is based on the concept that the freezing time of a casting or a casting section can be approximated by using Chvorinov's rule:

$$t = k^2 \left(\frac{V_c}{A_c} \right)^2 = k^2 M_c^2 \qquad \textbf{(Eq 1)}$$

where t is the freezing time of the casting, V_c is the volume of the casting, A_c is the surface area of the casting, and k is the constant governed by metal and mold properties.

This concept was developed by Wlodawer for practical riser calculations by eliminating the need to calculate actual solidification times in favor of simply determining the relative solidification times of casting sections and risers (Ref 14). Chvorinov's rule is thus simplified to:

$$t \sim \frac{V_c}{A_c} \qquad \textbf{(Eq 2)}$$

The volume-to-area ratio of the casting is termed the casting modulus, M_c:

$$M_c = \frac{V_c}{A_c} \qquad \textbf{(Eq 3)}$$

The freezing times of risers and castings are proportional to their respective moduli, and if the modulus of the riser, M_r, is sufficiently greater than the modulus of the casting, M_c, good feeding will be obtained. In steel, if $M_r = 1.2 \cdot M_c$, feeding will be satisfactory.

For other skin-forming alloys, including many aluminum- and copper-base alloys, the M_r/M_c ratio of 1.2:1 is appropriate. With gray and ductile irons, depending on the carbon equivalent, the required M_r/M_c ratio can range from 0.8:1 to 1.2:1 because the riser may not be required to supply feed metal throughout the entire solidification time of the casting.

Wlodawer simplified the modulus method by showing that many casting sections can be reduced to simple geometric shapes for which M_c can be readily found without elaborate calculations of actual surface areas and volumes (for example, for a plate section, M_c = half the plate thickness). Wlodawer further simplified the method by providing simple conversion charts, such as that shown in Fig. 21. This chart allows easy calculation of risers of various shapes if the necessary modulus is known.

One note of caution must be kept in mind when using the modulus approach to riser design. This method can recommend risers that are too small on very rangy, thin-section castings. In such cases, the thermal requirements of the casting would indicate very small risers, but the demand for feed metal volume can still be substantial. For such volume-controlled castings, the riser size arrived at through modulus calculations must be verified against riser volume charts such as that given in Table 2.

Computerized Methods. Over the past decade, a variety of computer programs have become available to assist in riser design. These can be grouped into two general categories.

The first category includes programs that generate recommendations for riser sizes (Ref 22, 23, 24, 25, 26). These programs are generally run on microcomputers, and the basis of the calculation is often one or more of the manual calculation methods discussed above. These programs usually contain subroutines to assist in calculating casting weights, section modulus, and feeding distance. Riser calculations generally require simple inputs of such factors as section weight and shape, shrinkage percentage, section modulus, mold medium, ingate location, and desired riser shape for the program to provide a variety of riser alternatives.

The second category comprises programs that simulate solidification to predict riser performance (Ref 27, 28, 29, 30). These generally use heat transfer calculations to simulate the progress of solidification in a casting/riser combination. Some are limited to a two-dimensional analysis, while others provide three-dimensional analysis. The latter can require considerable computing power. These programs seldom provide recommendations for riser sizes, so riser sizes must be determined by other methods. As shown in Fig. 22, these programs are often used to analyze the solidification of a casting to predict the location of the last points to solidify, so that risers (or chills, and so on) can be placed to eliminate the expected shrinkage in these locations.

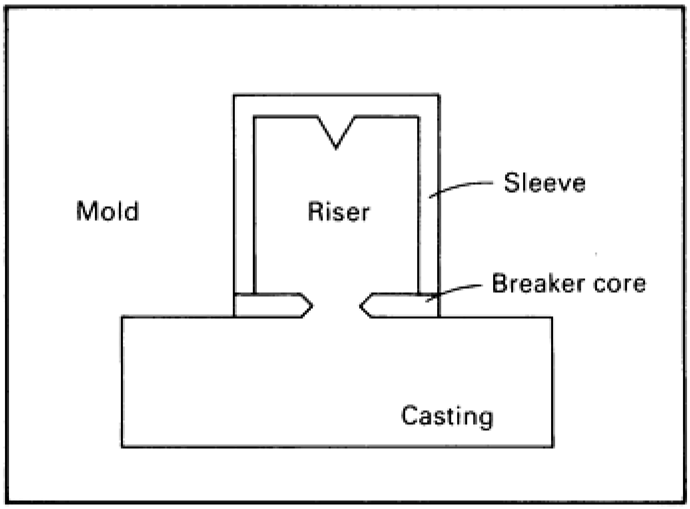
Riser Design

Lee A. Plutshack and Anthony L. Suschil, Foseco, Inc.

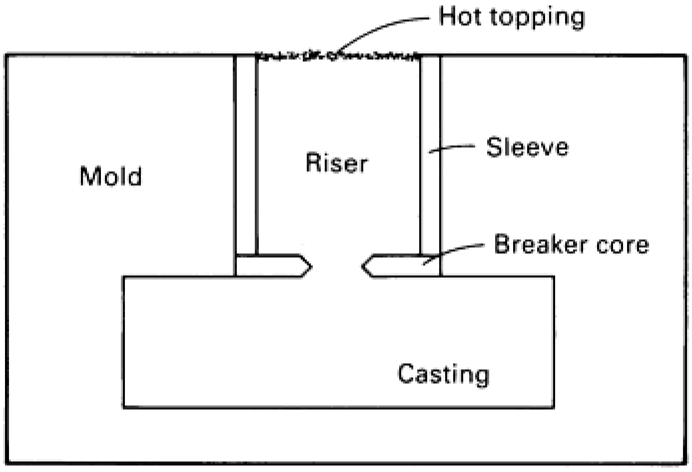
Feeding Aids Used in Riser Design

Feeding aids are widely used by the foundry industry to increase casting soundness and to reduce the cost of casting manufacture. Feeding aids reduce the rate of heat transfer from the riser to the molding medium and to the atmosphere. In riser design, three types of feeding aids are commonly used:

- Riser sleeves or panels are used to insulate the riser sidewall or riser top from the mold
- Topping compounds are used to insulate the top of open risers from the atmosphere
- Breaker cores are used between the riser and the casting to facilitate the removal of the riser from the casting; the use of these materials is illustrated in Fig. 23



(a)



(b)

Fig. 23 Schematic showing the application of feeding aids for a closed-top riser (a) and for an open-top riser (b)

Metal is transferred from the riser by three mechanisms: gravity, atmospheric pressure (or pressure applied by other means, as in die-casting), and capillary action. For most casting processes, atmospheric pressure is the most important.

Feeding Aid Advantages

Feeding aids delay solidification and the formation of a skin of solid metal in the riser. This promotes atmospheric puncture of the riser, assisting in the transfer of metal from the riser to the casting. Alloys, specifically those that have a wide freezing range, benefit the most from feeding aids.

Feeding aids increase the temperature gradient between riser and casting. As a result, directional solidification from casting to riser is promoted; that is, a stronger feeding path is established.

Feeding aids, by reducing the rate of heat transfer between the riser and the mold, increase the effective modulus of a riser when compared with the geometric modulus of that riser. For a given riser modulus, a riser incorporating feeding aids will be smaller than an uninsulated riser. Less liquid metal is needed to produce a given casting, and the cost of producing that casting is reduced (Ref 31). Reducing riser size may allow a given casting to be produced in a smaller mold or may allow the production of more castings in a given mold, both resulting in lower cost.

The value of feeding aids in delaying riser solidification is indicated in Table 3, in which the solidification time of a 102 mm (4 in.) diam, 102 mm (4 in.) high riser is calculated in three alloys with various combinations of insulation on the riser sidewall and top. Also given is the percentage of total heat lost from the solidifying riser through radiation from the riser top. This highlights the fact that hot topping to reduce radiative heat loss is significantly more important in steel casting than in aluminum casting.

Table 3 Effect of risering aids on the solidification times of various alloys

Alloy cast	**Radiation loss through top, %**	Solidification time, min			
		Sand riser/ open end	**Sleeved riser/ open top**	**Sand riser/ insulated top**	Sleeved riser/ insulated top
					Steel	42	5	7.5	13.4	**43.0**
Copper	26	8.2	15.1	14.0	**45.0**
Aluminum	**8**	**12.3**	**31.1**	**14.3**	**45.6**

Thermal Properties of Materials. Riser sleeves and topping compounds are classified by thermal properties as exothermic, insulating, and exothermic-insulating. The generalized thermal properties of each of these classifications are shown in Fig. 24.

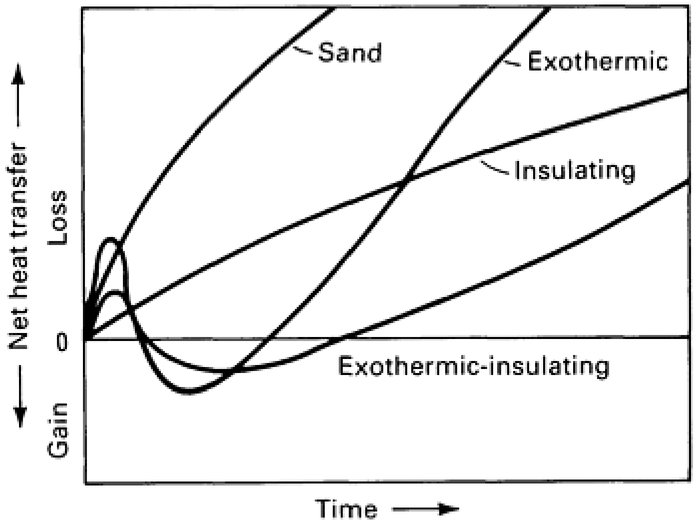

Fig. 24 Heat loss from a riser as a function of time for the major classifications of feeding aids, with sand included as the basis for comparison

Exothermic feeding aids are based on the oxidation of aluminum to produce heat. These feeding aids tend to be of relatively high density, and the matrix has thermal properties similar to those of a sand mold after the exothermic reaction has subsided. They display an initial chilling effect on the molten metal and rely on a strong exothermic reaction to remelt any metal that may have solidified. Exothermic materials tend to be used on small and intermediate-size risers and are not generally recommended for large risers having a long solidification time. Exothermic materials also have the greatest likelihood of metal contamination.

Metal-producing topping compounds are a special class of exothermic material, and they have a composition based on the thermite reaction. These materials are sometimes used on large risers. Contamination must be carefully monitored; the metal produced by the thermite reaction should not be allowed to feed into the casting.

Insulating feeding aids are formulated from refractory materials to have a low density. They exhibit a very low initial chill of the molten metal and rely on their low density to minimize heat loss from the riser. Insulating feeding aids tend to be used on small to intermediate-size risers and alloys having lower pouring temperatures. They are not generally recommended for large risers, because these low-density materials thermally degrade when exposed to high pressure and high temperature for extended periods of time. Insulating feeding aids are least likely to cause problems with metal contamination.

Exothermic-insulating feeding aids consist of exothermic materials surrounded by a highly refractory, insulating matrix. These materials are the most versatile, having a low initial chill, extended exothermic reaction, and good insulation after the exothermic reaction has subsided. Exothermic-insulating materials are used for the entire range of riser sizes. Their propensity for metal contamination lies between insulating and exothermic materials.

Metal Contamination. Feeding aids are formulated to minimize the possibility of metal contamination. Depending on the formulation of the feeding aid and its method of application, certain elements may be absorbed by the metal in the riser. Carbon, silicon, aluminum, oxygen, nitrogen, and sulfur may be absorbed. The widespread use of feeding aids in riser design is an indication that contamination is not normally a problem, but the possibility should not be overlooked.

Factors in Riser Size

The thermal properties of feeding aids can be readily incorporated into the modulus method of riser calculation discussed above (Ref 33). Cylindrical risers are the most common because this shape has a high modulus for a given volume of metal and because this shape is easy to mold. The modulus of a cylindrical riser, M_r, is given by:

$$M_r = \frac{V_r}{A_r} = \frac{p R^2 H}{2p RH + p R^2} = \frac{RH}{2H + R} = \frac{DH}{4H + D} \quad \textbf{(Eq 4)}$$

where *R* is the riser radius, *D* is the riser diameter, and *H* is the riser height.

Riser insulation in the form of a sleeve and hot topping may be regarded as effectively decreasing the surface area of the riser. The effect of the sidewall (sleeve) insulation may be represented by a factor *x* and that of a hot topping by a factor *y*, both relative to sand (where *x* = 1 for sand). The factors *x* and *y* have been termed apparent surface alteration factors (ASAF). The effective modulus M_r of a cylindrical riser incorporating feeding aids on both the sidewall and top is given by:

$$M_r = \frac{DH}{4Hx + Dy} \quad \textbf{(Eq 5)}$$

The ASAF values of insulating and exothermic feeding aid materials vary and generally range from 0.50 to 0.90. The smaller the ASAF value, the more efficient the insulation. For example, if $x = 0.65$ and $y = 0.7$, then for a cylindrical riser with a height-to-diameter ratio of 1:1 (where $H = D$):

$$M_r = \frac{D^2}{4D(0.65) + D(0.7)} = \frac{D^2}{3.3D} = 0.303D \quad \textbf{(Eq 6)}$$

This should be compared with the modulus of a similar 1:1 sand-lined riser, which is 0.2*D*. The ASAF values for feeding aids are generally available from manufacturers of these products. Although the size of a riser incorporating feeding aids can be readily calculated using the approach described above, computer programs are now widely available to speed the process of designing risers--both conventional sand-lined risers and risers incorporating feeding aids.

Riser Necks and Breaker Cores

To promote directional solidification from the casting into the riser, the modulus of the riser neck, M_n, should be intermediate to the moduli of the casting and riser, M_c and M_r (Ref 14). The general rule given above for the required riser modulus was $M_r = 1.2\ M_c$.

The general rule for riser neck design--at least for skin-forming alloys--is $M_n = 1.1\ M_c$. Once again, the graphitic cast irons are an exception because the graphite expansion phase makes it unnecessary for the riser neck to stay open for feed metal transfer throughout the entire solidification time of the casting. Depending on the chemistry of the casting, riser necks for gray and ductile irons can have moduli in the range of 0.67 to 1.1 times the casting modulus (Ref 5). General design rules for riser necks for iron castings are widely available (Fig. 25).

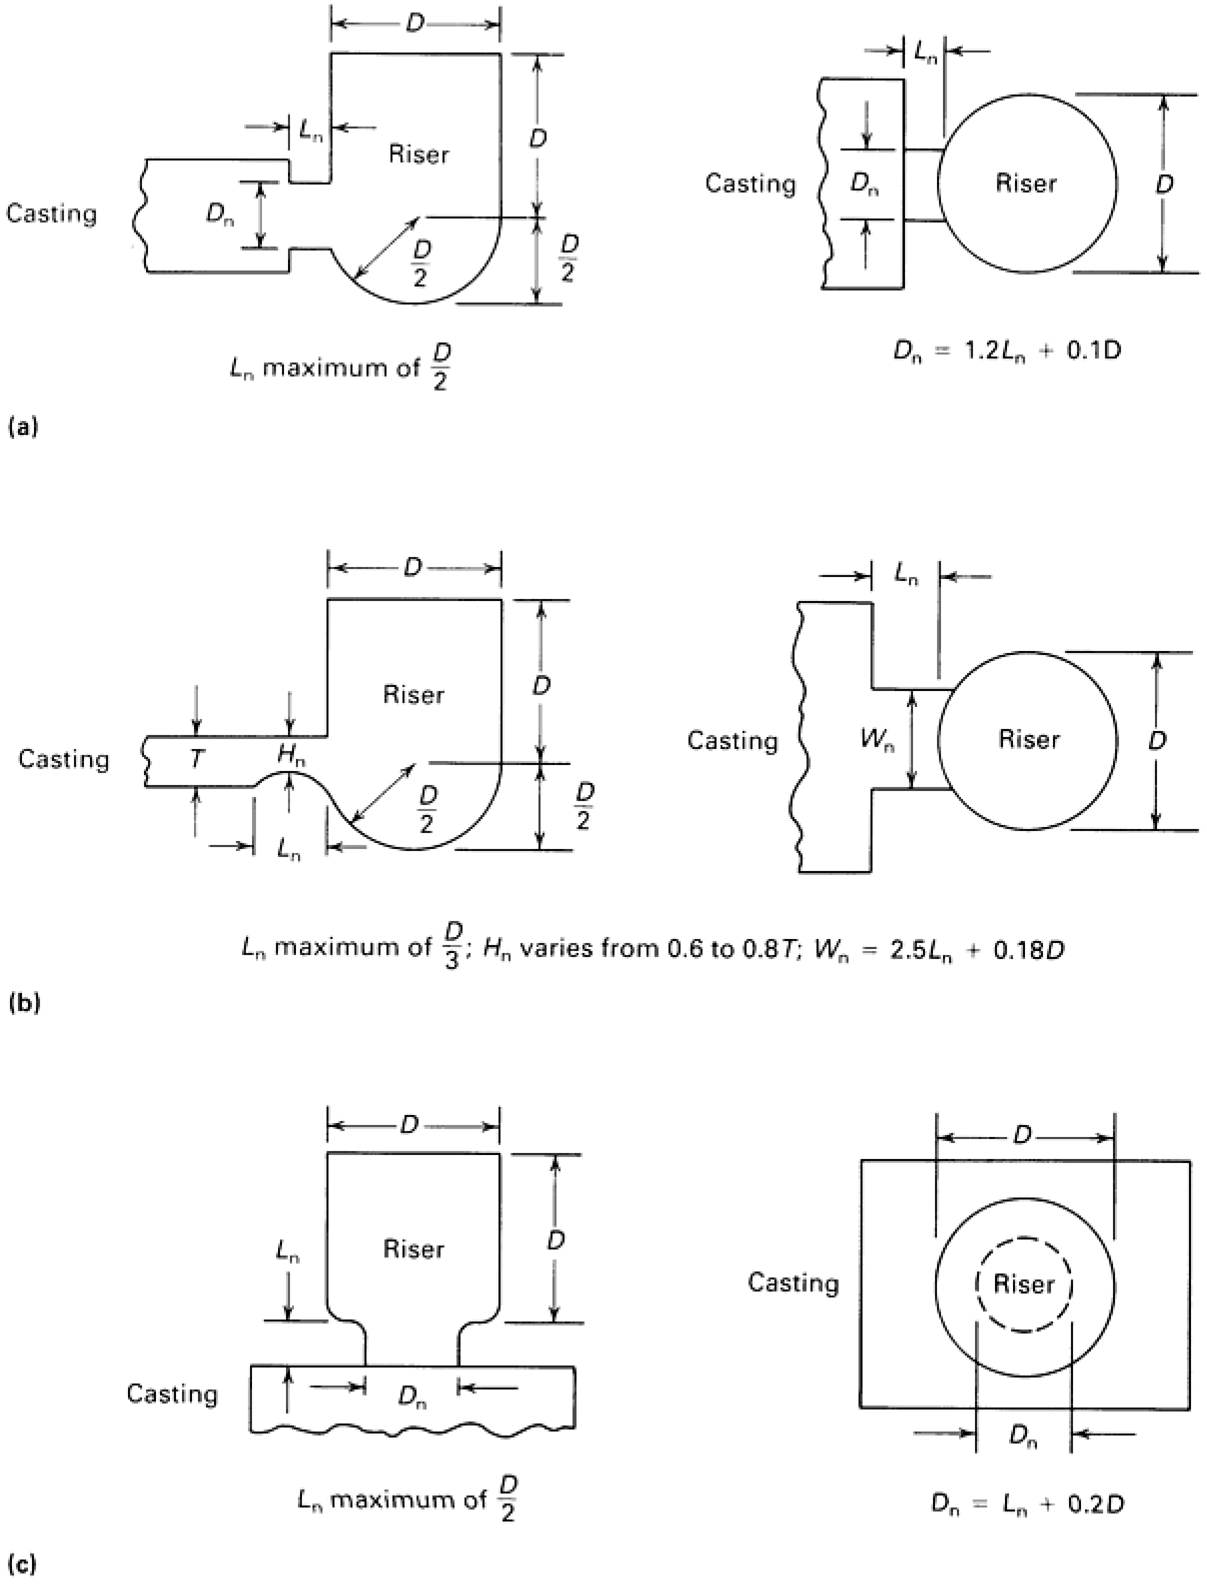

Fig. 25 General design rules for riser necks used in iron casting applications (side view and top view, respectively). (a) General type of side riser. (b) Side riser for plate casting. (c) Top round riser. Source: Ref 34

For the economical removal of risers, breaker cores can be used between the riser and the casting, as shown in Fig. 23. Breaker cores are typically made of bonded sand or fused ceramic materials. For risers lined with sleeves, the breaker core thickness is generally 10% of the riser diameter, and the breaker core opening is generally in the range of 40 to 50% of the riser diameter. By keeping the mass of the breaker core small, the breaker core quickly reaches the temperature of the surrounding metal and does not appreciably affect the solidification of the riser.

Optimum Riser and Neck Configurations

Applying the required riser to a specific casting may generate problems. For example, the necessary riser or neck size may not easily fit the casting configuration. An important problem may be created simply by attaching the riser, because the new riser/ casting configuration will have its own solidification pattern, sometimes with unintended results.

This is illustrated in Fig. 26, in which the attachment of a side riser at the center of the rim of a gear blank casting generates a hot spot inside the casting, where shrinkage would be expected to occur after the neck freezes. As seen in Fig. 26, this problem can be avoided either by moving the attachment of the side riser or by using a top riser on the rim. The top riser has the added benefit of improving casting yield.

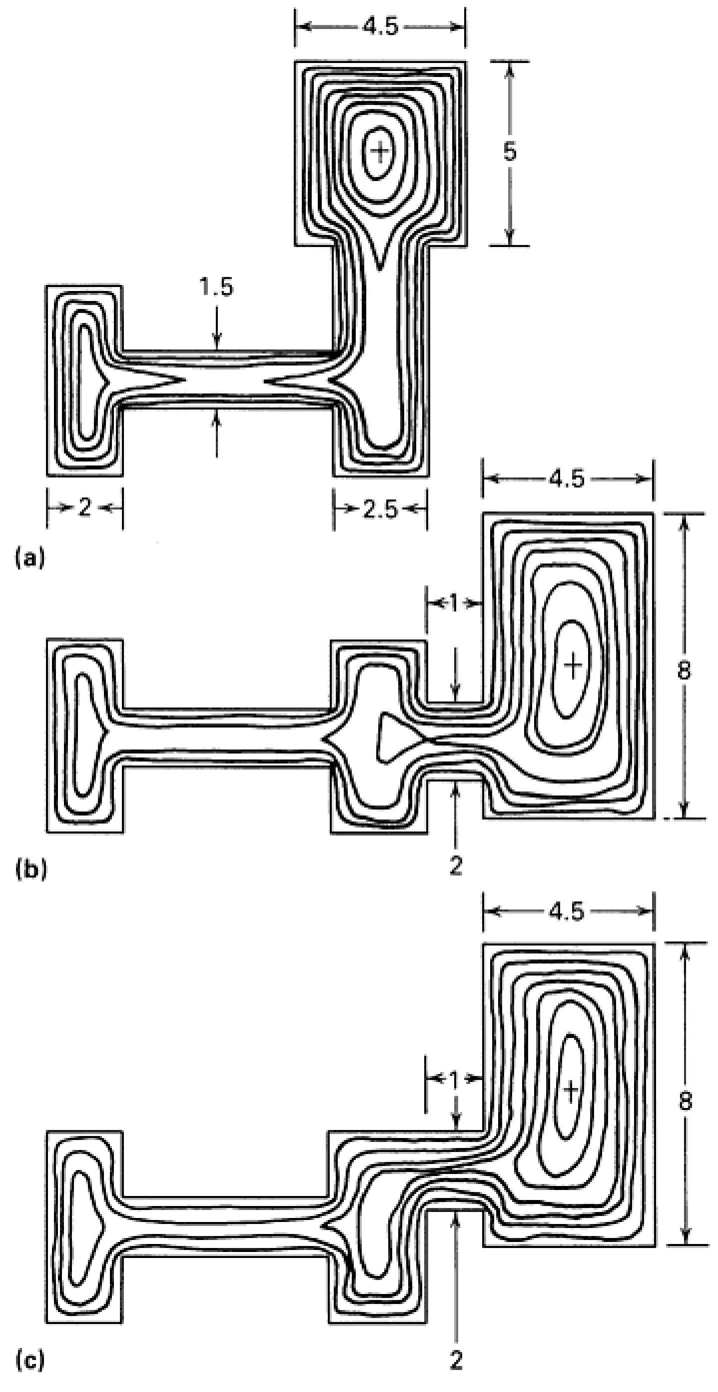

Fig. 26 Effect of risers and riser contacts on solidification wave fronts in the gear blank casting shown in Fig. 22. In (a) the side riser attached directly at rim center generates a hot spot inside the casting itself. The addition of a thin section between the workpiece and the riser in both (b) and (c) overcomes the problem of hot

spots inside the casting. Dimensions given in inches

Gating Design

Anthony L. Suschil and Lee A. Plutshack, Foseco, Inc.

Introduction

A GATING SYSTEM is the conduit network through which liquid metal enters a mold and flows to fill the mold cavity, where the metal can then solidify to form the desired casting shape. The basic components of a simple gating system for a horizontally parted mold are shown in Fig. 1. A pouring cup or a pouring basin provides an opening for the introduction of metal from a pouring device. A sprue carries the liquid metal down to join one or more runners, which distribute the metal throughout the mold until it can enter the casting cavity through ingates.

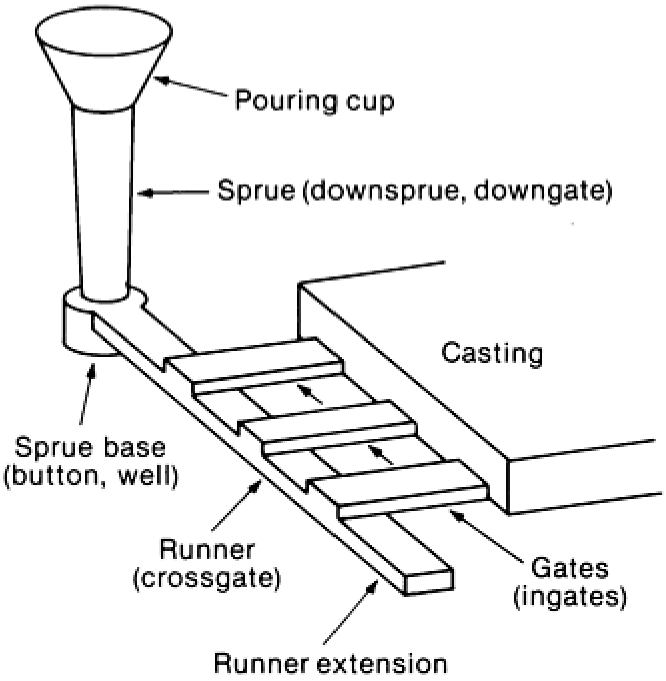

Fig. 1 Basic components of a simple gating system for a horizontally parted mold.

Design Variables

Methods used to promote any of the desirable design considerations discussed below often conflict with another desired effect. For example, attempts to fill a mold rapidly can result in metal velocities that promote mold erosion. As a result, any gating system will generally be a compromise among conflicting design considerations, with the relative importance of the consideration being determined by the specific casting and its molding and pouring conditions.

Rapid mold filling can be important for several reasons. Especially with thin-section castings, heat loss from the liquid metal during mold filling may result in premature freezing, producing surface defects (for example, cold laps) or incompletely filled sections (misruns). Superheating of the molten metal will increase fluidity and retard freezing, but excessive superheat can increase problems of gas pickup by the molten metal and exaggerate the thermal degradation of the mold medium. In addition, the mold filling time should be kept shorter than the mold producing time of the molding equipment to maximize productivity.

Minimizing Turbulence. Turbulent filling and flow in the gating system and mold cavity can increase mechanical and thermal attack on the mold. More important, turbulence may produce casting defects by promoting the entrainment of gases into the flowing metal. These gases may by themselves become defects (for example bubbles), or they may produce dross or inclusions by reacting with the liquid metal.

Turbulent flow increases the surface area of the liquid metal exposed to air within the gating system. The susceptibility of different casting alloys to oxidation varies considerably. For those alloys that are highly sensitive to oxidation, such as aluminum alloys; magnesium alloys; and silicon, aluminum, and manganese bronzes, turbulence can generate extensive oxide films that will be churned into the flowing metal, often causing unacceptable defects.

Avoiding Mold and Core Erosion. High flow velocity or improperly directed flow against a mold or core surface may produce defective castings by eroding the mold surface (thus enlarging the mold cavity) and by entraining the dislodged particles of the mold to produce inclusions in the casting.

Removing Slag, Dross, and Inclusions. This factor includes materials that may be introduced from outside the mold (for example, furnace slags and ladle refractories) and those that may be generated inside the system. Methods can be incorporated into the gating system to trap such particles (for example, filters) or to allow them time to float out of the metal stream before entering the mold cavity.

Promoting Favorable Thermal Gradients. Because the last metal to enter the mold cavity will generally be the hottest, it is usually desirable to introduce metal in those parts of the casting that would already be expected to be the last to solidify. One obvious method of accomplishing this is to direct the metal flow from the gating system into a riser, from which it then enters the mold cavity. Because the riser is generally designed to be the last part of the riser/casting system to solidify, such a gating arrangement will help promote directional solidification from the casting to the riser.

If the gating system cannot be designed to promote some desirable thermal gradient, it should at least be designed so that it will not produce unfavorable gradients. This will often involve introducing metal into the mold cavity through multiple ingates so that no one location becomes a hot spot.

Maximizing Yield. A variety of unrecoverable costs must go into the metal that will fill the gating system and risers. These components must then be removed from the casting and generally returned for remelt, where their value is downgraded to that of scrap. Production costs can be significantly reduced by minimizing the amount of metal contained

in the gating system. The production capacity of a foundry can also be enhanced by increasing the percentage of salable castings that can be produced from a given volume of melted metal.

Economical Gating Removal. Costs associated with the cleaning and finishing of castings can be reduced if the number and size of ingate connections with the casting can be minimized. Again, it may be advantageous to introduce metal into the mold cavity through a riser, because the riser neck can also serve as an ingate.

Avoiding casting distortion is especially important with rangy, thin-wall castings, in which uneven distribution of heat as the mold cavity is filled may produce undesirable solidification patterns that cause the casting to warp. In addition, the contraction of the gating system as it solidifies can pull on sections of the solidifying casting, resulting in hot tearing or distortion.

Compatibility With Existing Molding/Pouring Methods. Modern high-production molding machines and automated pouring systems often severely limit the flexibility allowed in locating and shaping the pouring cup and sprue for introducing metal into the mold. They also generally place definite limits on the rate at which metal can be poured.

Controlled Flow Conditions. A steady flow rate of metal in the gating system should be established as soon as possible during mold filling, and the conditions of flow should be predictably consistent from one mold to the next.

Principles of Fluid Flow

Proper design of an optimized gating system will be made easier by the application of several fundamental principles of fluid flow. Chief among these principles are Bernoulli's theorem, the law of continuity, and the effect of momentum.

Bernoulli's Theorem

This basic law of hydraulics relates the pressure, velocity, and elevation along a line of flow in a way that can be applied to gating systems. The theorem states that, at any point in a full system, the sum of the potential energy, kinetic energy, pressure energy, and frictional energy of a flowing liquid is equal to a constant. The theorem can be expressed as:

$$wZ + wPv + \frac{wV^2}{2g} + wF = K \qquad \textbf{(Eq 1)}$$

where *w* is the total weight of the flowing liquid (in pounds), *Z* is the height of the liquid (in inches), *P* is the static pressure in liquid (in pounds per square inch), v is the specific volume of liquid (in cubic inches per pound), *g* is the acceleration due to gravity (386.4 in./s^2), *V* is the velocity (in inches per second), *F* is the friction loss per unit weight, and *K* is a constant.

If Eq 1 is divided by *w,* all the terms reduce to dimensions of length and will represent:

- Potential head *Z*
- Pressure head, *P*v
- Velocity head $V^2/2g$
- Frictional loss of head *F*

Equation 1 allows prediction of the effect of the several variables at different points in the gating system, although several conditions inherent in foundry gating systems complicate and modify its strict application. For example:

- Equation 1 is for full systems, and at least at the start of pouring, a gating system is empty. This indicates that a gating system should be designed to establish as quickly as possible the flow conditions of a full system
- Equation 1 assumes an impermeable wall around the flowing metal. In sand foundry practice, the permeability of the mold medium can introduce problems, for example, air aspiration in the flowing liquid

- Additional energy losses due to turbulence or to friction (for example, because of changes in the direction of flow) must be accounted for
- Heat loss from the liquid metal is not considered, which will set a limit on the time over which flow can be maintained. Also, solidifying metal on the walls of the gating system components will alter their design while flow continues

Bernoulli's theorem (Eq 1) is illustrated schematically in Fig. 2, and several practical interpretations can be derived. The potential energy is obviously at a maximum at the highest point in the system, that is, the top of the pouring basin. As metal flows from the basin down the sprue, potential energy changes to kinetic energy as the stream increases in velocity because of gravity. As the sprue fills, a pressure head is developed.

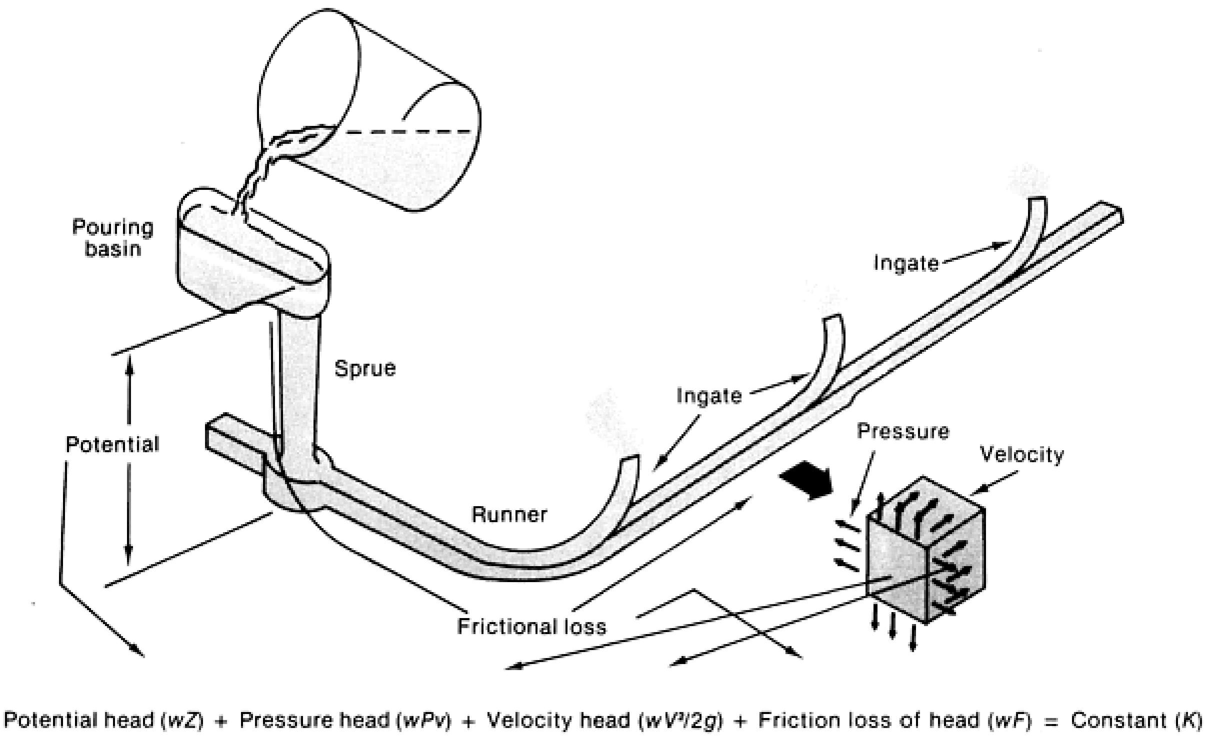

Fig. 2 Schematic illustrating the application of Bernoulli's theorem to a gating system. Source: Ref 1.

Once flow in a filled system is established, the potential and frictional heads become virtually constant, so conditions within the gating system are determined by the interplay of the remaining factors. The velocity is high where the pressure is low, and vice versa.

The Law of Continuity

This law states that, for a system with impermeable walls and filled with an incompressible fluid, the rate of flow will be the same at all points in the system. This can be expressed as:

$$Q = A_1 v_1 = A_2 v_2 \quad \textbf{(Eq 2)}$$

where Q is the rate of flow (in cubic inches per second), A is the cross-sectional area of the stream (in square inches), V is the velocity of the stream (in inches per second), and the subscripts 1 and 2 designate two different locations in the system. Again, the permeability of sand molds can complicate the strict application of this law, introducing potential problems into the casting process.

One practical implication of the law of continuity is illustrated in Fig. 3, which illustrates the flow of metal from a pouring basin. As indicated in Eq 1, potential energy is high but velocity is low as the stream leaves the basin. Velocity increases as the stream falls, so the cross-sectional area of the stream must decrease proportionately to maintain the balance of the flow rate. The result is the tapered shape typical of a free-falling stream shown in Fig. 3(a).

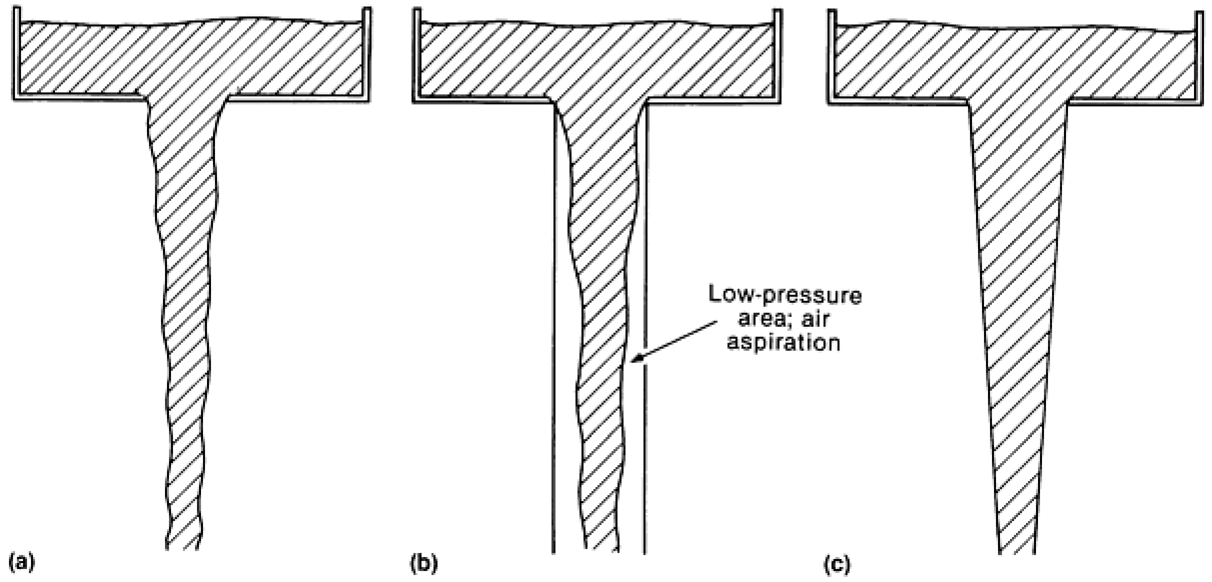

Fig. 3 Schematic showing the advantages of a tapered sprue over a straight-sided sprue. (a) Natural flow of a free-falling liquid. (b) Air aspiration induced by liquid flow in a straight-sided sprue. (c) Liquid flow in a tapered sprue.

If the same flow is directed down a straight-sided sprue (Fig. 3b), the falling stream will create a low-pressure area as it pulls away from the sprue walls and will probably aspirate air. In addition, the flow will tend to be uneven and turbulent, especially when the stream reaches the base of the sprue.

The tapered sprue shown in Fig. 3(c) is designed to conform to the natural form of the flowing stream and therefore reduces turbulence and the possibility of air aspiration. It also tends to fill quickly, establishing the pressure head characteristic of the full-flow conditions required by Eq 1.

Many types of high-production molding units do not readily accommodate tapered sprues, so the gating system designer will try to approximate the effect of a tapered sprue by placing a restriction, or choke, at or near the base of the sprue to force the falling stream to back up into the sprue (Fig. 4).

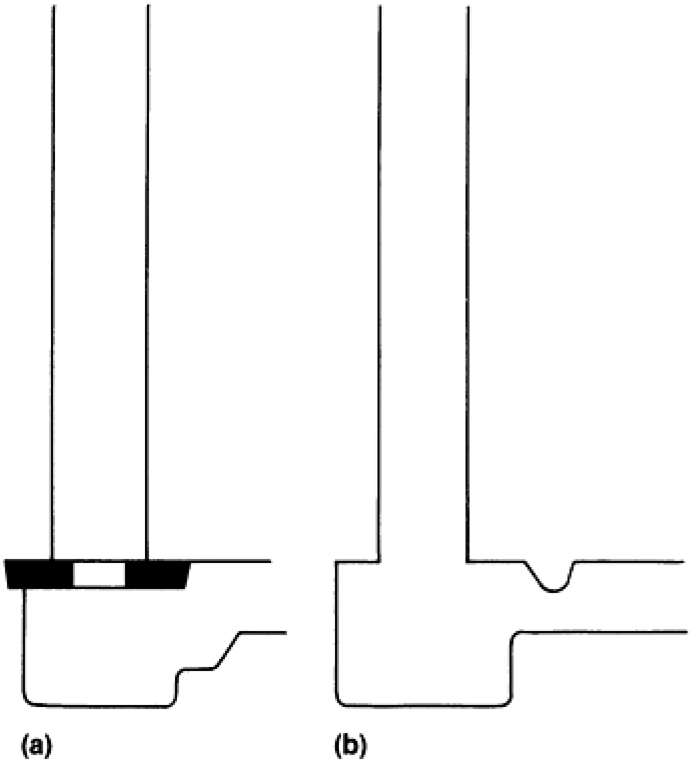

Fig. 4 Choke mechanisms incorporated into straight-sided sprues to approximate liquid flow in tapered sprues. (a) Choke core. (b) Runner choke.

Momentum Effects

Newton's first law states that a body in motion will continue to move in a given direction until some force is exerted on it to change its direction.

Reynold's Numbers and Types of Flow. The flow of liquids can be characterized by a special measurement called the Reynold's number, which can be calculated as follows:

$$N_R = \frac{vd\,r}{m} \qquad \textbf{(Eq 3)}$$

where N_R is the Reynold's number, ν is the velocity of the liquid, *d* is the diameter of the liquid channel, ρ is the density of the liquid, and μ is the viscosity of the liquid. As shown in Fig. 5, if the Reynold's number is less than 2000, the flow is characterized as laminar, with the molecules of the liquid tending to move in straight lines without turbulence (Fig. 5a).

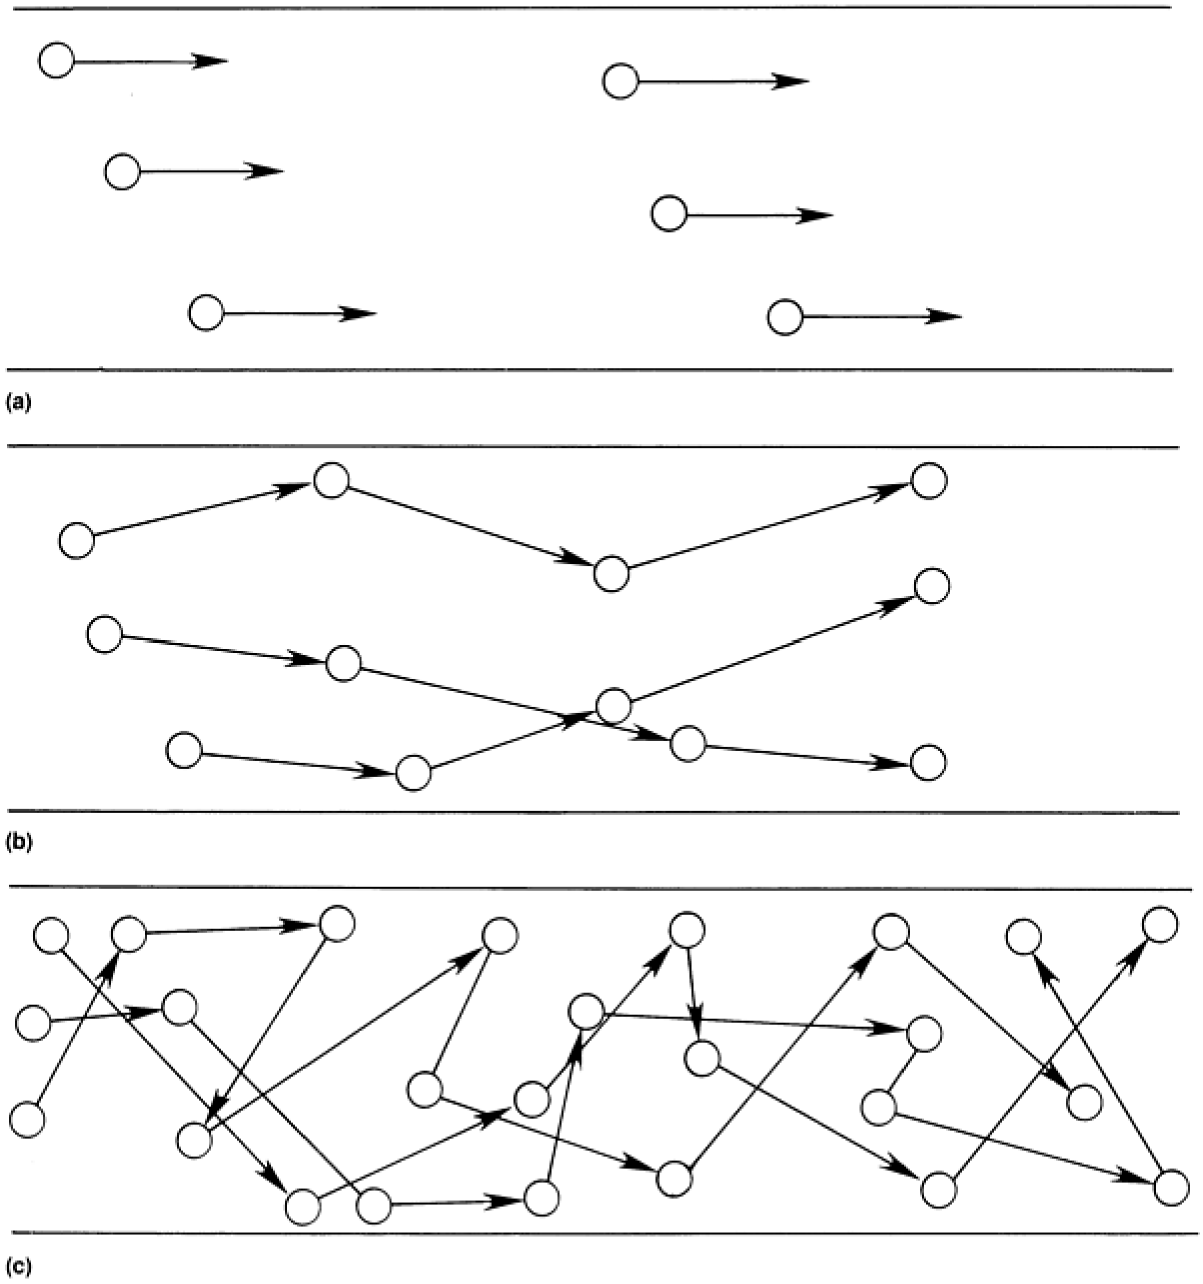

Fig. 5 Reynold's number, N_R, and its relationship to flow characterization. (a) $N_R < 2000$, laminar flow. (b) $2000 \leq N_R < 20{,}000$, turbulent flow. (c) $N_R \geq 20{,}000$, severe turbulent flow.

If a fluid flow system has a Reynold's number between 2000 and 20,000, some mixing and turbulence will occur (Fig. 5b), but a relatively undisturbed boundary layer will be maintained on the surface of the stream. This type of turbulent flow, common in most foundry gating systems, can be considered relatively harmless so long as the surface is not ruptured, thus avoiding air entrainment in the flowing stream.

With a Reynold's number of about 20,000, flow will be severely turbulent (Fig. 5c). This will lead to rupturing of the stream surface with the strong likelihood of air entrainment and dross formation as the flowing metal reacts with gases.

Abrupt Changes in Flow Channel Cross Section. As shown in Fig. 6, low-pressure zones--with a resulting tendency toward air entrainment--can be created as the metal stream pulls away from the mold wall. With a sudden enlargement of the channel (Fig. 6a), momentum effects will carry the stream forward and create low-pressure zones at the enlargement. With a sudden reduction in the channel (Fig. 6b), the law of continuity shows that the stream velocity must increase rapidly. This spurting flow will create a low-pressure zone directly after the constriction. The problems

illustrated in Fig. 6 can be minimized by making gradual changes in the flow channel cross section; abrupt changes should be avoided.

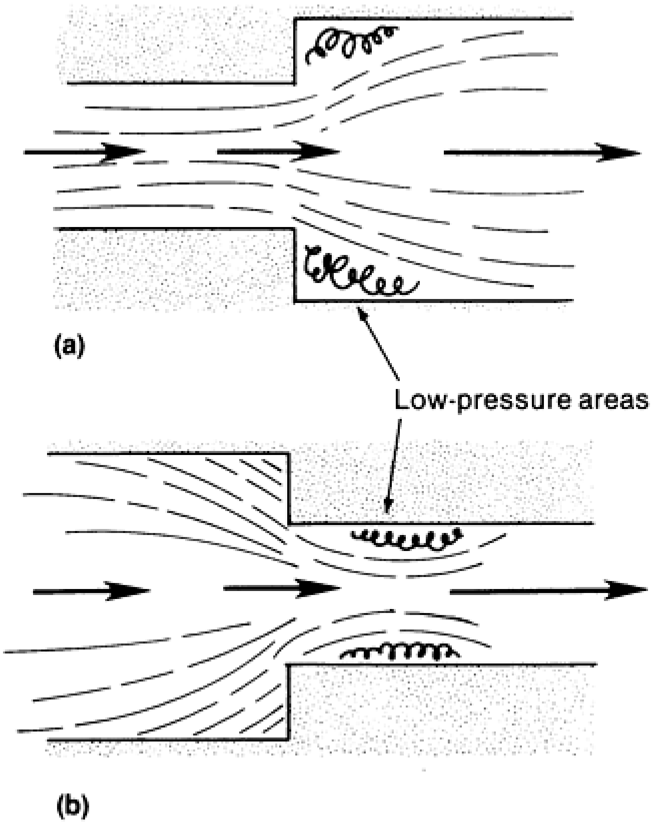

Fig. 6 Schematic showing the formation of low-pressure areas due to abrupt changes in the cross section of a flow channel. (a) Sudden enlargement of the channel. (b) Sudden reduction of the channel.

Abrupt Changes in Flow Direction. As shown in Fig. 7, sudden changes in the direction of flow can produce low-pressure zones, as described above. Problems of air entrainment can be minimized by making the change in direction more gradual.

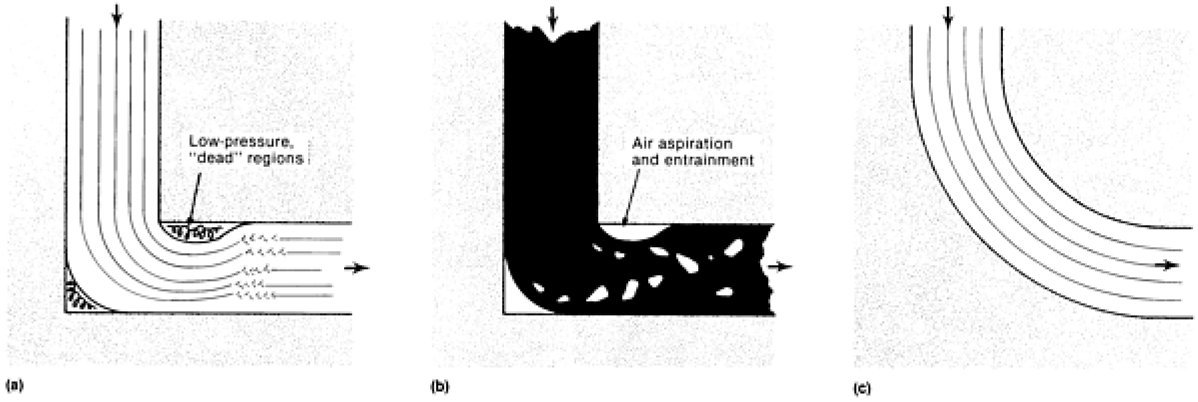

Fig. 7 Schematic illustrating fluid flow around right-angle and curved bends in a gating system. (a) Turbulence resulting from a sharp corner. (b) Metal damage resulting from a sharp corner. (c) Streamlined corner that minimizes turbulence and metal damage.

Abrupt changes in flow direction, in addition to increasing the chances of metal damage, will increase the frictional losses during flow. As shown in Fig. 8, a system with high frictional losses will require a greater pressure head to maintain a given flow velocity.

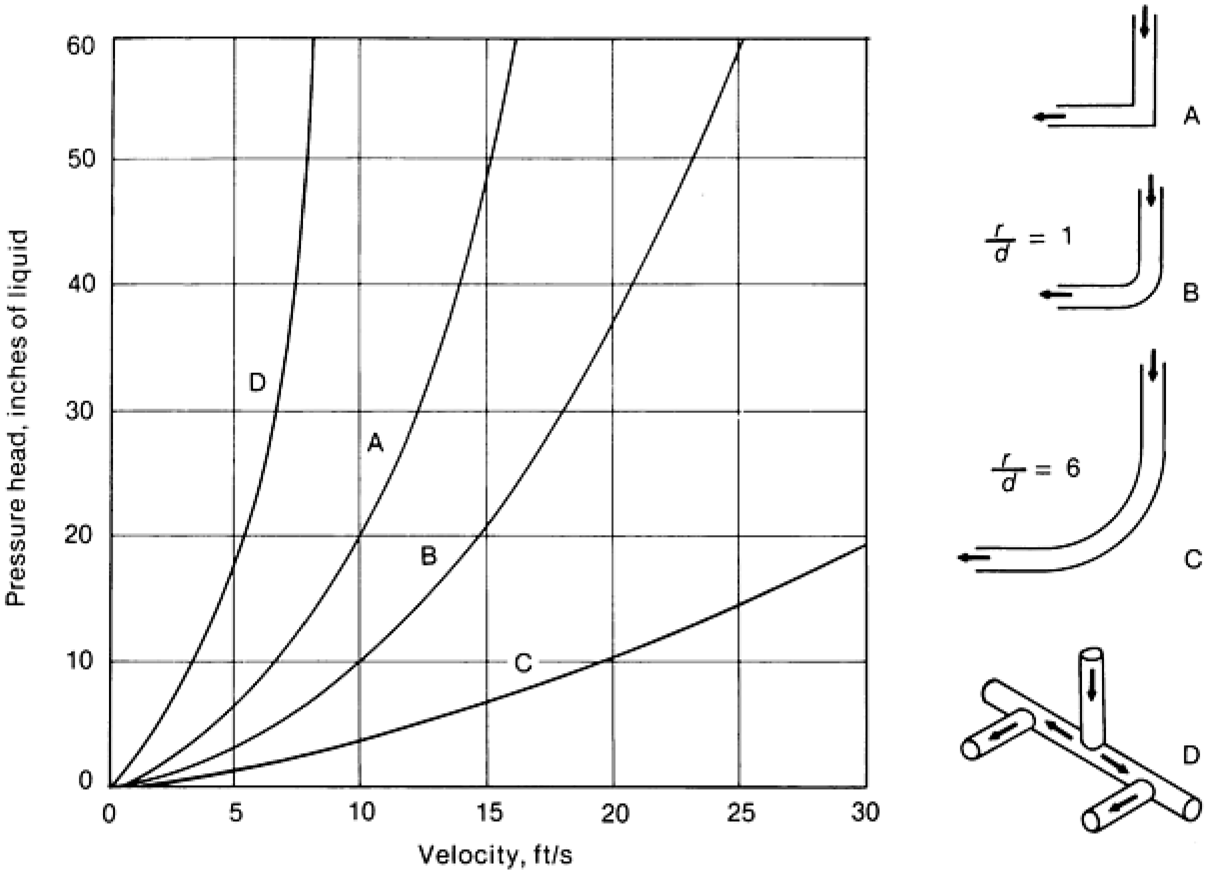

Fig. 8 Effect of pressure head and change in gate design on the velocity of metal flow. A, 90° bend; B, *r*/*d* = 1; C, *r*/*d* = 6; D, multiple 90° bends. The variables *r* and *d* are the radius of curvature and the diameter of the runner, respectively. Source: Ref 2.

Using a Runner Extension. Use of a runner extension beyond the last ingate is illustrated in Fig. 1. The first metal entering the gating system will generally be the most heavily damaged by contact with the mold medium and with air as it flows. To avoid having this metal enter the casting cavity, momentum effects can be used to carry it past the ingates and into the runner extension. The ingates will then fill with the cleaner, less damaged metal that follows the initial molten metal stream.

Equalizing flow through ingates by decreasing the runner cross section after the ingate is illustrated in Fig. 9; this is done for systems with multiple ingates. As noted earlier, in the filled system shown, potential and frictional energies become constants, so they can be dropped from consideration in Eq 1 to show the interaction of pressure and velocity effects.

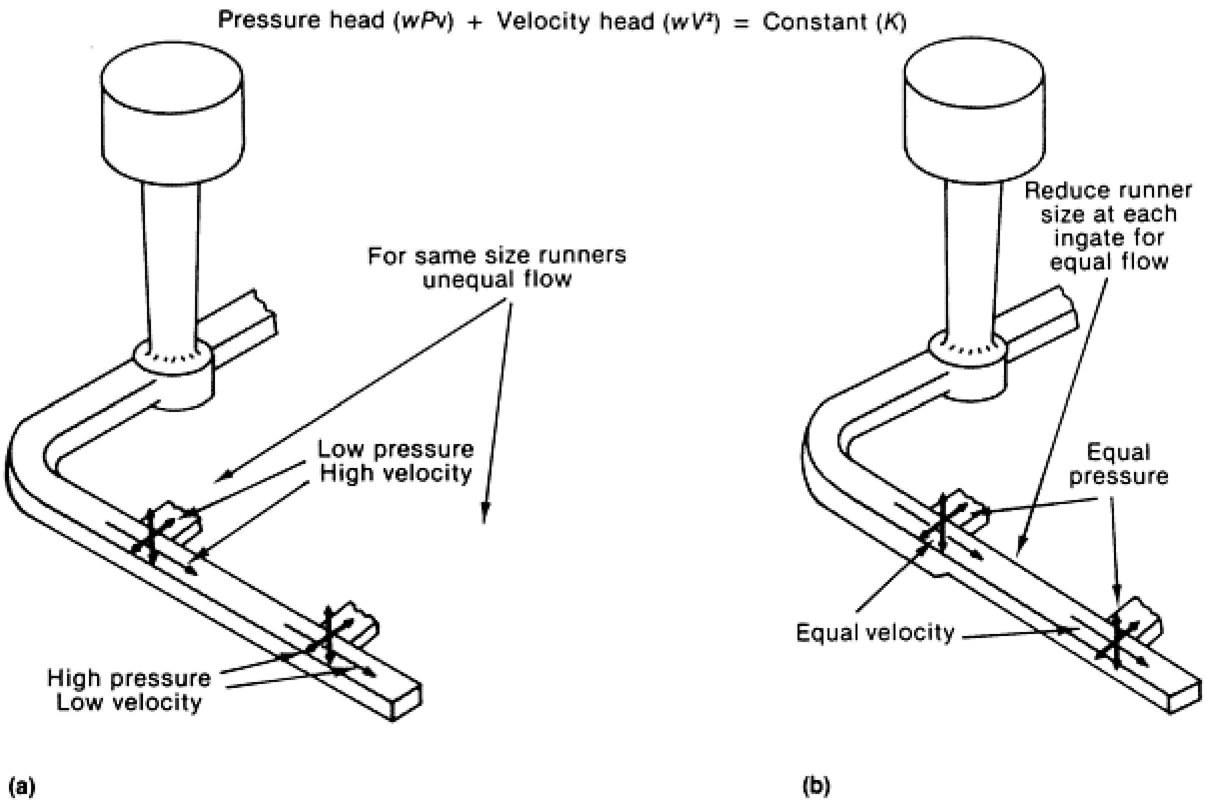

Fig. 9 Applying Bernoulli's theorem to flow from a runner at two ingates for a filled system and comparing velocity and pressure at the ingates for two runner configurations. (a) Same runner cross section at both ingates. (b) Stepped runner providing two different runner cross sections at each ingate. Source: Ref 1.

At the first ingate, velocity is high as momentum effects carry the flowing stream past the gate. At the second ingate, velocity decreases in the runner as it reaches the end, causing higher pressure and resulting in higher flow through the gate.

By stepping down the runner after the first ingate, metal velocities and pressures at the two ingates can be equalized. This effect can be achieved by gradually tapering the runner to a smaller cross section along its length, but patternmaking limitations usually make it simpler to incorporate actual steps in the runner. Additional information on gating systems and their effect on fluid flow is available in the article "Modeling of Fluid Flow" in this Volume.

Design Considerations

In applying fluid flow principles to the design of a specific gating system, several design decisions must be made before the actual sizes of the various components can be calculated.

Runner and Ingate. Figures 1 and 2 show gating systems with ingates coming off the top of the runner and then into the casting. This arrangement of cope ingates and drag runners is common and has the advantages that the runner will be full before metal enters the ingates. This establishes the full-flow conditions discussed earlier in this article. A full runner will reduce turbulence and will help to allow any low-density inclusions in the flowing stream to float out and attach themselves to the mold wall.

A system of cope runners and drag ingates (or ingates coming off the base of a cope runner) is also common and has strong proponents (Ref 3). The basis of this design is that momentum effects will carry the first metal past the ingates, and if the runner can be quickly filled (at least above the level of the ingates), clean metal will flow from the bottom of the runner, while inclusions carried along in the metal stream will float above the ingates.

A common element of this system is that the total cross-sectional area of the ingates should be smaller than the cross-sectional area of the runner. Such a pressurized system is intended to force the metal to back up at the ingates and rapidly fill the runner, although complete filling of a cope runner will often depend on at least partial filling of the casting. During this period of incomplete filling, turbulence and the potential for air entrainment and dross generation are increased.

Pressurized Versus Unpressurized Systems. The difference between these two systems is in the choice of the location of the flow-controlling constriction, or choke, that will determine the ultimate flow rate for the gating system. This decision involves the determination of a desired gating ratio, that is, the relative cross-sectional areas of the sprue, runner, and gates. This ratio, numerically expressed in the order sprue:runner:gate, defines whether a gating system is increasing in area (unpressurized) or constricting (pressurized). Common unpressurized gating ratios are 1:2:2, 1:2:4, and 1:4:4. A typical pressurized gating ratio is 4:8:3.

Both types of systems are widely used. The unpressurized system has the advantage of reducing metal velocity in the gating system as it approaches and enters the casting. Lower velocities help encourage laminar (or less turbulent) flow, so unpressurized systems are recommended for alloys that are highly sensitive to oxide and dross formation.

Pressurized systems generally have the advantage of reduced size and weight for a given casting, thus increasing mold yield. The single greatest disadvantage of pressurized systems is that, by design, stream velocities are highest at the gates just as the metal enters the casting. This increases the potential for mold or core erosion and places a premium on proper location of ingates to minimize such damage.

Vertical Versus Horizontal Gating Systems. This decision may simply be imposed by the orientation of the mold parting line. Figure 1 shows conventional, horizontally parted molds with the gating system most conveniently arranged along the parting line.

Vertically parted molds impose a vertical placement of gating components, but the design considerations for these components are often the same as those for horizontal systems, for example, the desirability of tapered sprues and runner extensions. In addition, the need for stepped-down sprues to equalize flow through multiple ingates is, if anything, more critical than in a horizontal system. This element of a properly designed vertical gating system is illustrated in Fig. 10.

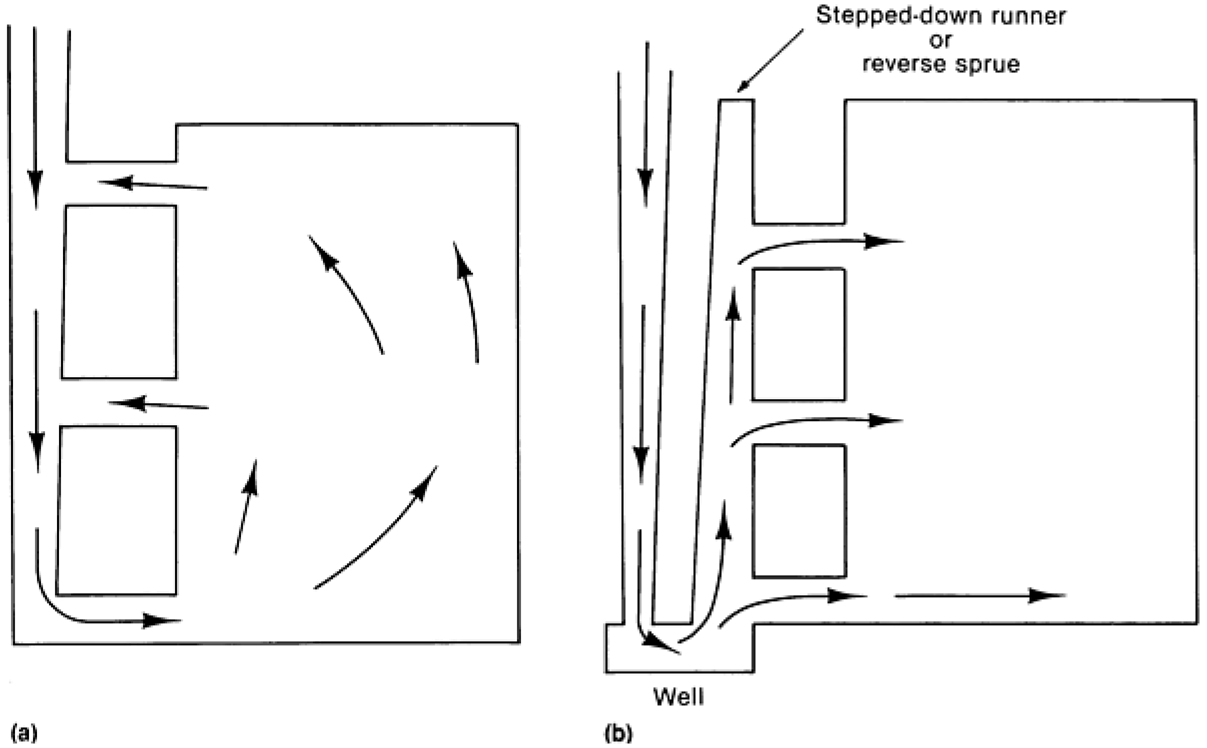

Fig. 10 Comparison of flow patterns in two vertical gating systems. (a) Poorly designed system. (b) Properly designed system utilizing a tapered runner that equalizes flow through the ingates.

One form of vertical gating common in both vertically and horizontally parted molds is called bottom gating. Elements of a properly designed bottom gating system are shown in Fig. 11. This method has the particular advantage of introducing metal into the casting cavity at its lowest point, thus helping to ensure smooth filling of the casting with minimal turbulence. Numerous examples of calculations for gating system design are available in the References cited at the end of this article and will not be covered in detail here.

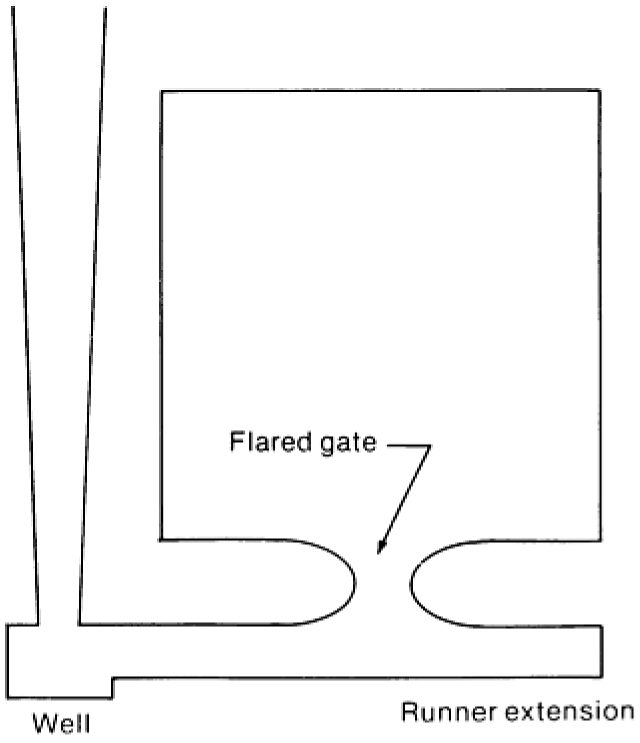

Fig. 11 Properly designed bottom gate that ensures smooth filling of the casting while producing minimal turbulence.

Optimum mold filling times are determined by such factors as metal type, casting weight, and typical casting section thickness. Once the optimum time is established, principles of fluid flow are used to determine the size of the system necessary to deliver the metal with the minimum flow rate required, which in turn determines the cross-sectional area of the choke. Once that is calculated, the rest of the components are easily calculated, moving downstream from the choke in an unpressurized system or upstream from the choke (that is, the gates) in a pressurized system.

Ceramic Filters in Gating Design

Ceramic filters are extensively used in the foundry industry to improve casting cleanliness and to reduce the cost of casting manufacture. Incorporated into the gating system, ceramic filters remove slag, dross, and other nonmetallic particles from the metal stream before the metal enters the mold cavity. Most casting alloys are subject to the presence of particles that can deleteriously affect the physical properties and appearance of the casting. These particles commonly include:

- Oxides formed during melting, metal transfer, and pouring
- Refractory particles from the furnace and ladle
- Refractory particles present in the gating system or dislodged from the mold or cores during pouring
- Reaction products from metallurgical operations
- Undissolved metallic or nonmetallic particles made as additions to the molten metal for metallurgical modifications

These particles, or inclusions, act as discontinuities in the metal matrix of a casting and can have a variety of adverse effects:

- Large inclusions can reduce mechanical properties such as tensile strength and elongation
- Fatigue life can be reduced (Ref 4, 5, 6)
- Machining can become more difficult, and the rate of tool wear can increase
- Surface finish can deteriorate in appearance
- Lack of pressure tightness can occur
- Subsequent surface treatments such as anodizing or ceramic coating can be adversely affected

The conventional approach taken to remove inclusions from the metal stream is through gating system design. Using this approach, gating systems are designed to encourage the separation of particles from the metal due to the density difference between the metal and the inclusion (Table 1).

Table 1 Densities of metals and metal oxides commonly used in casting alloys

Casting alloy	Density, g/cm^3
Aluminum alloys	

Al	**2.41**
Al_2O_3	**3.96**
$3Al_2O_3 \cdot 2SiO_2$	**3.15**
Magnesium alloys	
Mg	**1.57**
MgO	**3.58**
Copper alloys	
Cu	**8.00**
CuO	**6.00**
ZnO	**5.61**
SnO	**6.45**
BeO	**3.01**
Iron alloys	
Cast iron	**6.97**
Low-carbon steel	**7.81**
2% C steel	**6.93**
FeO	**5.70**
Fe_2O_3	**5.24**
Fe_3O_4	**5.18**
$FeSiO_4$	**4.34**
MnO	**5.45**

Cr_2O_3	**5.21**
SiO_2	**2.65**

Both pressurized and unpressurized gating systems are used for this purpose. To be effective, the gating system must have sufficient length to allow the lower-density particles sufficient time to float and adhere to the mold surface before they can enter the casting cavity. In practice, this approach does not always provide castings of adequate quality, and casting yield is often reduced, especially with unpressurized systems.

Filter Advantages. Ceramic filters, when correctly applied, can be relied on to trap particles before they can enter the casting cavity. This feature can result in the following advantages:

- Inclusion-related scrap and inclusion-related rectification can be reduced
- Gating system size can be reduced and casting yield increased (Fig. 12)
- Casting machinability can be improved
- Machine tool life can be increased
- Machine stock allowances can be reduced
- Casting physical properties can be increased
- Casting surface finish can be improved
- Reliability of the casting process can be increased

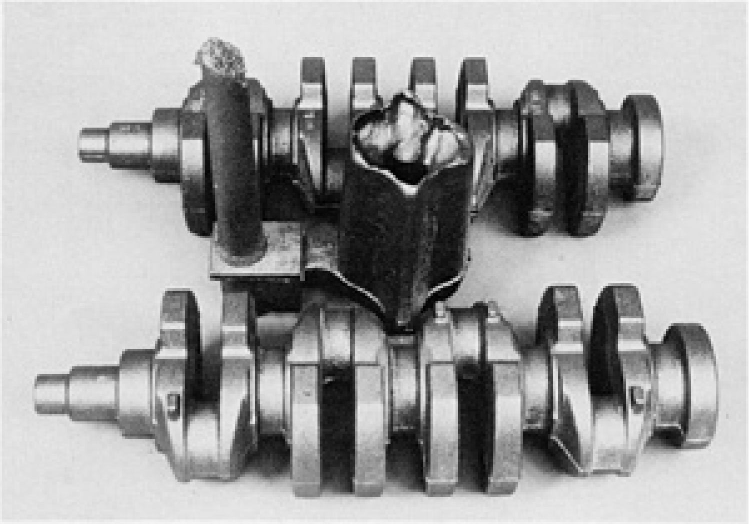

Fig. 12 Two crankshafts produced using a ceramic foam filter positioned vertically in the drag just downstream of the sprue. Casting yield is 91%.

The use of a ceramic filter in a gating system of conventional design can be effective in reducing inclusion-related defects, but a gating system designed specifically to incorporate ceramic filters will be more effective. Typical gating systems for horizontally parted molds designed to incorporate a ceramic filter are shown in Fig. 13. By relying on a filter to remove particles from the metal stream, the gating system can be designed with the following features and advantages:

- The system can be unpressurized, resulting in reduced metal velocity as metal enters the casting cavity
- Runners can be reduced in size--both length and cross-sectional area--thus increasing casting yield
- Runners are in the drag, resulting in more rapid, complete filling of the runner and reduced opportunity for metal oxidation

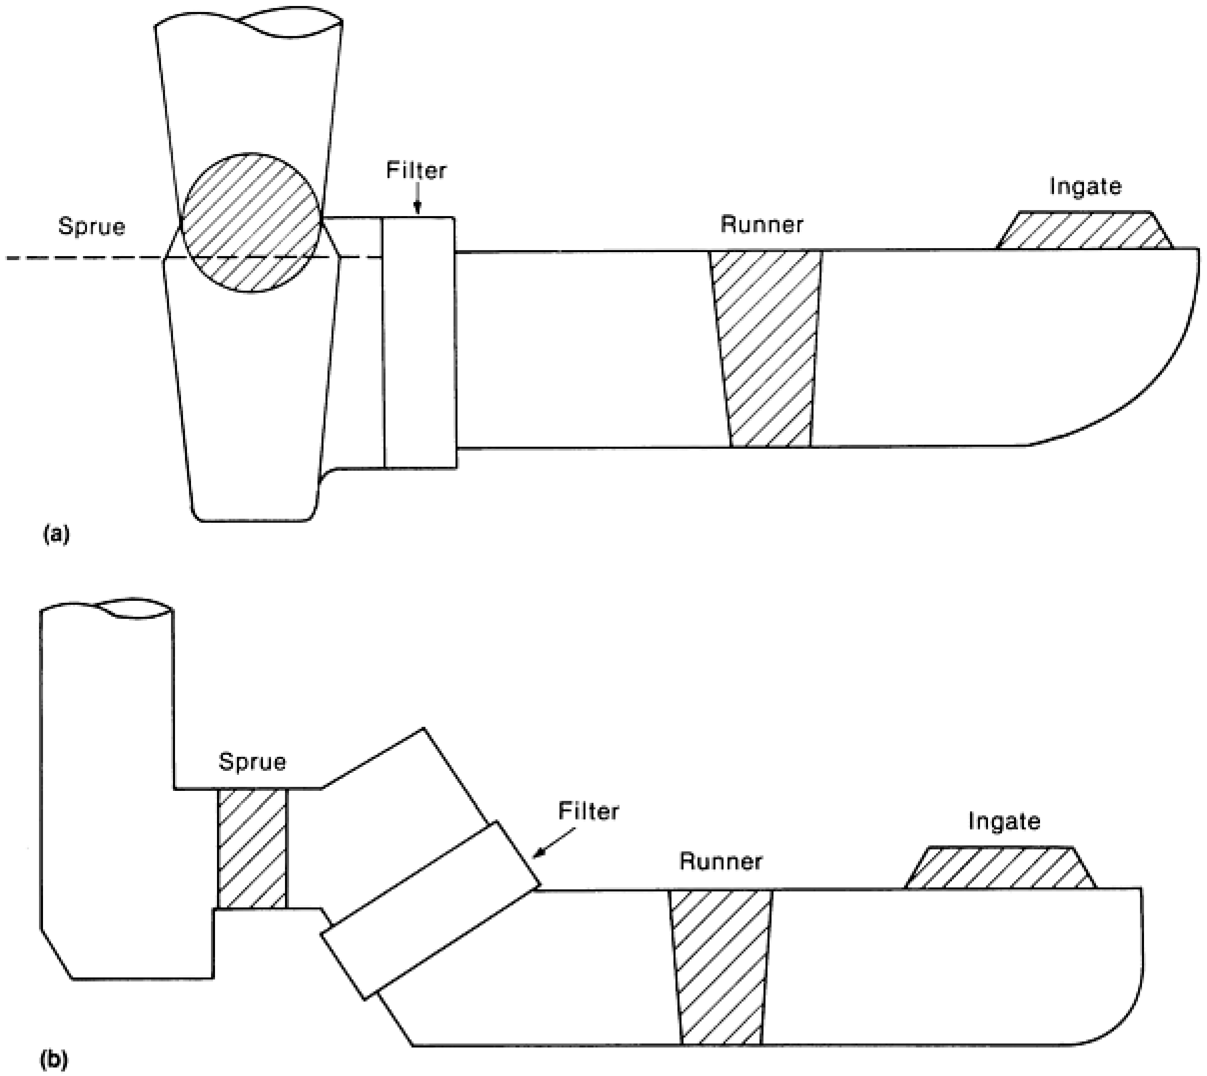

Fig. 13 Gating system designs for optimizing the effectiveness of ceramic filters in horizontally parted molds having sprue:filter:runner:ingate cross-sectional area ratios of 1:3-6:1.1:1.2 (a) and 1.2:3-6:1.0:1.1 (b).

Filter Types. Ceramic filters are available in a wide variety of materials and in many different forms. Mullite, alumina, cordierite, silica, zirconia, and silicon carbide are all commonly used. The most common forms are open-weave cloth, reticulated foam, extruded cellular shapes, pressed shapes, and perforated sheets (Fig. 14). Ceramic foams and cellular ceramics have been shown to be the most effective for inclusion removal and are the most widely used. Strainer cores were widely used prior to the advent of ceramic filters, and it is important to note the distinction between these two devices and their applications.

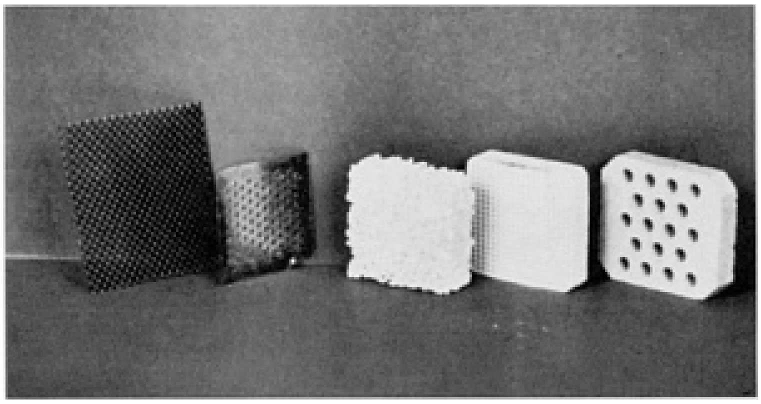

Fig. 14 Several common filtration and flow modification devices (from left to right): strainer core, extruded ceramic filter, ceramic foam filter, mica screen, and woven fabric screen. The two types of ceramic filters are by far the most widely used.

Strainer (choke) cores are designed to function as a restriction or choke in the gating system. The open frontal area--the ratio of the area available for metal passage to total part cross-sectional area--is in the range of 20 to 45%. Strainer cores are designed into a gating system to control the rate of mold filling and can aid rapid filling of the gating system. This action can assist in the flotation and separation of large particles from the molten metal stream, but strainer cores are not intended to remove particles. Their large, widely spaced holes split the metal flow into several separate metal streams, often resulting in aspiration and subsequent oxide formation downstream.

Ceramic filters, on the other hand, are designed to remove inclusions from molten metal. Filtering occurs by two mechanisms: physical screening (or sieving) and chemical attraction (Fig. 15). When properly designed into a gating system, filters do not act as a significant restriction to metal flow. The open frontal area of most ceramic filters is in the range of 60 to 85%, and the flow downstream of the filter is much less turbulent than with strainer cores.

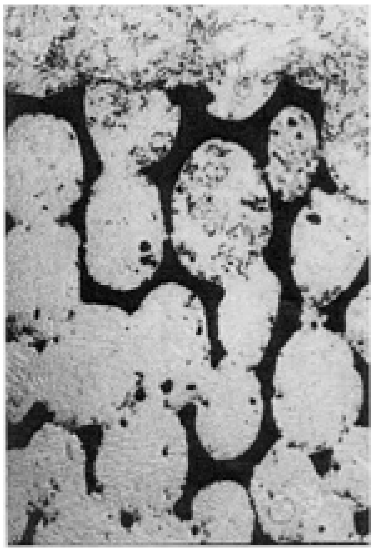

Fig. 15 Cross section through a runner bar containing a ceramic foam filter. Particle capture occurs at the front face (top) and inside the filter. The alloy is aluminum-base LM25.

Use of Ceramic Filters. Design of the optimum gating system for ceramic filter use incorporates the following principles:

- Filter placement must be easily accomplished
- Mold filling time must be constant and not affected by the presence of the filter
- Filter type must be correct for the application
- Gating system design must provide minimum metal turbulence downstream from the filter and in the casting cavity
- Gating system size must be kept to a minimum

Filter Placement. The location and position of a ceramic filter are influenced by the molding method, pattern layout, and any metallurgical processes performed inside the mold cavity, such as the nodularizing and inoculating additions made in certain iron castings. The molding method is particularly important in determining filter position. In molding processes that use an expendable pattern, filters are most easily incorporated into the pouring basin. In horizontally parted molds, filters are commonly positioned as shown in Fig. 16. Filters should not be placed at the base of the sprue, because this increases the possibility of filter breakage and reduces filter effectiveness. In vertically parted molds, filters are commonly positioned as shown in Fig. 17. Although the pouring basin location is often used, filters are more effective when located farther down the gating system. When metallurgical additions are made in the mold cavity, filters must be located downstream, as shown in Fig. 18.

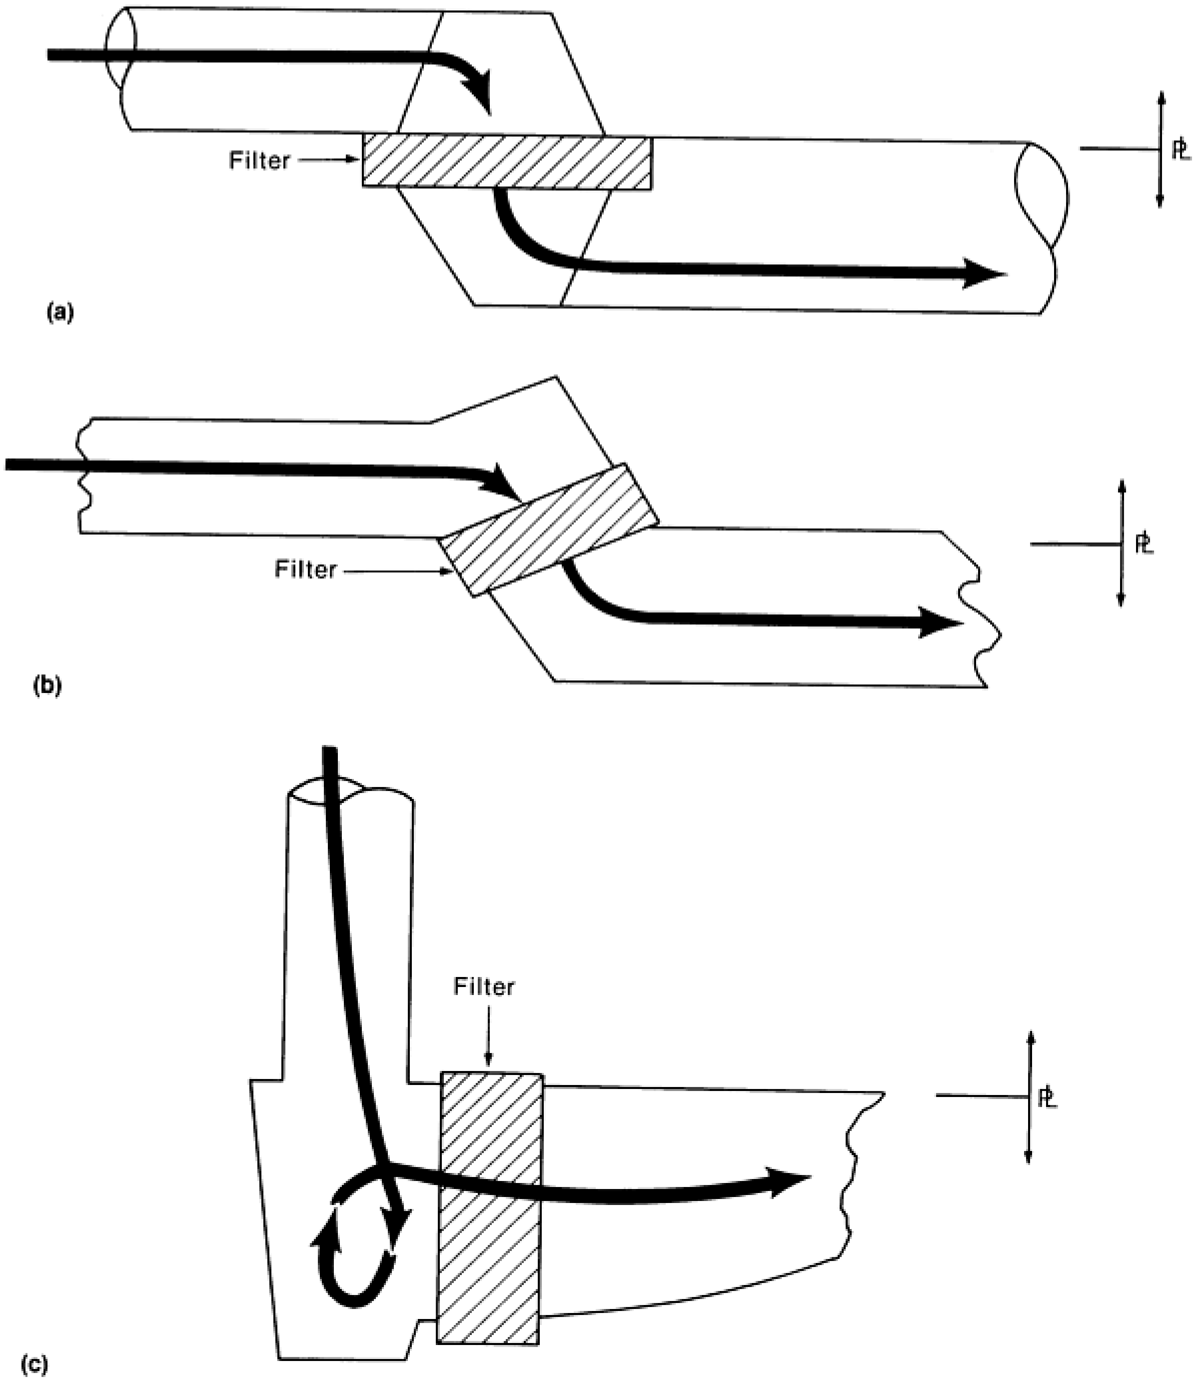

Fig. 16 Common methods of filter placement in horizontally parted molds. (a) Parallel to parting line. (b) Between 0 and 90° to parting line. (c) 90° to parting line. Arrows indicate the direction of metal flow.

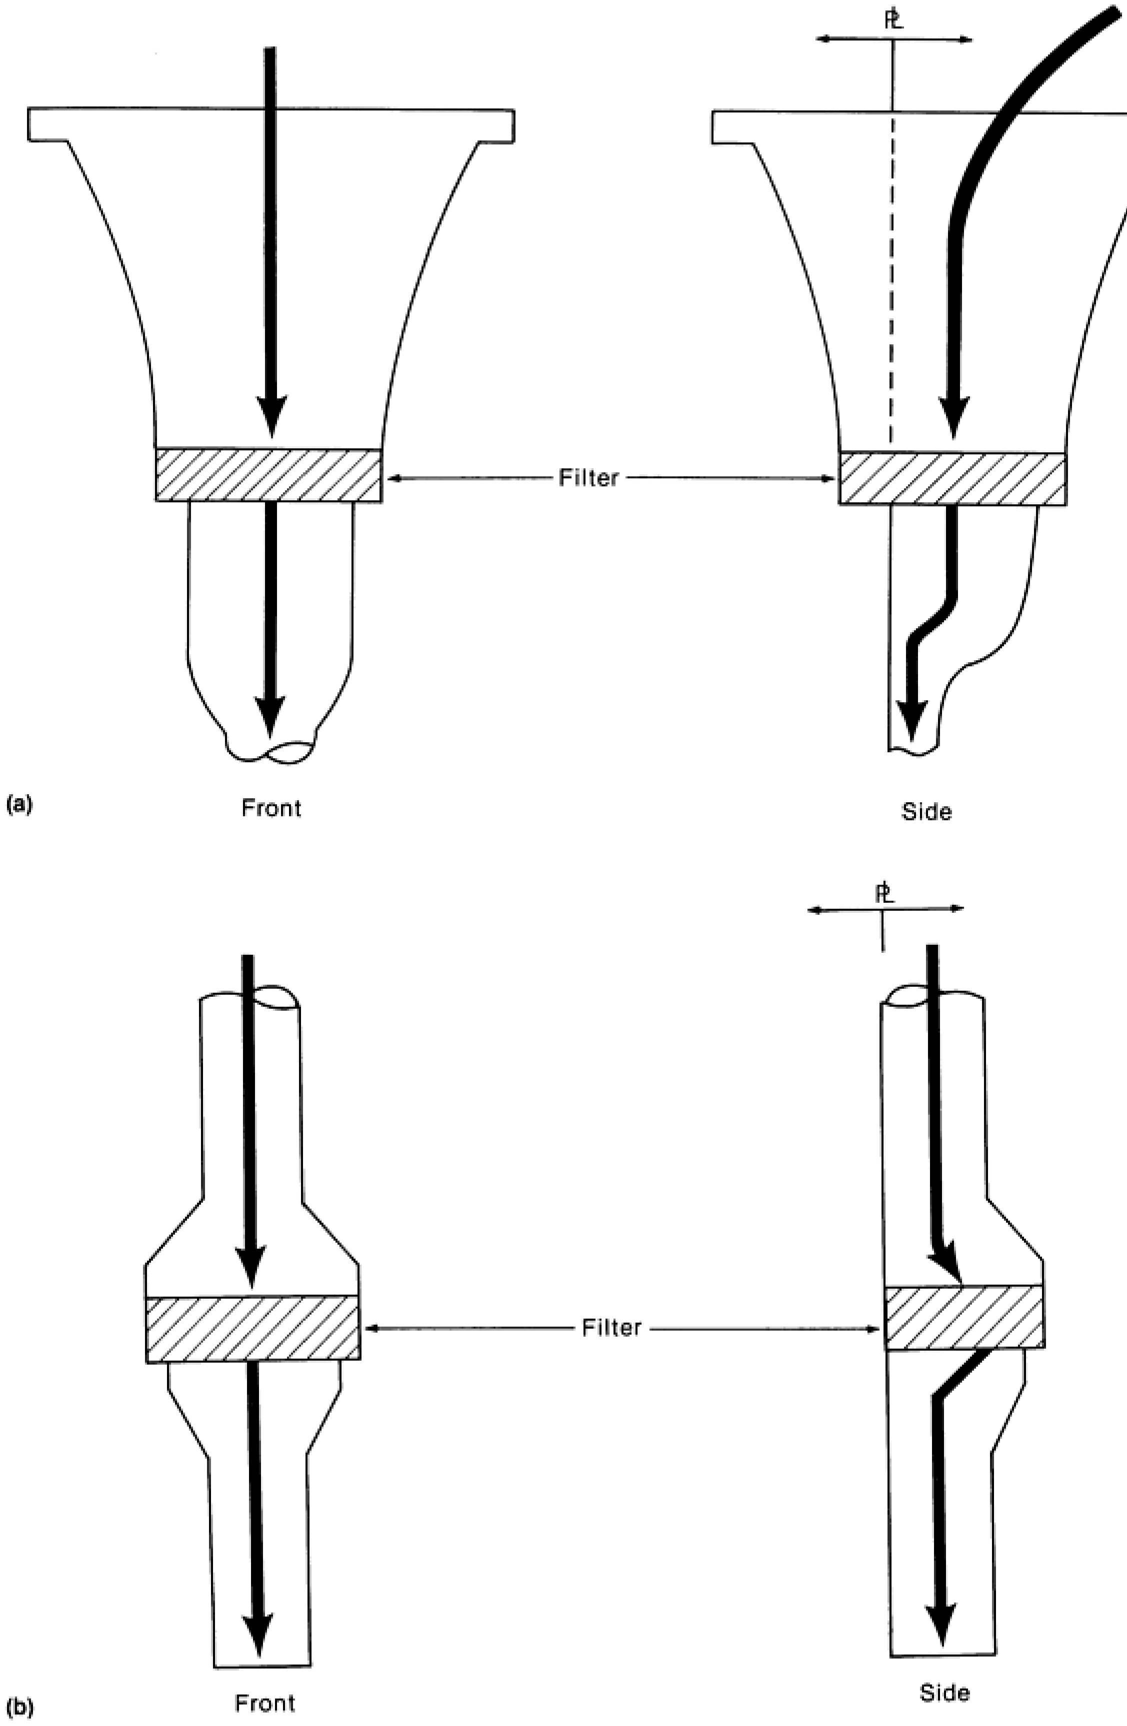

Fig. 17 Common methods of filter placement in vertically parted molds. (a) Filter located in pouring basin. (b) Filter located inside the mold. Arrows indicate the direction of metal flow.

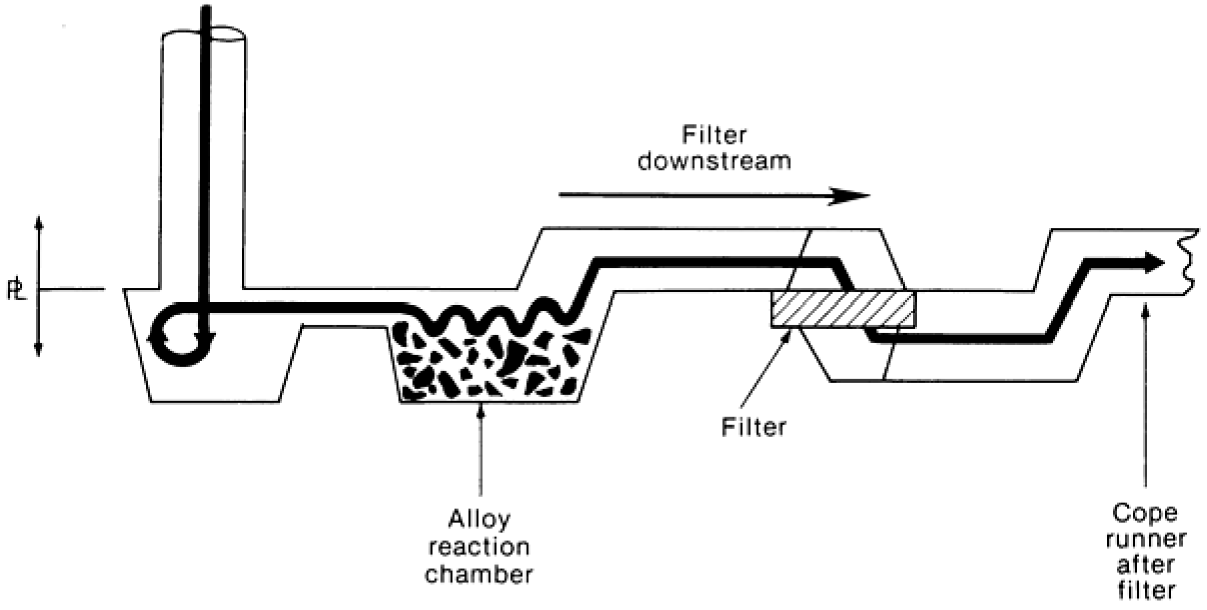

Fig. 18 Filter placement when a metallurgical operation (that is, magnesium treatment or inoculation of iron) occurs in the mold.

Filter Area/Choke Area Ratio. The size and number of ceramic filters required are determined by the rate of mold filling required and the volume of metal to be filtered. As filtration occurs, individual cells in a filter become blocked, and the rate at which the filter can pass metal is reduced. This phenomenon is illustrated in Fig. 19.

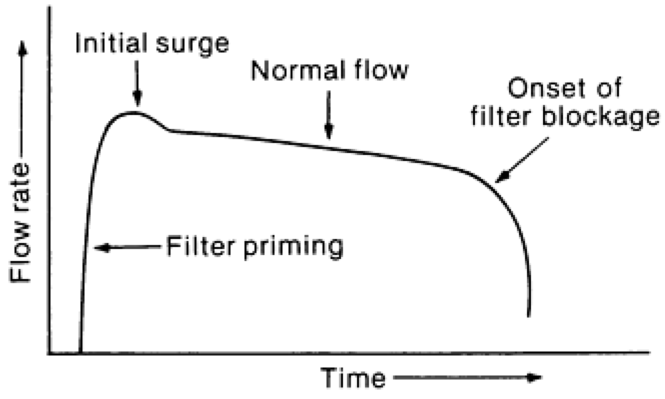

Fig. 19 Plot of flow rate versus time showing the behavior of a ceramic filter during the course of pouring until complete blockage occurs.

Filter size is determined such that the filter operates in the range termed normal flow in Fig. 19. In general, the necessary ratio of filter area to choke area is in the range of 2:1 to 4:1 at the start of pouring. If the filter is greatly undersize, complete filter blockage can occur, and incomplete mold filling will result.

Casting Design

Ronald M. Kotschi, Kotschi's Software & Services, Inc.

Introduction

A DESIGN ENGINEER committing pencil to paper is not only creating a shape but also strongly influencing the cost required to place that shape into use. In other words, well-designed parts are less costly to obtain than poorly designed parts and are more likely to be delivered to the customer on time. Although this is true of every method of manufacture, it is particularly true of shapes to be made by the casting process. The casting process has gained the reputation as a technique that can be used to create almost any shape the designer can envision, but whether or not a shape can be cast economically is another matter. If the manufacturing process were considered at the design table, an inherently easier to manufacture design would result. Ease of manufacture translates into castings that are purchased at a lower cost, are of high quality, and are delivered on time.

All aspects of this topic cannot be covered in a single article. However, through an understanding of only a few of the most important aspects of this approach to casting design, a great deal of the potential economic savings can be realized.

Casting Design

Ronald M. Kotschi, Kotschi's Software & Services, Inc.

Solidification

The first aspect that is important to casting designers is an understanding of solidification (the freezing of molten metal inherent in all casting processes). The solidification of a casting can involve as many as three separate contractions as a result of cooling:

- Liquid-liquid contraction
- Liquid-solid contraction
- Solid-solid contraction

Liquid-liquid contraction occurs as a result of the liquid cooling from its pouring temperature (usually 110 to 165 °C, or 200 to 300 °F, above its melting point) down to the melting point or solidification temperature. This particular factor is of little consequence to designers and is fairly easily dealt with by the foundry engineer. However, the design engineer must consider the other two contractions if cost-effective designs and specifications are to be realized.

Solid-solid contraction occurs after a casting has solidified and as it cools from the solidification temperature to room temperature. The design engineer must be concerned with this contraction. To ensure that the dimensions of the casting are correct, the pattern used to produce a given casting usually must be made slightly larger than the casting dimensions at room temperature. The patternmaker compensates for this pattern enlargement for a particular alloy by using a shrink rule specifically for the alloy involved. Further, because the amount of solid contraction is a function of the particular metal to be cast, problems with dimensions can often occur when changing alloys if the same pattern equipment is used. Whenever such a change is contemplated, the foundry engineer should be provided with this information because other factors such as gating and risering could also be involved. Therefore, the designers specifying the alloys should carefully consider any change in alloy to ensure that the cost of new equipment does not cancel out the benefits to be achieved by such changes.

Solid-solid contraction should also be considered in part design, because it is one of the primary causes of warped and cracked castings. A basic concept that governs the way castings cool is the casting modulus (the volume of a portion of a casting divided by the surface area of that portion of the casting). This relationship of geometry to cooling is easily understood by considering the effects of both volume and surface area on cooling rates. As volume increases, more hot metal will be contained within it, and the casting will therefore take longer to cool. Conversely, because all the heat within a casting must pass through a surface at the metal/mold interface, the greater the surface area, the faster the casting will cool. Thus, as the volume-to-surface area ratio (casting modulus) increases, the time required for cooling and solidification is extended.

Using this tool, one can easily see the problems created by the design shown in Fig. 1. Because the design contains a rather wide range of section thicknesses, the various sections will cool and solidify at different rates. The first portion of the casting to solidify would be the sections having a modulus of 1. At some later time, the section with a modulus of 5 would solidify and begin cooling to room temperature. However, the thinner sections will have cooled and contracted by solid-solid contraction before the thicker section, and because of this the thicker section applies a compressive stress to the thinner sections as it cools. Such stresses have been measured to levels as high as 552 MPa (80 ksi), depending on the alloy and section size variations. Therefore, a casting designed in this way will have a strong tendency toward warpage as a result of the imposed stresses. Although a casting may not be warped when taken from the mold, the internal stresses that develop as a result of design can appear at later stages as cracks or warping, often after heat treatment welding, and machining.

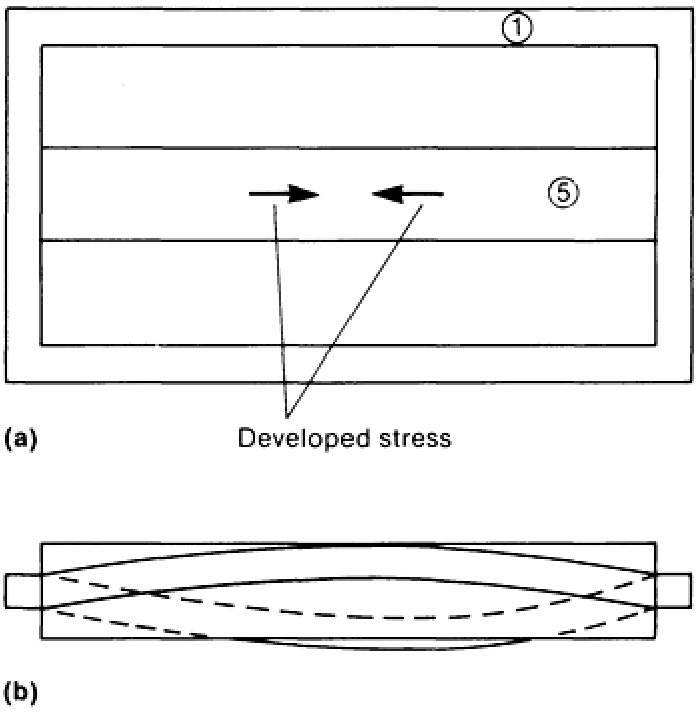

Fig. 1 The effects of design on distortion of castings. (a) Top view of casting; numbers indicate moduli of the two sections. (b) Distortion caused by solidification stresses.

If design features result in warpage, foundrymen often compensate for this by using tie bars that are usually small cast-on bars attached to various parts of the casting to brace the casting and therefore prevent warpage. Although such devices may result in castings that are not warped, other problems can result. For example, such devices cannot prevent the stresses that cause the castings to warp and therefore do nothing to prevent the cause of the problem. In some cases, warpage is eliminated at the expense of increased residual internal stresses. Because such stresses cannot be detected with nondestructive testing, they remain undetected, and upon application of heat or other stresses, warpage, cracking, or premature failure can result. In most cases, castings produced with the bars present no problems in service. However, tie bars do nothing to solve the root cause of the problem, namely, the stresses caused by design features; therefore, it is best to avoid their use by employing uniform section sizes whenever possible.

The importance of solid-solid contraction as applied to design means that an attempt should be made to reduce dramatic variations in the section sizes of castings. Other factors in foundry practice that can lead to the distortion of castings include improper heat-treating practices, difficult-to-collapse molds or cores, shakeout procedures, rigging, and the way in which the casting cools; these factors are under the control of the foundry engineer. Problems with warpage and cracks can often be eliminated through the cooperative effort of casting designers and foundry engineers.

Liquid-solid contraction is by far the greatest difficulty due to solidification that faces the foundry engineer. It is also one of the greatest opportunities for the design engineer to design for low cost, high quality, and timely delivery. Most metals contract as they pass from the liquid to the solid state. Certain compositions of gray and ductile iron are the exceptions to this rule in the major alloys produced by foundries. The entire founding process is possible only because volumetric contraction locates itself in solidifying castings in a systematic way.

Solidification Sequence

The aspect of liquid-solid contraction that allows castings to be produced is that all of the contraction is concentrated in the last portion(s) of the casting to solidify. The foundryman uses this principle to produce sound castings by attaching a volume of metal to the last portion of the casting to solidify. This technique is illustrated in Fig. 2. Such feed metal reservoirs are called risers. Proper placement of risers on castings changes the way in which both casting and riser(s) solidify such that the riser is the last to solidify. When used properly, this produces a casting free of shrinkage because all the shrinkage for the entire mass of both casting and riser will be concentrated in the riser. However, in many cases, the design of the casting restricts the proper placement of risers, making the production of sound castings difficult if not impossible. In this way, casting designers have a significant impact on quality and cost.

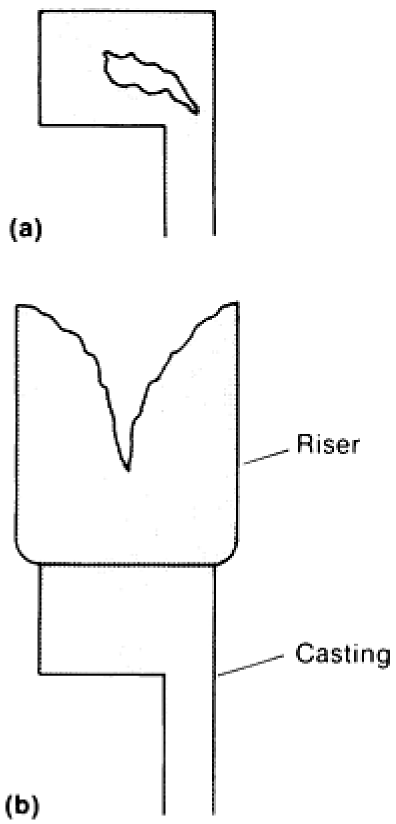

Fig. 2 The function of risers. (a) Shrinkage in casting at last portion to solidify without a riser. (b) Shrinkage in riser allows the production of a sound casting.

The technique of designing castings that are easily risered can be best understood by considering a simple shape such as a wedge (Fig. 3a). The solidification direction, as seen in Fig. 3(b), is related to the casting modulus, which is the volume-to-surface-area ratio. Because a wedge casting has a natural solidification direction, if the design is such that a riser cannot be placed at the wide end of the wedge, a shrinkage cavity will develop in the casting even though a riser was attached. As shown in Fig. 3(a), this occurs because solidification begins somewhere near the middle of the wedge/riser combination. Thus, from a solidification or thermal design point of view, there are actually two castings in this example, each having a last place to solidify. If the design allows for the placement of the riser at the proper end of the wedge, as in Fig. 3(b), a sound casting will result because of the unidirectional solidification pattern. Shrinkage defects may not always represent a problem, but in cases where they jeopardize mechanical strength, appearance, or pressure tightness, the castings would have to be repaired or scrapped. Under such circumstances, the final costs (including delays in delivery) can be severe.

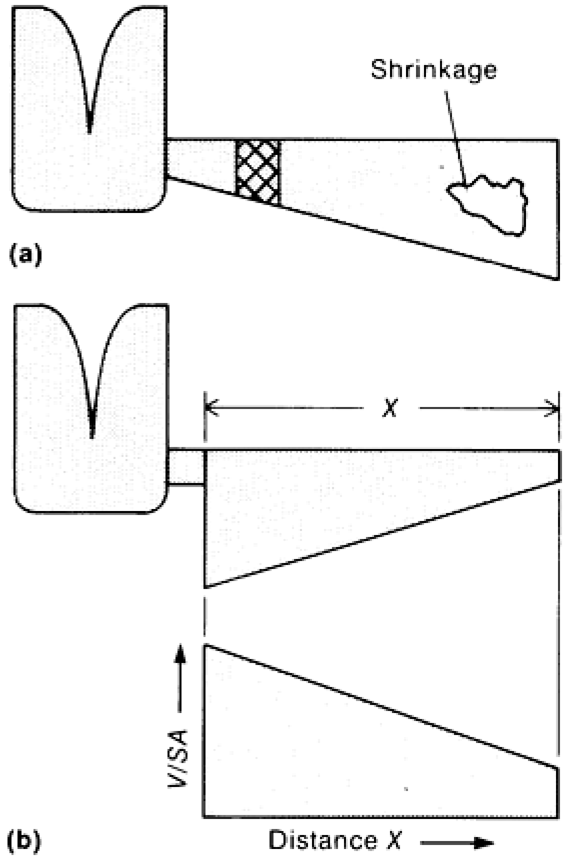

Fig. 3 Casting design and solidification of a simple wedge. (a) Riser placed at narrow end of wedge; shrinkage occurs at wide end. The crosshatched region represents the approximate area of the casting where solidification is first complete, thus cutting off the feeding path of the casting. (b) Correct riser placement. *V/SA* is the volume-to-surface-area ratio (casting modulus).

Very few castings are as simple as the wedge shown in Fig. 3; therefore, a technique capable of determining the solidification sequence of complex shapes is needed if design engineers are to take advantage of the potential cost savings. Regardless of their apparent complexity, castings can usually be resolved into a series of rather simple shapes that make up the complex shape. These simple shapes are:

- T-sections (plate intersections forming a T)
- X-sections (plate intersections forming an X)
- L-sections (plate intersections forming an L)
- Plates
- Cylinders
- Cylinder/plate intersections

Most casting geometries can be covered by using these basic shapes. For example, a box shape can be simulated by a series of L-sections, and a hub casting can be simulated as a T-section revolved about a central axis. By solving the relationship between casting design parameters and the manner in which these simple shapes solidify, designers can obtain a useful guide to cost reduction and improved quality through casting design.

T-Sections

Figure 4(a) shows a hub casting. There are four possible ways to position the risers, depending on the casting design. These four alternatives are shown in Fig. 4(b) and 4(c). Selection of one of these alternatives by the foundry engineer depends on the casting design. Figure 4(d) shows the dimensions and critical sections involved. In Fig. 4(d), as well as in

each figure in this article that illustrates the dimensions of a given section type, a special notation is used to differentiate between the dimensions describing the size of the section components and the section itself. Although the same letter is used, for example, T and *T*, the roman T refers to the section, while the italic *T* refers to the dimension of the section.

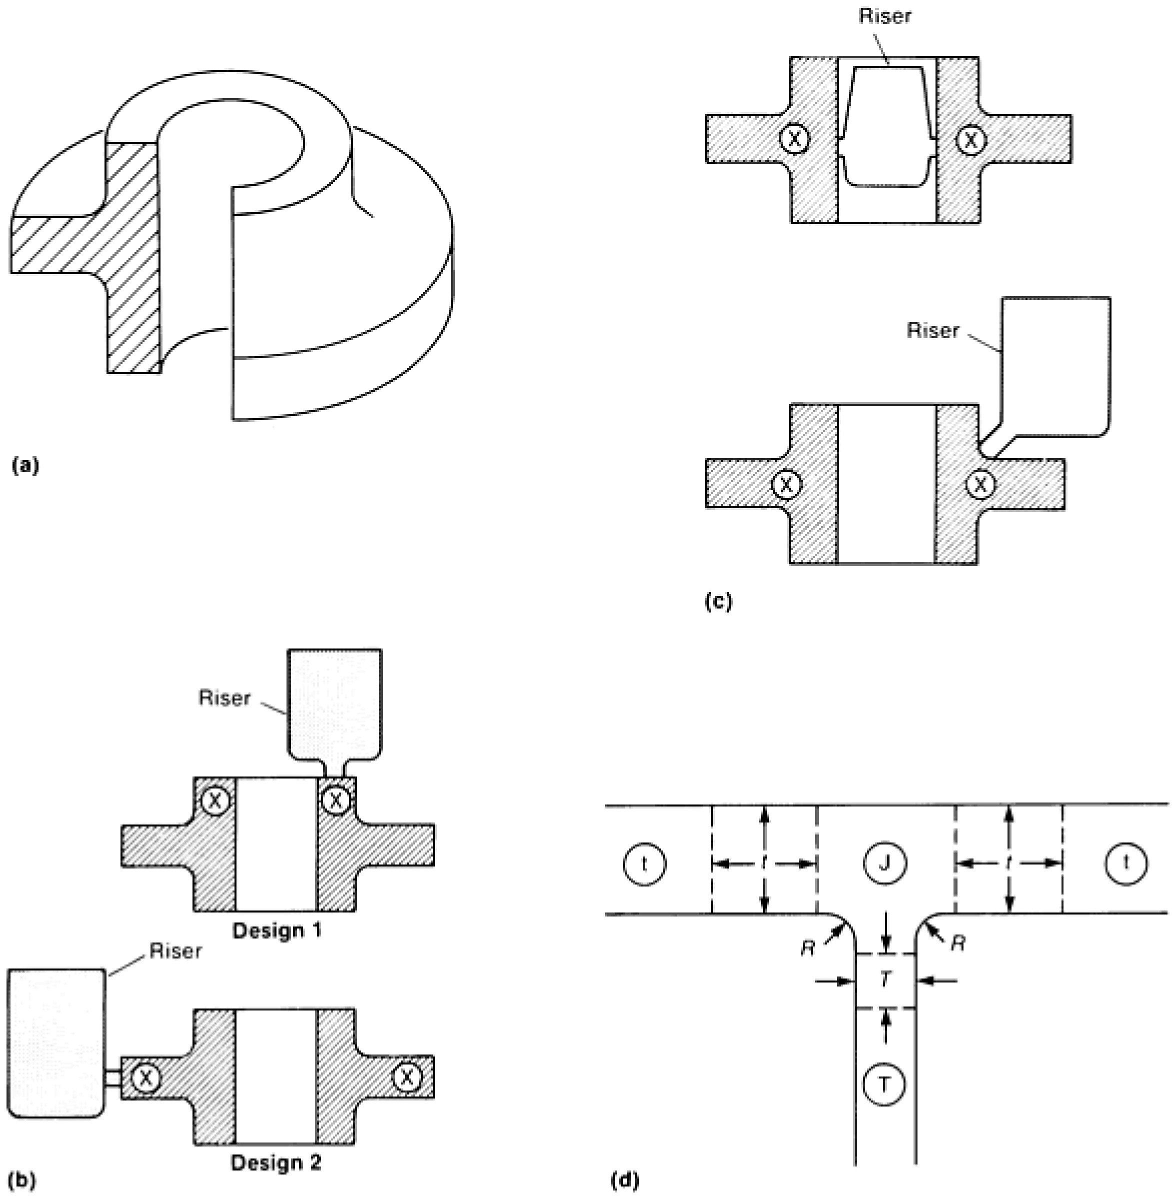

Fig. 4 Cross section (a) of a hub casting showing that it is actually a T-section revolved around an axis. (b) and (c) Possible riser placements; X indicates the last portion of the casting to solidify. See text for discussion. (d) Principal design dimensions of T-section and component sections; see text for discussion.

Factors Influencing the Solidification Sequence. There are three basic design dimensions for a T-section: *t*, *T*, and *R*. If the cross plate dimension *t* is large with respect to the intersection plate dimension *T*, the last portion of the casting to solidify will be area t in Fig. 4(d). This will require the riser placement labeled Design 1 in Fig. 4(b). If the intersecting plate dimension *T* is large compared to that of the cross plate dimension *t*, the last portion to solidify will be area T in Fig. 4(d). This type of design will require the riser placement labeled Design 2 in Fig. 4(b). Finally, if the dimensions *t* and *T* are nearly the same, either of the two possibilities shown in Fig. 4(c) can be used, because area J in Fig. 4(d) will tend to be the last area of the casting to solidify.

In a solidification sequence in which the last portion of a hub casting to solidify is the J portion of the T-section, as shown in Fig. 4(d), one of two difficulties usually arises. In many designs of this type, the hole cavity formed by the rotation of the T-section about its central axis is too small to allow a riser of sufficient size to feed the section. When this cavity is

too small, there is no alternative but to place the riser outside of the casting, as shown in Fig. 4(c), which necessitates the use of a core, thus adding cost.

If the enclosed cavity should be large enough to contain a riser of sufficient size, the problem then usually involves the removal of the riser from within the cavity. In a high-production environment, such as automotive applications, special equipment to extract such internal risers can be economically feasible if the design allows placement in the internal cavity of the hub.

Such a special case is the manner in which cast automotive connecting rods are produced. For this particular type of casting, a small wafer riser is placed within the crankshaft receiver end of the connecting rod, which adequately feeds this portion of the casting. However, the use of this casting design and the wafer riser is predicated on high production requirements, which allow the use of specially designed punch presses to remove the riser and the associated gating system. Without such special equipment, the internal riser placement would be highly undesirable.

This case is an exception to the overall undesirable nature of solidification sequences in which the J portion of a hub casting is the last section to solidify. This points out a very important concept; There are no definitive rules that always apply to casting design. It is this potential for alternative solutions based on specialized conditions that makes the topic of casting design so interesting but very difficult to confine within a rigid set of guidelines. The goal is to design the casting with a particular solidification sequence in mind so that the cast part can be risered easily and subsequent riser removal can be accomplished with ease.

In general, however, either of the two riser placements shown in Fig. 4(c) can usually be considered undesirable. Because of the added costs imposed by a solidification sequence of this type, such designs generally should be avoided. However, if such a design is unavoidable, some modifications can be made to facilitate manufacture. The key is to recognize the problem, namely, that area J of the T-section of the hub (Fig. 4d) is the last to solidify. Once this is known, appropriate measures can be taken to modify the solidification sequence.

One alternative would be to alter the casting modulus by changing the shape of the hub to reduce the volume contained and/or to increase the surface area. This would be an effective solution to the problem if the design already required a core to form the hole in the hub before the change in shape. If such a design change increases the number of cores required to produce the casting, this technique may not be cost effective, because additional cores usually necessitate increased casting costs.

Another possible solution to the same solidification sequence problem might be the use of a feed pad (Fig. 5). Once again, by recognizing the solidification sequence problem imposed by the design, the designer could elect to add metal to the flange of the hub to change the solidification sequence. Foundrymen refer to this technique as padding. This is a good alternative solution if the pad can either remain on the casting in use or does not affect machining costs adversely. There are many other possible design alternatives, but the designer must first be aware of the problem caused by the solidification sequence.

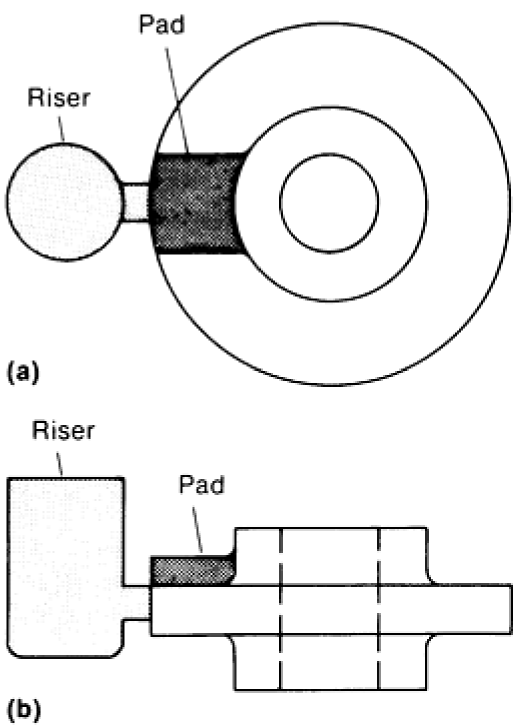

Fig. 5 A hub casting with a pad to provide a feeding channel from the riser. (a) Top view. (b) Side view.

Either of the riser placements shown in Fig. 4(b) is an effective alternative if large production quantities are not required. Because of the need to extract the riser through the top of the cope half of the mold, Design 1 is less compatible with high-production molding techniques than the side riser used in Design 2. Therefore, if high production is expected, the preferred solidification sequence would be that in which area T in Fig. 4(d) is the last portion of the casting to solidify.

Development of Solidification Sequence Graphs. A series of graphs has been developed to assist designers and foundry engineers in determining the solidification sequence of the basic shapes listed earlier. These graphs show the solidification sequences as a function of the design parameters constituting the sections. Considering the T-section shown in Fig. 4(d), one can easily see that there are three parameters governing the manner in which the section solidifies, namely, dimensions *T*, *t*, and *R*. As each of these parameters changes, the casting modulus of each component making up the T-section changes. The solidification sequence can be estimated by comparing the modulus of each component (t, T, and J) of the T-section. With the use of a computer, this process was employed to evaluate all the possible designs of the T-section from t = 0 to 10 and T = 0 to 10 while holding R = 0. The results of this analysis are shown in Fig. 6(a).

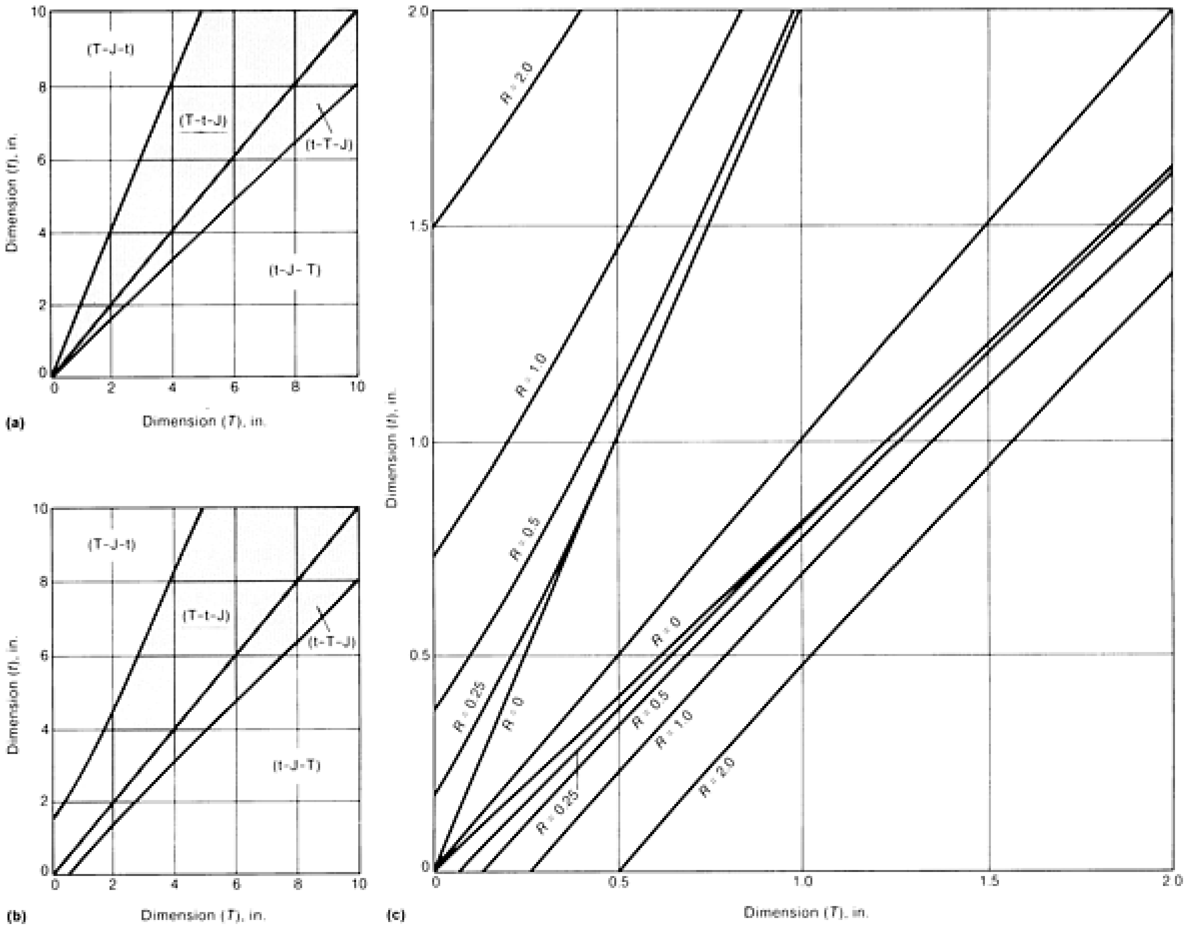

Fig. 6 Solidification sequence curves for T-sections. Letters indicate the order of solidification of the various parts of the casting (see Fig. 4d). (a) Fillet radius *R* = 0. (b) *R* = 2. (c) Composite of design curves for various fillet radii.

The technique used in this analysis was the well-known Chvorinov's rule, which is commonly used to compare the solidification times of simple casting shapes. Although originally developed for the solidification of pure metals and alloys solidifying over a very narrow temperature interval, the concept is more broadly applicable and states that the total solidification time of a casting (or casting section) is proportional to the square of the volume-to-area ratio of the casting (or casting section). This rule can be stated mathematically as follows:

$$t_f = K.\left(\frac{Vc}{Ac}\right)^2$$

where t_f is the total solidification time for the casting or casting section, V_c is the volume of the casting or casting section, A_c is the surface area of the casting or casting section, and K is a constant for a given metal and mold combination.

The factors that relate to the constant K are mold temperature, metal temperature, the density of the solidifying metal, the specific heat of the mold, the density of the mold material(s), the thermal conductivity of the metal, the thermal conductivity of the mold, and the specific heat of the metal. These factors involve the specifics of a given casting manufactured in a given mold. For a mold that consists of a single material, these factors can be considered a constant throughout the mold.

For factors that are constant throughout the part of the mold containing a given portion of the casting, Chvorinov's rule becomes a proportional equation in which the time for solidification is proportional to the square of the volume divided by the surface area. In this form, the results of the equation are independent of the type of mold and metal being considered, provided they are the same over the casting section to which the results are to be applied. Furthermore, for the purposes of providing a proper solidification sequence, the actual time for a given portion of a casting to solidify is not needed. In this type of analysis, it is important only to determine the order in which each component solidifies with respect to the other components being studied. By remembering these facts, the proportionality equation discussed above (that is, solidification time is proportional to the volume/surface area ratio) is all that is required to study the solidification sequence of various section components relative to one another.

Consider the components making up the T-section in Fig. 4(d). There are three basic dimensions (*T*, *t*, and *R*) that describe the section, and the section consists of two plates labeled T and t whose intersection forms another section labeled J. Assuming from a thermal point of view that the formed section is infinite (that is, the ends of plates in the *z*-direction perpendicular to the drawn section do not influence the solidification of the section or the plates), the volume of the section and plates can be determined from the perimeter and enclosed cross-sectional areas of the sections. Such an assumption is valid if the thickness of the section in the *z*-direction is five times the thickness of the thickest section.

For this case, the volume of the plate having a thickness *T* is equal to T^2. The surface area is equal to 2*T*; therefore, the volume-to-surface-area ratio (casting modulus) of the plate is *T*/2. Similarly, it can be shown that the casting modulus for the other plate making up the section is *t*/2. To study the relationship of the solidification sequence of all the components making up the T-junction, all that remains is to develop the casting modulus for the junction of the two plates referred to as J in Fig. 4(d). Assuming that the thermal effect of the junction extends one plate thickness beyond the tangent point of the radii (that is, the junction length along the t plate is considered to be 2*t* + 2*R* + *T*), the volume and surface area of the junction can be written as follows:

$$Volume = 2r^2 + t(2R+T) + RT + T^2 + \frac{(4R^2 - 3.1416R^2)}{2} \qquad \textbf{(Eq 1)}$$

$$\text{Surface area} = 4t + 2R + T + 3.1416\,R + 2T \qquad \textbf{(Eq 2)}$$

Therefore, the casting moduli for the T-junction J and the plates making up the junction are as follows. For the t-plate, the casting modulus is $t/2$. For the T-plate, the casting modulus is $T/2$. For the J section (the T-junction itself), the casting modulus is:

$$\frac{2r^2 + 2Rt + tT + RT + T^2 + 0.4292R^2}{4t + 3T + 5.1416R} \quad \textbf{(Eq 3)}$$

Based on Eq 1, 2, and 3 and the design parameters of *R*, *t*, and *T*, it is a simple matter to determine the solidification sequence of a T-section. By entering the dimensions of *t*, *T*, and *R* into the respective equations and calculating the resulting casting moduli, one obtains the solidification sequences based on the design parameters of the T-section and the plates making up the section. The results of such calculations for values of $R = 0$ and $R = 2.0$ for plate thicknesses from 0 to 10 are shown in Fig. 6(a) and 6(b).

A series of T-section design curves for *R* values of 0, 0.25, 0.5, 1.0, and 2.0 for values of *t* and *T* from 0 to 2 are presented in Fig. 6(c). For design curves not covered, one can easily use Eq 1, 2, and 3 for the junction and the respective plates of thickness *t* and *T*.

Equations 1, 2, and 3 are not specific for the use of inches only, because the form of Eq 1, 2, and 3 and the results are purely numeric. Thus, one can use metric units such as centimeters or millimeters as the dimensions and use any of the graphs directly. Equations 1, 2, and 3 also allow the user to convert any of the graphs to any radius. All that is needed is to determine a ratio of the desired radius to a specific radius on the graph and then use this ratio as a scaling factor to adjust the scale of the two dimensional axes *t* and *T*. For example, assume a graph for a 1 in. or 1 cm radius was needed but only Fig. 6(b) was available. Because the scaling ratio for this case is $\frac{1}{2}$, the *T* dimension of the horizontal axis could be labeled 0, 1, 2, 3, 4, and 5, replacing the 0, 2, 4, 6, 8, and 10 currently on the graph. By following this same procedure for the *t* dimension on the vertical scale, one would produce the graph form necessary for the $R = 1$ problem. Thus, the user of these graphs is not limited to the cases presented, and any combination based on the required *R* value can be used.

The following example further illustrates the use of such curves. Figure 4(a) shows the cross section of a hub casting. With reference to Fig. 4(d), it can be determined that the T-section dimensions are as follows:

- $T = 4$ in.
- $t = 6$ in.
- $R = 0$

Note that T-sections with $R = 0$ are not recommended, because of the stress concentration and the potential for hot tears or cracks.

By referring to Fig. 6(a) and plotting the *T* and *t* dimensions, it can be seen that for this design the $T = 4$, $t = 6$ point on the graph lies in the zone of the graph labeled T-t-J. Thus, based on casting modulus, a solidification sequence of T-t-J would be expected. Because the J portion of the section is the last to solidify, the riser would have to be attached to this portion of the casting. Therefore, because of the solidification sequence imposed, a riser placement scheme similar to that shown in Fig. 4(c) must be used. However, this type of solidification sequence is generally undesirable, and design alternatives should be considered. Some metal can be removed from the junction, or the *T* dimension should be increased somewhat above 8 in. as either a pad (Fig. 5) or a complete increase of the entire flange of the casting. Yet another approach would be to increase or decrease the hub thickness dimension *t*.

These are a few of the potential solutions to the problem that are available to the design engineer. The designer knows both the stresses and the environment in which the part will function; therefore, the designer alone must make the final decision on any proposed changes. It is important to inform the design engineer of a potential manufacturing problem early in the designing process while flexibility still exists, not at later stages when the flexibility is lost.

The previous example considered a T-section in which the radius *R* was 0. This case is somewhat academic because, in terms of well-known design principles, the design discussed leads to undue stress concentrations at the sharp corners. This is to be avoided from the standpoints of pure design and casting manufacture. Because of the contraction of the metal as it

solidifies and cools, such stress concentration can lead to cracking of the casting (either hot tearing or cold cracking). *Therefore, the first rule of economical casting design is to use generous fillet radii whenever possible*.

Figure 6(b) was obtained by following the same procedure discussed for the development of Fig. 6(a). In Fig. 6(b), the radius dimension *R* of Fig. 4(a) was set to 2 in. A comparison of Fig. 6(a) and 6(b) reveals the effects of adding a 2 in. fillet radius. Very little difference in the solidification sequence is observed at the heavy plate thicknesses (the upper right-hand corner of the graph). However, in those designs in which thin plates are used (the lower left-hand corner of the graph), there is a much stronger tendency for the plate junction J to be the last portion of the T-section to solidify. It must be remembered that Fig. 6(b) represents all the design variations of the T-section from *T* and *t* = 0 to *T* and *t* = 10 to which a constant 2 in. fillet radius is applied. A series of design curves for various fillet radii are shown in Fig. 6(c).

Whenever any fillet radius is applied, an effect on the solidification sequence must be expected because the fillet radius causes an increase in volume and a decrease in surface area in the vicinity of the fillet. The increase in volume and the decrease in surface area caused by the use of a fillet are only functions of the fillet radius; therefore, the effect of adding a given fillet radius to the casting modulus of the t-junction is a constant based on the radius. Furthermore, because the casting modulus of the junction is a function of the plate thickness, the addition of a 2 in. fillet to thin plate designs increases the casting modulus of the junction far more with respect to the modulus of the plate than for thick plates. Thus, the effect of the 2 in. fillet addition is far greater in thin plate designs than in heavier plate T-sections.

Using these graphs, the designer can recognize potential problem areas by remembering *the second rule of casting design for economy, which states that the last place of any casting to solidify must be accessible for riser placement*. Ideal riser placement is at the parting line and at the outer perimeter of the casting. If this rule is not followed, weld repair, scrapped castings or sudden catastrophic failure could result, and these outcomes will cause increased casting costs, delivery delays, and a serious danger of premature failure.

X-Sections

Another simple shape of importance to designers is the X-section. However, for X-sections, the designer must consider two conditions in order to cover all the possible design combinations that might be encountered.

Equal Opposite Legs. The first type of X-section design is that in which the opposite legs of the X are equal. The model for this case is shown in Fig. 7. The solidification sequence curves of this model, which contain fillet radii of *R* = 0 and *R* = 2, are presented in Fig. 8(a) and 8(b). Design curves for various fillet radii are shown in Fig. 8(c). As before, the casting modulus equations for the plates making up the X-section are *T*/2 and *t*/2. For X-sections in which the opposite legs of the section are equal, the casting modulus for the J- or X-junction is as follows:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{2t^2 + 2T^2 + 2Rt + 0.8584R^2}{4t + 4T + 6.2832R} \qquad \textbf{(Eq 4)}$$

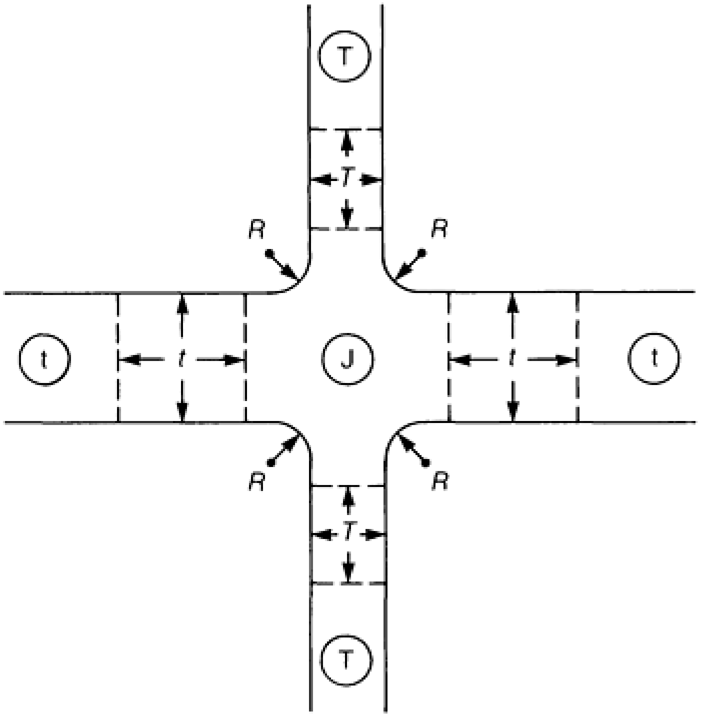

Fig. 7 Model of X-section with opposite legs equal. See Fig. 8 for solidification sequence curves.

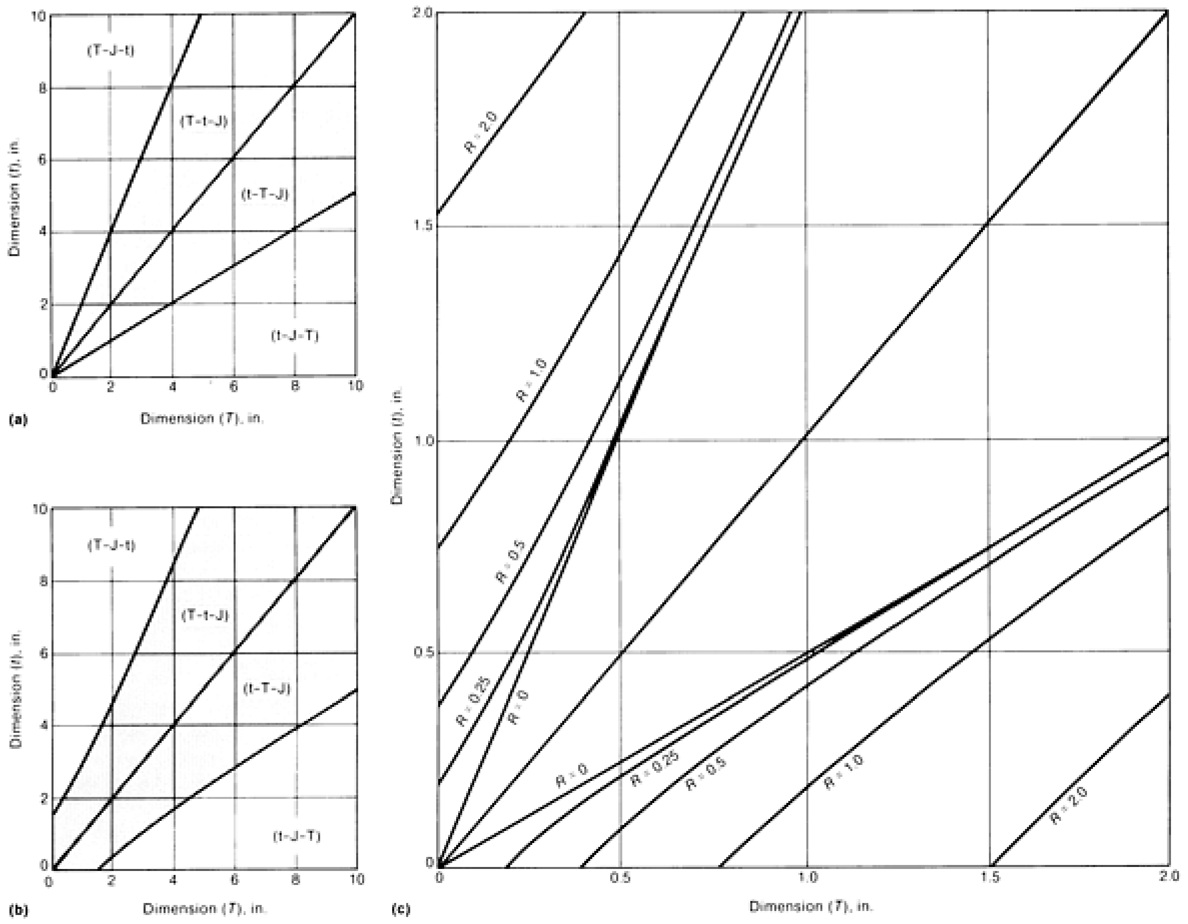

Fig. 8 Solidification sequence curves for X-section with opposite legs equal (see Fig. 7). (a) *R* = 0. (b) *R* = 2.

(c) Composite of design curves for various fillet radii.

Because of the greater volume of metal at the junction, there are far more designs in which the J- or X-junction is the last to solidify compared to the T-junction curves discussed earlier. This is why many authors do not recommend the use of X-sections in casting design. However, this type of thinking can often cause excellent opportunities for cost reduction to be overlooked.

Merely because the junction portion of an X, T, L, or boss section solidifies last does not mean that the section is poorly designed. The most economically produced design will often take advantage of this very fact. The junction of a section solidifying last becomes a problem only when it violates the second rule of economical casting design; that is, it leaves that portion of the casting solidifying last in an inaccessible area for riser placement. Although accessibility for riser placement is essential, limiting the number of risers required can further improve economy by design. *Thus, the third rule for economical design is to create designs requiring as few risers as possible.*

Solidification proceeds through the casting in what is called the solidification or feeding path. Each feeding path will require a riser, and each riser adds to the cost of the casting. Less expensive and better-quality castings will result from reducing the number of feeding paths and ensuring that the end of each feeding path is accessible. Therefore, designs in which the junctions solidify last can be advantageously used to combine feeding paths, thus reducing the overall cost while increasing the quality of the part.

Three Legs Equal. The second type of X-section is shown in Fig. 9. In this design, three of the plates constituting the section have the same thickness. The corresponding solidification sequence curves for this case in which R = 0 and R = 2 are shown in Fig. 10(a) and 10(b), respectively. There is a difference in the curves across the isothickness line running diagonally from left to right on the curves. The upper left portions of the curves represent those designs in which a thick plate of dimension t is being chilled by the three equal thickness plates whose dimensions are T. This portion of the curve is similar to the curves discussed previously and is fairly straightforward.

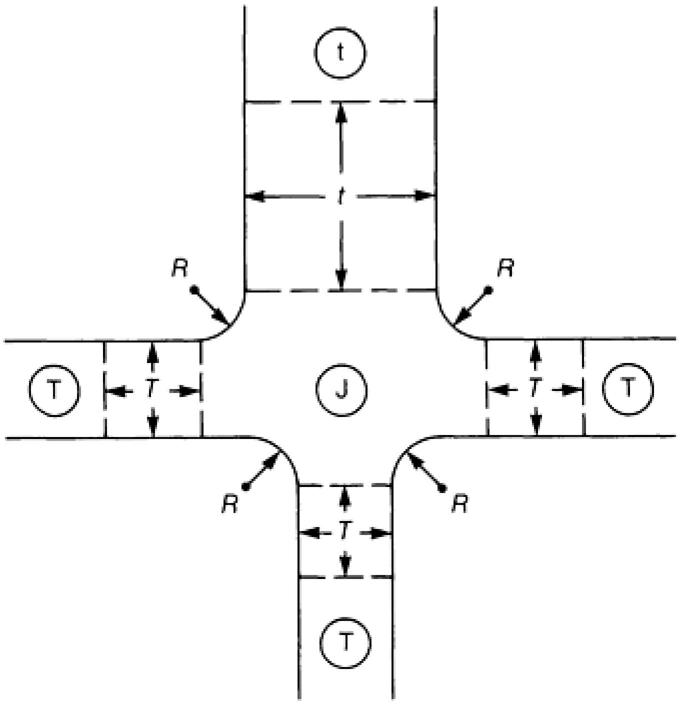

Fig. 9 Model of X-section with three legs equal. See Fig. 10 for solidification sequences.

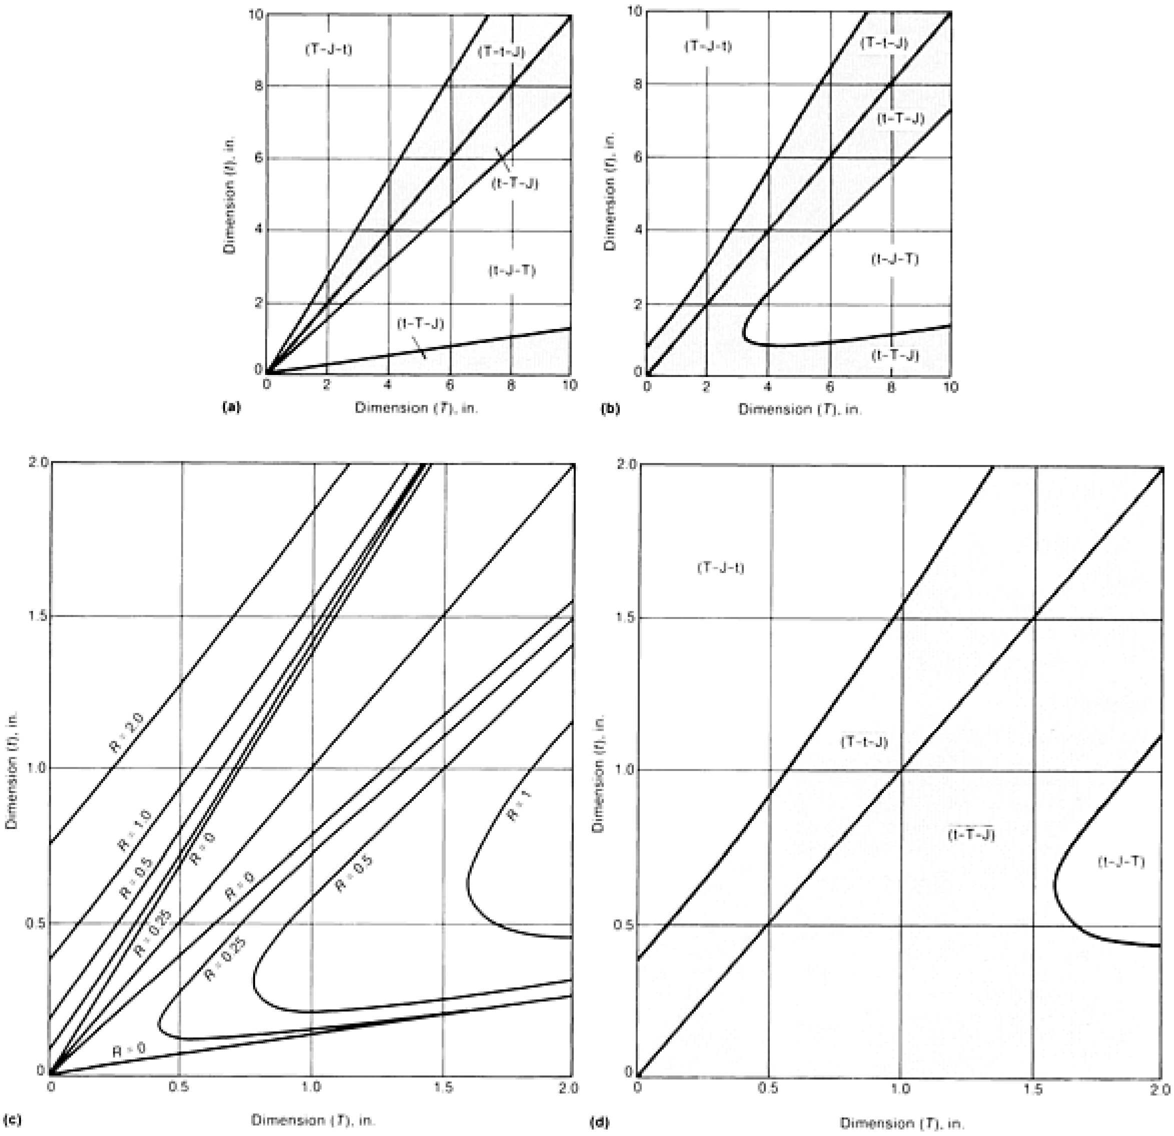

Fig. 10 Solidification sequence curves for X-section with three legs equal. (a) *R* = 0. (b) *R* = 2. (c) Composite of design curves for various fillet radii. (d) One segment (*R* = 1) of the composite design curve shown in (c).

The lower right-hand portion of the curve represents the case in which a T-section is to be chilled by the addition of a thin plate. In this case, if the thin plate is too small, it does not provide sufficient surface area to chill the T-junction, thus causing it to solidify before the plates making up the T-junction. This is the t-T-J sequence portion near the horizontal axis of the curve. Only when the t plate provides sufficient surface area to chill the T-junction can the t-J-T sequence be achieved. Finally, as the thinner plate continues to increase, the t-T-J sequence is again encountered.

When one of the legs that make up the X-section has a different dimension than the remaining three legs, two separate casting moduli equations must be used. For the case in which the odd plate labeled t on Fig. 9 is larger than the other three plates labeled T, the following casting modulus equation applies for the resulting J junction:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{2t^2 + 3T^2 + 3RT + Rt + Tt + 0.8584R^2}{5T + 3t + 6.2832R} \qquad \textbf{(Eq 5)}$$

Equation 5 will apply to the upper left corner of the resulting design curves in which *t* is greater than *T*. For the case in which the dimension *T* is greater than *t*, the following casting modulus applies for the J junction:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{6t^2 + 3T^2 + tR + 3Rt + 0.8584R^2}{11T + 7T + 6.2832R} \quad \textbf{(Eq 6)}$$

The effect of adding a 2 in. radius to this X-section is identical to that seen on the T-section previously discussed. This can be demonstrated by comparing Fig. 10(a) and 10(b). Design curves for various fillet radii are shown in Fig. 10(c) and 10(d).

L-Sections

The third basic shape of importance to design engineers is the L-section. The model of an L-section is shown in Fig. 11. Two different radii are used to describe this section: internal radius *r* and external radius *R*. Because two different radii are required in describing this type of section, two design cases arise: one in which *R* is greater than *r* and one in which *R* is less than *r*.

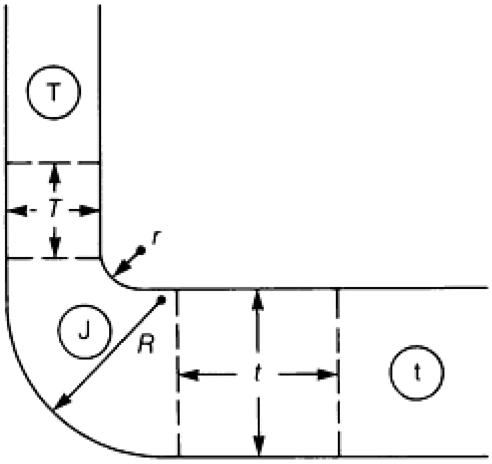

Fig. 11 Model of L-section for *R* > *r*. Compare with Fig. 12. See also Fig. 13 for solidification sequences.

For the case in which the internal radius *r* is less than the external radius *R*, an L-section similar to that shown in Fig. 11 will result. For cases in which *r* is greater than *R*, L-sections of the form shown in Fig. 12 will result.

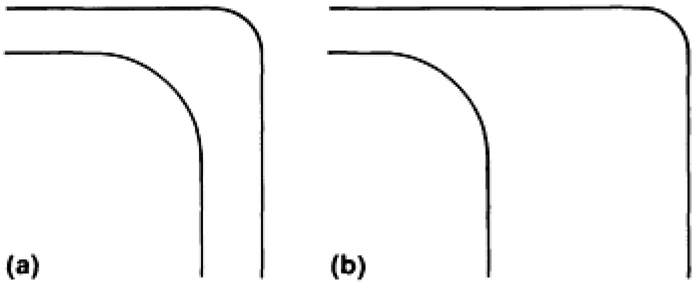

Fig. 12 Two L-section designs that can occur when *R* < *r*. (a) L-section has a higher modulus than the plates when plate thicknesses are nearly equal. (b) Plate thicknesses are very unequal; the modulus of the L-section is less than that of the thick plate.

External Radius Greater than Internal Radius. The casting moduli equations for the J- or L-junction in which *R* > *r* are also a function of the design parameters being considered, and four equations must be used. For $R > t + r$ and $R < T + r$, the casting modulus of the junction is:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{T^2 + t^2 + TR + tr + 0.2146r^2 - 0.2146R^2}{t + 3T + 1.5707r + 1.5707R} \qquad \textbf{(Eq 7)}$$

For $R > T + r$ and $R > t + r$, the casting modulus of the junction is:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{T^2 + t^2 + RT - tr + 0.2146r^2 + 0.2146R^2}{t + T + 2.8584R - 0.4292r} \qquad \textbf{(Eq 8)}$$

For $R < T + r$ and $R < t + r$, the casting modulus of the junction is:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{T^2 + t^2 + Tt + rt + rT + 0.2146r^2 - 0.2146R^2}{3T + 3t + 2.8584r - 0.4292R} \qquad \textbf{(Eq 9)}$$

For $R > T + r$ and $R < t + r$, the casting modulus of the junction is:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{T^2 + t^2 + Rt + Tr + tT + 0.2146r^2 - 0.2146R^2}{3t + T + 1.5707R + 1.5707r} \qquad \textbf{(Eq 10)}$$

Although the sequencing curves for $R > r$ shown in Fig. 13(a) and 13(b) seem complex, the complexity is easily understood by remembering that both the internal and external radii (r and R, respectively) are held constant on any given graph. The first unusual feature of graphs of this type is the forbidden zone, that is, the dark area in the lower left corner of the graph. In this area, L-sections using the radii combinations given in the figure caption are impossible, and the internal radius punctures the external radius (Fig. 14a).

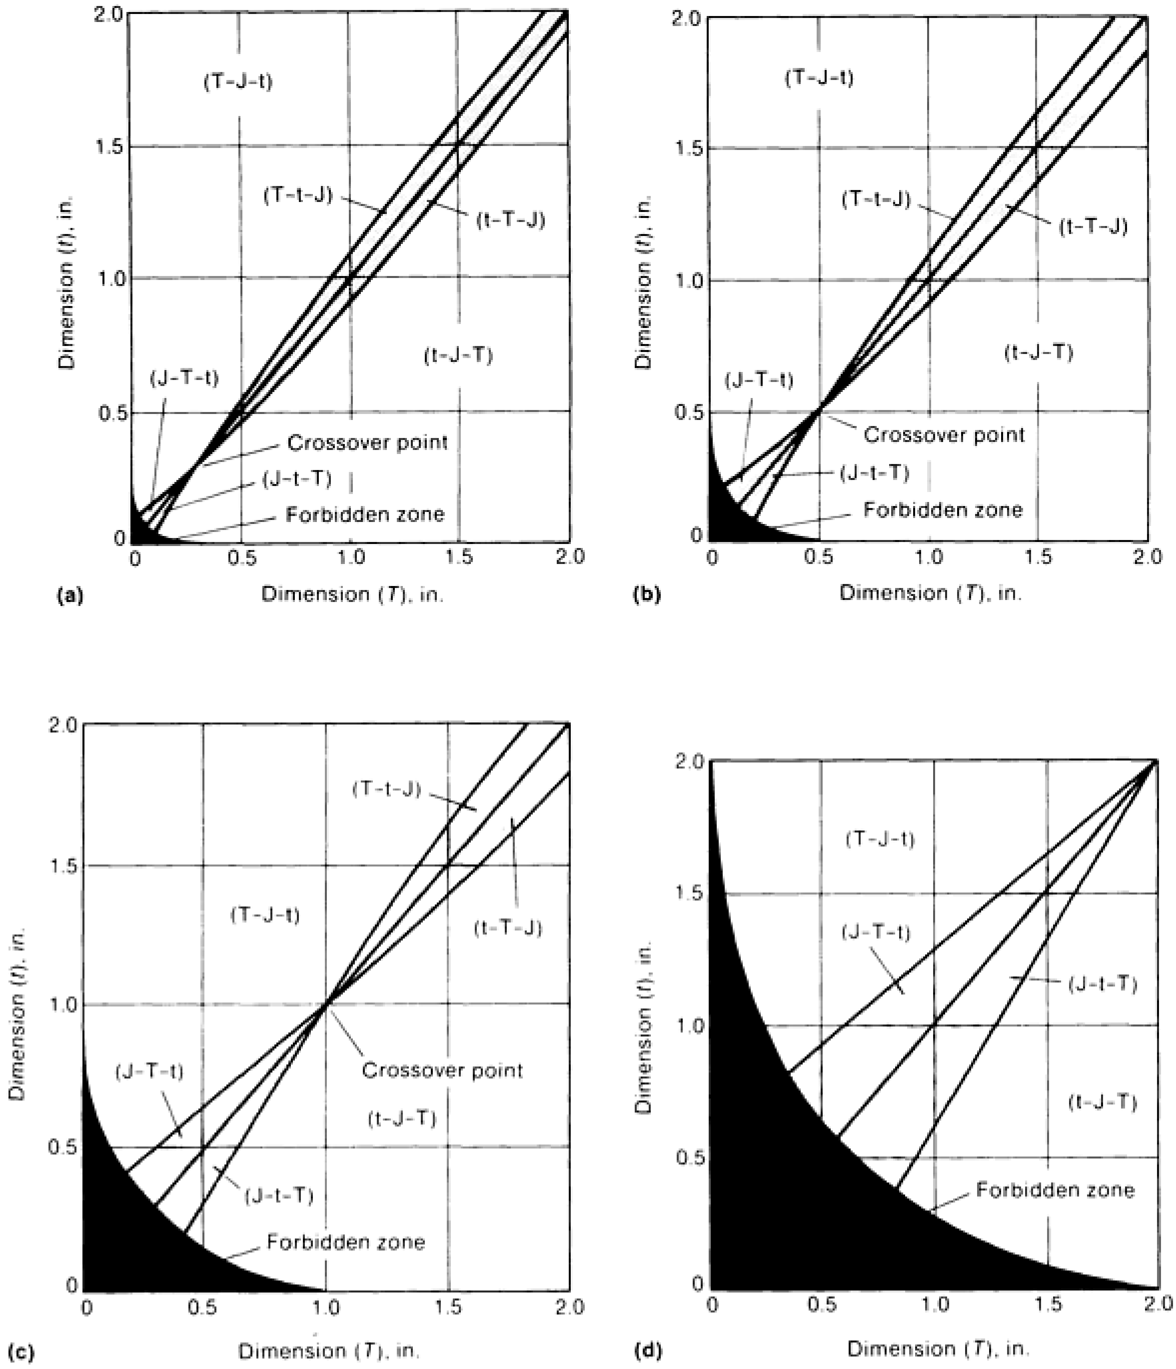

Fig. 13 Solidification sequence curves for the L-section shown in Fig. 11 with $R > r$. (a) $r = 0.25$, $R = 0.5$. (b) $r = 0.5$, $R = 1$. (c) $r = 1.0$, $R = 2.0$. (d) $r = 2.0$, $R = 4.0$.

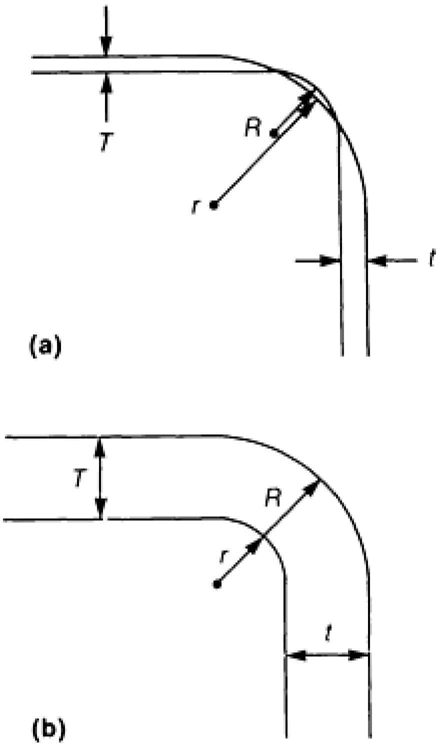

Fig. 14 L-section designs that fall in the forbidden zones of Fig. 13. (a) Internal radius *r* punctures external radius *R.* (b) Crossover point occurs when moduli of all the components are equal--in this case at $t = T = 0.25$, as shown in Fig. 13(a).

Another unusual feature of these curves is the crossover point, which in Fig. 13(a) occurs at $t = T = 0.25$. At this point, the casting moduli of all the components of the L-section (t, T, and J) are equal. This occurs because a uniformly thick plate results from these particular design conditions, as shown in Fig. 14(b). The crossover point always occurs when $t = T = (R - r)$ for L-sections in which $R > r$. The effects of increasing the radii can be seen by comparing Fig. 13(a) with 13(d).

External Radius Less Than Internal Radius. If the external radius *R* of an L-section is designed to be less than the internal radius *r*, completely different sequencing curves result. The simplified geometry of L-sections in which $r > R$ also considerably simplifies the casting modulus of the resulting J- or L-junctions. Because of the geometry, only the following casting modulus equation is required:

$$\frac{Volume}{Surface\ \text{Area}} = \frac{T^2 + t^2 + rT + rt + Tt + 0.2146r^2 - 0.2146R^2}{3T + 3t + 3.5707r - 0.4292R} \quad \textbf{(Eq 11)}$$

Curves for L-sections with two such $R < r$ combinations are shown in Fig. 15. No crossover point occurs, nor does the curve contain a forbidden zone. The reasons for this can be determined by noting the features of such L-section designs (Fig. 12).

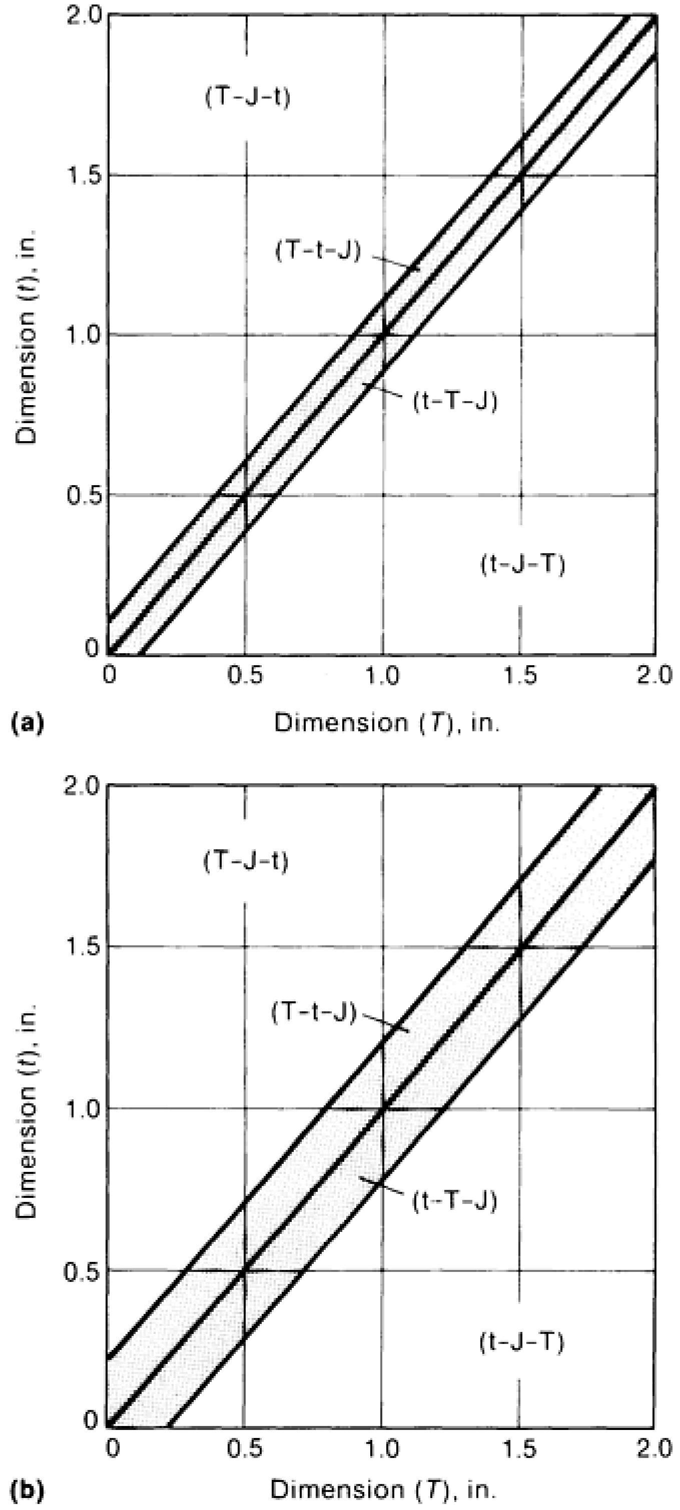

Fig. 15 Solidification sequence curves for L-sections with *r* > *R*. (a) *r* = 0.5, *R* = 0.25. (b) *r* = 1, *R* = 0.5. Compare with Fig. 13.

Feeding

Solidification of Flat Plates. The L-, X-, and T-sections discussed to this point consist of a combination of plates and the junctions themselves. Any discussion of casting design must also consider the solidification of simple flat plates as well as their more complex junctions.

The solidification of metals does not occur as a flat moving front, but rather as a series of protuberances ranging in shape from cone points to very complex, branched shapes called dendrites. The complexity of these shapes is a function of the speed of growth of the front, the cooling rates involved, and the composition of the alloy. For the purposes of design, the nature of these shapes concerns the ability of metal to develop a feeding path through uniform flat plates or cylinders. Because these protuberances in most alloys of interest at commonly found growth rates and thermal gradients usually manifest themselves as dendrite-type shapes, they can provide a significant barrier to the continued flow of metal. This phenomenon can lead to shrinkage defects in castings because the feed metal supply cannot reach into the solidifying front at which the liquid-solid contraction is causing a feed metal demand. In particular, this effect influences casting design in the area of feeding distances.

In a simple plate having a constant thickness *T*, a set of solidification fronts will move from each of its surfaces until they meet at its centerline. However, as these fronts move together, their dendritic character begins to cause a blockage of the metal flow from a feeding path, which will result in some degree of shrinkage. This phenomenon has been quantified, and it has been determined that the ability of a riser to feed through a plate is very limited (Ref 1). Often, sound casting production can be achieved only for a few thicknesses along the plate even when chills are used. This is very important because long flat plates will require extensive risering for this reason alone. This limited ability to feed can be overcome by simply reducing the tendency for the front closure to occur as a straight line. This is accomplished by using a plate whose cross section is not uniform in thickness but is continuously changing in thickness, such as the wedge casting discussed earlier.

Another way of accomplishing the same objective without changing the geometry of the plate is to alter the thermal shape of the casting through the use of an insulating or chilling material to change the rate of heat extraction. Still another way of accomplishing feeding through an extensive constant plate thickness is to create a series of feeding paths close to each other.

Consider a circular flat plate with a single riser at the center of the plate, as shown in Fig. 16(a). If the feeding distance creates a problem, multiple feeding paths could be considered as a solution. The design of feeding paths involves the development of shape geometries that permit solidification to be directed to a portion of the casting that can be easily fed by a riser.

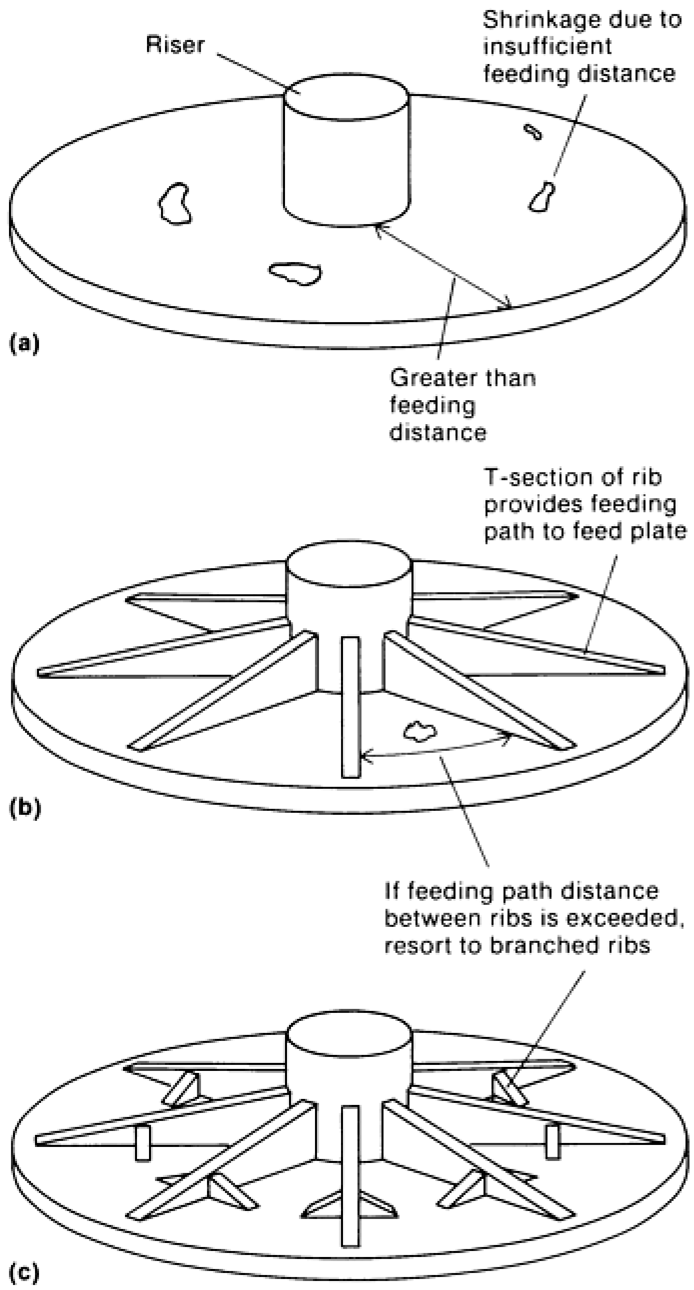

Fig. 16 Feeding path design considerations. (a) Circular flat plate with a single riser. (b) Addition of wedge-shaped ribs to ensure proper solidification. (c) Branched ribs to overcome feeding problems at the circumference of the plate.

For this example, it is necessary to create a feeding path to the center of the plate where it can be fed by the riser. If the addition of radial ribs presents no problem, wedge-shaped ribs could be added, with the taper increasing as the rib nears the center of the plate (Fig. 16b). Because feeding distance is a problem only for continuous-dimensioned flat plates if the distance between these ribs does not exceed the feeding distance for the plate thickness, the ribs will ensure feeding of the plates to soundness. Because the ribs themselves are tapered to create a path to the riser, they should also be sound (free of shrink). If feeding distance again becomes a problem at the outer circumference of the circular plate, the ribs could be branched to ensure that the feeding distance for the flat plate is maintained (Fig. 16c). If the geometry of the rib causes difficulty with the design of the resulting casting, the same idea could be applied through the use of insulating or chilling materials to create the same effect thermally without the addition of the added metal of the ribs. However, because the use of molding materials to create the needed feeding path would no doubt increase the cost and complexity of the solution, it should be avoided if possible.

Solidification of Cylinders. A restriction of feeding distances similar to that in plates also occurs in cylinders. Once again, this can be overcome through a change in the thermal shape by developing a cone shape either geometrically or through the use of chilling or insulating materials. Cylinders, however, do create a new condition.

The new condition of concern is the junctions produced by the intersection of a cylinder and other cylinders or plates. If the cylinders are hollow, it is not necessary to consider them separately, because these conditions can be visualized as L- or T- sections merely revolved about an axis. However, a separate geometric case develops when the cylinder is solid. Figure 17 shows an example of such a case as well as the resulting design curve. On this curve, the solidification sequence is either D-J-T or T-J-D, and no case exists in which the junction J is the last to freeze. For such a junction, either the cylinder acts as a chill for the junction or the plate tends to act as a chill dependent on the cylinder diameter *D* and the plate thickness *T*. Thus, such intersections are straightforward and should cause little problem for designers or casting engineers if the feeding distance relationships and other thermal shape factors for promoting directional design are followed.

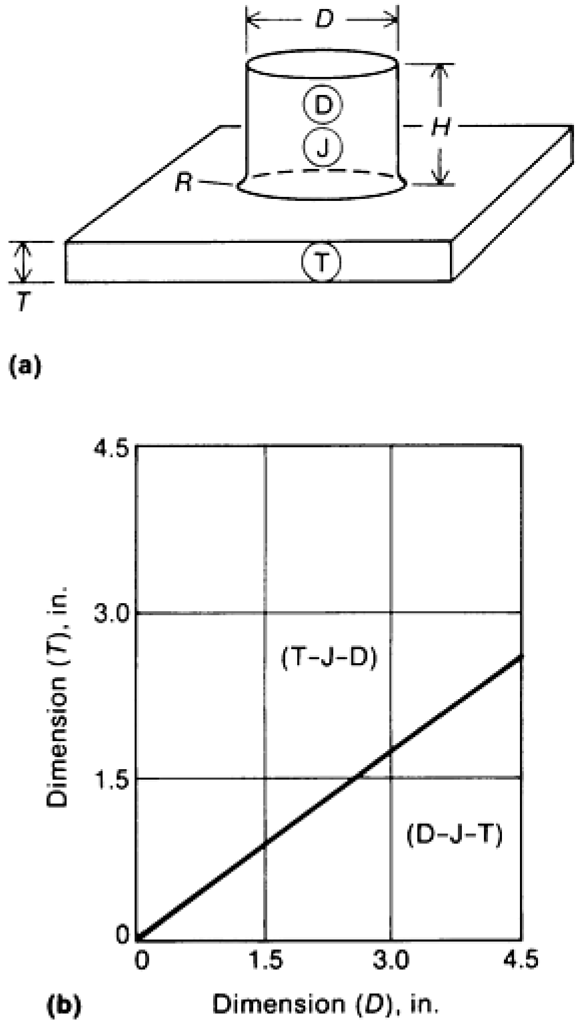

Fig. 17 Example of a design using a solid cylinder (a) and the solidification sequence curves for such a design (b).

Changing Thermal Shape

Thus far, this article has considered the designs of plates, cylinders, and T-, X-, and L-sections, in which all of the components of the mold extract heat uniformly. However, there are many instances in casting manufacture in which this is not the case. Such situations occur during the normal course of the casting process and in some cases are done intentionally to change the solidification sequence--for example, the use of a core or a chill.

Use of Cores and Chills. Cores are often used in casting, but their effect on the solidification sequence of a section depends on the relative heat extractive capability or heat diffusivity differences between the mold and core components. If the heat extractive character of the core components is greater than that of the mold components, the core will tend to act as a chill. This occurs because heat is removed more efficiently from the portions of the casting in contact with the chill than from those in contact with mold components.

More commonly, the diffusivity of the core when made of resin bonded silica sand is lower than that of the green sand mold components, and the core acts as an insulator with respect to the mold components. It must be remembered that the relative heat extractive capacity of the various mold components determines the resulting solidification sequence. The results shown here are independent of the actual mold and cores being considered because the solidification sequence is important in casting design, not the time required for an individual portion of the shape to solidify.

Only in a few rare cases, as in continuous casting and slush casting (the manufacture of hollow castings through decantation of unsolidified liquid), is the actual time for solidification important. In these cases, the actual position of the solidification front at a particular time is important. This is not true for most casting design situations, in which only the sequence of events is important because the order affects the formation of a feeding path. However, the actual time required for an individual component to solidify is usually relatively unimportant if its position in the overall solidification sequence can be determined.

Because of this comparative unimportance of the actual solidification time of a given component, only the relative ratios of the thermal diffusivities of the two materials involved, rather than the actual diffusivity of each, need be considered in the design curves. Thus, to understand the major effects on the design of T-, X-, and L-sections, only two cases must be considered: one in which one mold component is insulating with respect to the other, and a second in which one component has a chilling effect compared to the other. By convention, the diffusivity ratio is always defined as the ratio of a material divided by the diffusivity of the mold. For example, in a green sand mold, the ratio is the diffusivity of the non-green sand component and the diffusivity of green sand, and for a permanent mold application, the ratio equals the diffusivity of a given component/diffusivity of die material.

If one mold component is insulating with respect to the mold material, the diffusivity ratio would be less than 1. A common condition of this type exists for the case in which a resin bonded solid sand core is placed in a green sand mold. The diffusivity ratio would be approximately 0.85 for this case. However, as stated above, the actual materials involved are relatively unimportant provided the same diffusivity ratio exists; the principal concern is the ratio of diffusivities rather than their actual values.

L-Sections. Before discussing the design curves for L-sections, it is important to consider the geometric consequences of such placements. An L-section is shown in Fig. 18(a). In such a section, there are two possible positions, A and B, that might be occupied by the insulating material. The basic difference between these two possible placements has to do with the amount of casting surface area exposed to each. For placements of insulation material in the inner corner (the A position), less area at the J-junction is exposed to the insulation material per unit volume than is exposed along the plates making up the section. This is important because one might expect the placement of insulation material along a junction to slow the solidification of the section.

Fig. 18 Model for an L-section (a) cast using two different molding materials A and B. (b) Solidification sequence model for L-section shown in (a) in which the insulating material is in the A position; *r* = 0.25, *R* = 0.5, diffusivity of mold material A = 2, diffusivity of mold material B = 1. (c) Baseline curve for comparison with Fig. 18(b), 19, 20, and 21 in which *r* = 0.25, *R* = 0.5, A = 1, and B = 1 where insulating materials are the same for positions A and B. See also Fig. 19, 20, and 21.

However, when the resulting L-section design curve (Fig. 18b) for this situation is observed, the exact opposite seems to be the case; that is, there are far fewer designs in which the junction solidifies last. This occurs because in position A the material extracts heat differently from the junction than the material along its outer area (position B). Because a greater percentage of surface area is contacted by a material in position A along the plates making up the L-section than from the junction itself, the plates are insulated to a greater degree than the junction. This means that insulation material placed in the A position tends to act as a chill from the point of view of the junction with respect to the plates making up the section. This occurs because a greater effect of insulation is experienced by the plates due to the increase in surface area exposed to the insulation material than by the junction. This results in a slowing of solidification of the plates more than its effect on the junction. Note that there are fewer designs in which J solidifies last in Fig. 18(b) than in Fig. 18(c), in which the mold (insulating) materials are the same for the A and B positions.

A similar apparent reversal of the expected effect when a chilling material is placed in the A position of an L-section can be seen in Fig. 19 for a relative diffusivity ratio of 2.0. Once again, the chill has a greater effect on the plates making up the L-section than on the junction itself. Such chill materials, when placed in the A position, tend to act as insulation materials from the point of view of the L-section. That is, because the plates are chilled to a greater degree than the junction due to the exposed surface area to the chill, chill placement in the A position creates more designs in which the junction tends to be the last portion to solidify, as can be seen in Fig. 19.

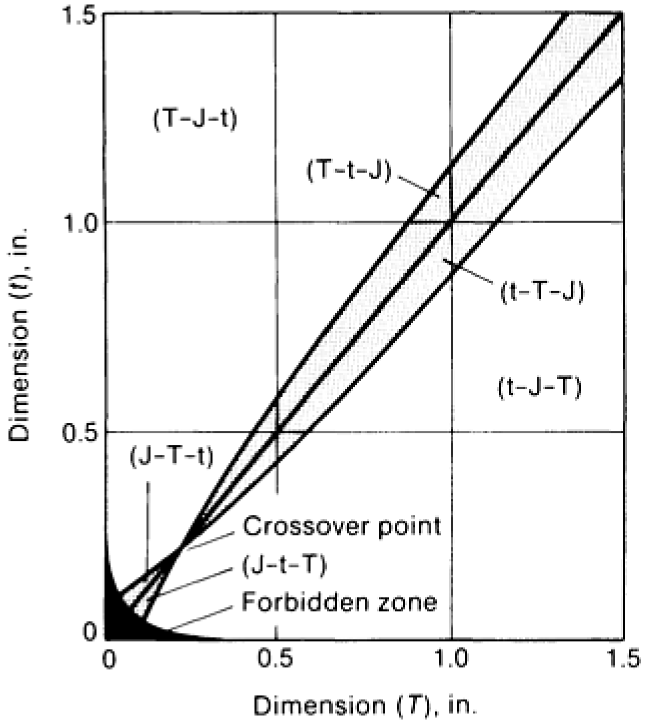

Fig. 19 Another solidification curve for the L-section shown in Fig. 18(a) in which a chill has been placed in the A position. In this case, *r* = 0.25, R = 0.5, A = 2, and B = 1 . See also Fig. 18(b) and 18(c), 20, and 21.

If material having an insulation character is placed in the B position of an L-section, it contacts a greater amount of surface area to volume in the junction than is contacted by the plates making up the section; the result of this is the reverse of that discussed for materials placed in the A position. This placement is illustrated in Fig. 20. Because the insulation effect is greater in this case on the junction due to the greater surface area contact, it creates more designs in which the L-

junction solidifies after the plates. The effect of a chill placed in the B position can be seen in Fig. 21. It is clear from Fig. 18 that, because the chill affects the junction to a greater degree than the plates, the resulting design curves contain more designs in which the junction is the first to solidify. In addition, a radius in the A position placements tends to increase the area in contact with materials in the A position. However, external radii tend to lessen the surface area in contact with a material in the B position.

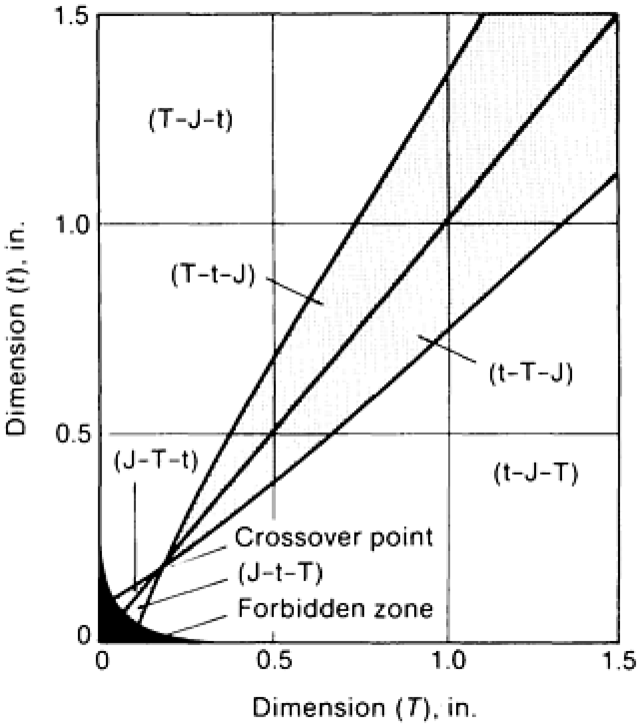

Fig. 20 Another solidification curve for the L-section shown in Fig. 18(a) in which the insulating material has been placed in the B position. *r* = 0.25, *R* = 0.5, A = 1, and B = 0.85. See also Fig. 18(b) and 18(c), 19, and 21.

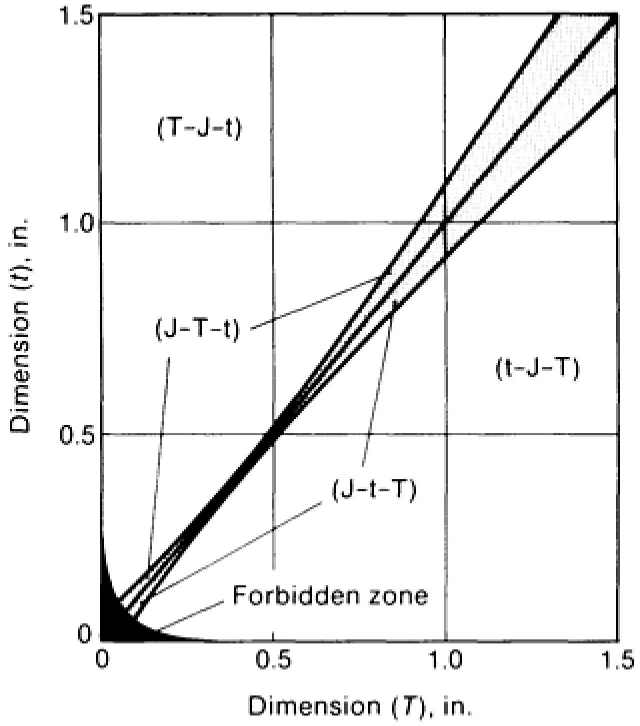

Fig. 21 Another solidification curve for the L-section shown in Fig. 18(a) in which a chill has been placed in the B position. *r* = 0. 25, *R* = 0.5, A = 1, and B = 2. Note that there is no crossover point in this figure. See also Fig. 18(b) and 18(c), 19, and 20.

T-Sections. In the case of a T-section, there are three potential positions in which insulating or chilling materials can be placed, namely, positions A, B, and C, as can be seen in Fig. 22. The T-shape causes several interesting effects. The first of these is similar to that observed for the L-sections. Materials placed in either the A or B position have a greater influence on the plates making up the section than on the T-section itself. Similarly, material in the C position has a greater influence on the solidification of the T-junction than on the plates making up the section.

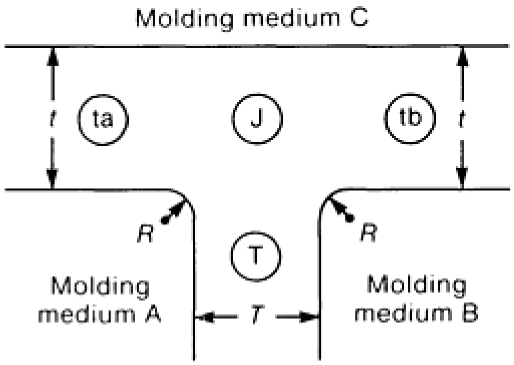

Fig. 22 Model of a T-section cast using three different mold materials. See Fig. 23, 24, and 25 for possible solidification sequences.

These effects are similar to those discussed for the L-sections, but because of the particular geometry involved in a T-section, several others also occur. For example, when the material in the C position is different from that in the A and B positions, the effects on the plates ta and tb are indistinguishable (Fig. 23). If the materials in the A and B positions are different, there will be a difference in the solidification of the two halves of the cross plates ta and tb. Figure 24 illustrates this effect, in which each of the plates ta and tb are shown to provide an independent section on the design curve. This effect is a result of the imbalance of the heat extraction across the intersecting plate labeled *T* in Fig. 22, and it is also evident in the use of chilling as well as insulating materials (Fig. 25). In addition, if A and C or B and C are similar materials, an imbalance still exists across the intersecting plate of the T-section, resulting in a design curve in which the plates ta and tb separate into individual effects (Fig. 24 and 25).

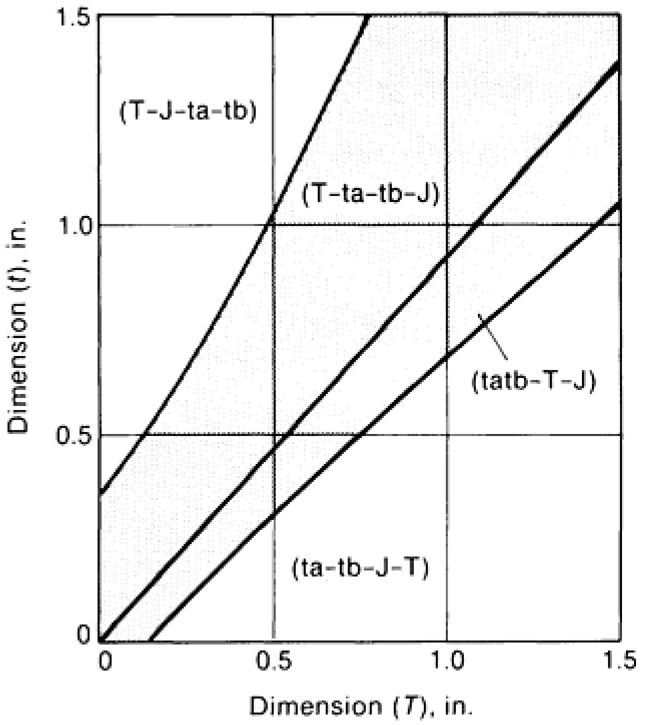

Fig. 23 Solidification sequence curve for T-section shown in Fig. 22 with *R* = 0.5, A = 1, B = 1, and C = 0.85. Note that in one case (area marked tatb-T-J), ta and tb solidify at the same time. See also Fig. 24 and 25.

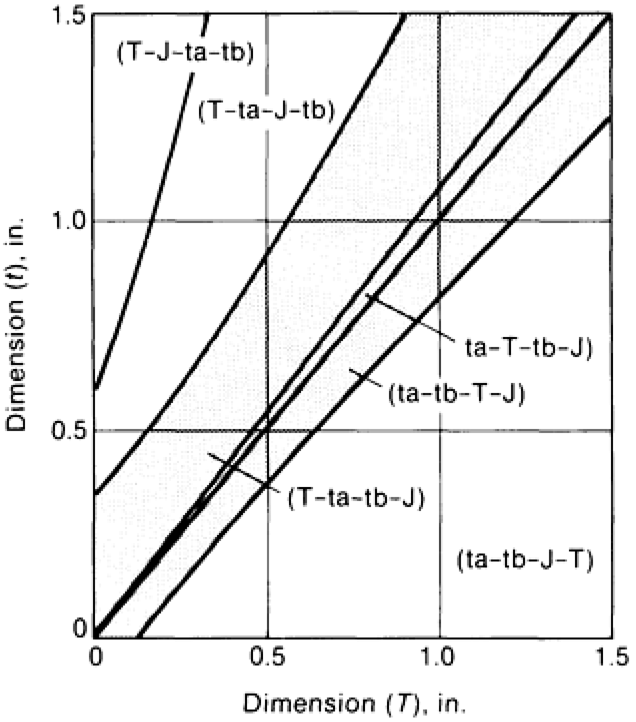

Fig. 24 Solidification sequence curve for T-section shown in Fig. 22 with *R* = 0.5, A = 1, B = 0.85, and C = 1. See also Fig. 23 and 25.

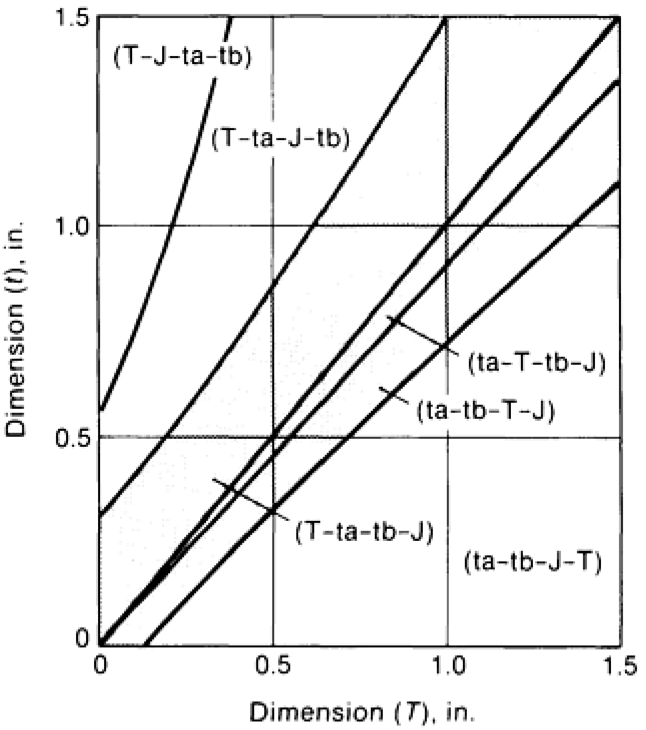

Fig. 25 Solidification sequence curve for T-section shown in Fig. 22 with *R* = 0.5, A = 0.85, B = 1, and C = 0.85. See also Fig. 23 and 24.

X-Sections. In the case of X-sections, a geometry-related effect exists. When an insulating or chilling material is placed in a single position, it influences two of the plates but not the other two plates. It also has an effect similar to placements on L-sections in their inner corner in that the material has a greater influence on the plates making up the section than on the X-section itself. This means that the effects are similar to those seen in L-sections discussed previously; chills tend to act as insulating materials from the point of view of the X-section. In addition, diagonal placements across the section cause a matched effect on all of the plates making up the section.

Therefore, when mold materials of different diffusivities are employed, the results can be predicted, but geometric effects can often produce results that may not be obvious. Thus, to predict the results of a given set of conditions, one must consider the effects very carefully. However, the amount of contact area of each portion of a section in direct contact with a chill or insulator plays a significant role in the eventual solidification behavior.

Computer-Aided Casting Design

Computer-aided design and manufacture (CAD/CAM) systems are becoming increasingly prevalent in industrial design, and their use offers both opportunities and problems for casting designers. These systems greatly reduce the cost of the engineering and design time involved in preparing engineering drawings. When using CAD systems, most designers still use primarily straight lines and chordal parts of circles. This is unfortunate, because the true power of such systems (as related to casting design) would be the full use of the superior design capability of such shapes as sines and parabolas. Designers should make the effort to consider such shapes for both improved stress distribution and better casting designs.

Another problem with the use of CAD/CAM systems is that many companies are using wireframe systems rather than the newer solid modelers. This situation will probably not change for some time, because solid modeler CAD/CAM systems require the designer to work with three-dimensional shapes instead of the more familiar two-dimensional features. Further, the thought process taught to designers is not one of removing area from an existing shape, as required by solid modelers, but rather of developing a shape through a construction procedure. Thus, even though solid modelers are better algorithms for casting design, it is unlikely that they will be extensively used in the near future.

Because wireframes seem to be the preferred technique for the present, designers must recognize and deal with the problems of this algorithm. Wireframe algorithms were designed to create pictures and graphic representations of the

actual three-dimensional shape, not necessarily to produce shapes of true three-dimensional integrity. Until such three-dimensional representations of the desired shape are attempted to be used to create pattern equipment, the problem with these algorithms may not even be recognized. Because the shapes are not truly three dimensional, nonmatches of straight lines and arcs can go unnoticed until the pattern equipment attempts to use the CAD information to cut the pattern. This problem is recognized, and software is available to solve it and similar problems; but such software requires transfer of data from computer-aided design to pattern cutting, which is often difficult since data formats have not been standardized but are computer and software dependent.

If the full cost savings available through CAD-generated pattern equipment is to be realized, improved wireframe algorithms or solid modelers that eliminate these kinds of problems must be developed and used widely. There is also a significant need for better software that truly allows the error-free passage of CAD/CAM data to other computers and other software.

One very effective computer tool is available that uses CAD casting designs to simulate the solidification of a casting through solidification modeling. The developed algorithms of such simulations can be divided into three basic types:

- Those based on classical heat transfer equations
- Those based on finite-element methods or finite-difference methods (FEM or FDM), which are iterative techniques based on classical heat transfer
- Those based on ratios of surface area to volume, as discussed by Kotschi and Plutshack (Ref 2)

Heat Transfer Analysis. The first of these approaches involves attempts to write a single set of heat transfer equations to describe a solidification problem. Because of the complexity of the differential equations involved, this approach has not led to substantial developments. Further, many of the differential equations required for such a solution cannot be solved without significant simplification of the equations; therefore, the potential for this technique is limited until such techniques can be developed. Solutions to these problems have been attempted, but the sheer magnitude and complexity of the equations and iterations required even for supercomputers holds little hope of a viable solution of economic interest to industrial designers. This leaves the two remaining approaches, both of which have provided workable and usable algorithms to solve this problem.

FEM and FDM Analysis. Use of either the FDM or FEM technique involves the development of a three-dimensional grid. The grid blocks are then used as a set of differential elements to calculate the heating and cooling effects. The heat content of each element and its relationship to all the other grid elements in its influence are calculated. In this way, a solution of the entire shape is developed through a series of iterations as a function of time.

Selection of the grid points is critical to the accuracy of FEM or FDM solutions. The greater the accuracy desired from such calculations, the finer the mesh of the required grid. However, the cost of the solution increases dramatically as the number of grid points increases. Thus, to reduce the cost of such solutions, grid points are usually increased in areas of interest or areas having a significant effect on the solution. Similarly, the number of grid points is reduced in areas deemed less significant to the final solution. This has been a major problem in the extensive use of such systems in industry.

Unfortunately, the high-accuracy FEM or FDM systems employed to date have had no grid selection algorithm; therefore, selection is done by personnel skilled in this selection process and in FEM or FDM techniques. Such talent is not readily available, and even when it is, the expenditure of several weeks by several individuals on such a problem is hardly cost effective, especially since this is only 1 of 10 to 15 solutions required to develop an optimum manufacturable casting design.

An example of the cost of finite-element and finite-difference methods is provided by the analysis recently performed on a three-dimensional section of an engine block. A single cylinder (one of six in the complete engine) and its associated valve cavities were studied. Development of the grid and setup of the problem took four individuals a month. The actual analysis required 8 h on a supercomputer. With setup and grid development costs of $10,000 and computer time costs of $25 per minute (a very low estimate), the cost of a single analysis was $22,000. Considering that ten or more analyses may be required to obtain the optimal design, it can be seen that such analyses are not economically feasible for most companies.

The complexity of such problems, and therefore the cost of the solutions, can be reduced by simplifying the problem through, for example, the use of fewer grid points. In this simplified form, particularly in the case of only two-dimensional slices through a critical area, the computer overhead can be greatly reduced, and economically useful solutions can be found.

An example of such software using an FDM approach is the AFSolid Software available from the American Foundrymen's Society. This software analyzes only in two dimensions, incorporating a uniform pattern of grid points for ease of use, and it limits the number of grid points to 5000 as a maximum to hold down the iterative overhead. At the maximum number of grid points, the program can take approximately 15 to 20 min on a high-end desktop computer such as an IBM PS/2 model 80 with a math co-processor without including heat of fusion in the calculation; the program can take 2 h if heat of fusion is included. At this level of sophistication of both hardware and software, economically available answers are practical and cost effective. However, this type of software is of more value to foundrymen than to design engineers because it requires knowledge of the potential solidification problem to such a degree that it can be reduced to a two-dimensional problem.

Unfortunately, to assist design engineers at the drawing board or CAD station, three-dimensional solidification analysis software would be of more value, particularly if it were easily accessed from the CAD software. However, to go from two dimensions to three dimensions with the FDM or FEM approach, the complexity of the problem increases geometrically. For this reason, without substantial increases in hardware and software sophistication and speed, this approach will see only limited use in the future for the three-dimensional problem.

Volume-to-Surface-Area Ratios. Another algorithm was first proposed by Kotschi and Plutshack based on the use of volume-to-surface-area contour lines. These lines were shown to simulate the progression of solidification throughout the cross section of a two-dimensional slice of a solidifying shape. The importance of this approach is in the simplification of the algorithm and the resulting higher speed and lower cost for analysis. It must be remembered that, without low-cost analysis techniques, solidification simulation is of only academic interest. The method can also be applied to three-dimensional shapes with less increase in computer software overhead than with FEM or FDM techniques.

Software based on the use of the casting modulus contours suggested by Kotschi and Plutshack has been developed at the University of Wisconsin through a foundry consortium. This software, called SWIFT, holds much promise as a potential solution to the need for a three-dimensional solidification analysis that is useful to design engineers, but at present the marketing rights to the three-dimensional software are available only to consortium members. However, a two-dimensional system is being marketed, but is not available for MS-DOS or OS/2 machines. Most of the two-dimensional software packages of this type are currently running on VAX and Mini-VAX type machines.

An alternative software program developed for three-dimensional solidification analyses is SOLSTAR*. Although the algorithm is proprietary, the method is based on a type of FDM approach in which the time differential variable is eliminated from the model and each node is in some way compared with other nodes to determine the solidification sequence. The maximum capacity of SOLSTAR is 300,000 node points for a three-dimensional problem. Because of the simplification of the FDM approach, the computer running time for a 300,000 point simulation is reported to be 45 min on a system similar to the IBM PS/2 discussed above.

Only by simplifying the FDM/FEM models or by implementing new approaches can the computer overhead be reduced enough to provide economical solutions that can be used by the majority of the foundry and casting design industry. If the puristic FDM/FEM solutions are all that are available, the benefits of such techniques will affect only those corporations significantly large enough and requiring sufficient production quantities to afford them. This will of course change if supercomputers are available in the future at personal computer prices.

Mold Complexity

Casting solidification is the first major factor a designer should consider in reducing costs. However, there is a second major factor that should also be considered, namely, the mold complexity factor. This is usually related to a requirement for an excessive number of cores. *Thus, the fourth rule for economical casting design is to eliminate as many design features requiring cores as possible.*

The use of cores in the casting process provides a unique feature that is not available in most other methods of manufacture, yet each core required adds to the final casting cost. Thus, only those cores that are absolutely necessary for producing the desired shape should be used if design is to be directed toward lower cost castings.

The first principle that must be understood to eliminate cores is the method of mold manufacture. Even investment and expendable pattern (lost foam) molds require that the molds or tooling used to make the patterns be fabricated as separate pieces or mold halves. For example, in sand processes, a boxlike device called a flask is set over the pattern and filled with sand. The sand is hardened either through chemical or mechanical means, and the pattern is then removed. The pattern must be removed by drawing it away from the mold in a direction perpendicular to the parting line; therefore, the design factors related to this common practice must be considered by the design or casting engineers.

The required factor that assists pattern withdrawal is called draft. As can be seen in Fig. 26, the need to withdraw the pattern from the mold requires that some taper or draft be added to the pattern. Although pattern draft is usually not a problem, the requirement of removing the pattern by withdrawing it in a direction 90° from the parting line does restrict total design freedom if casting costs are to be minimized.

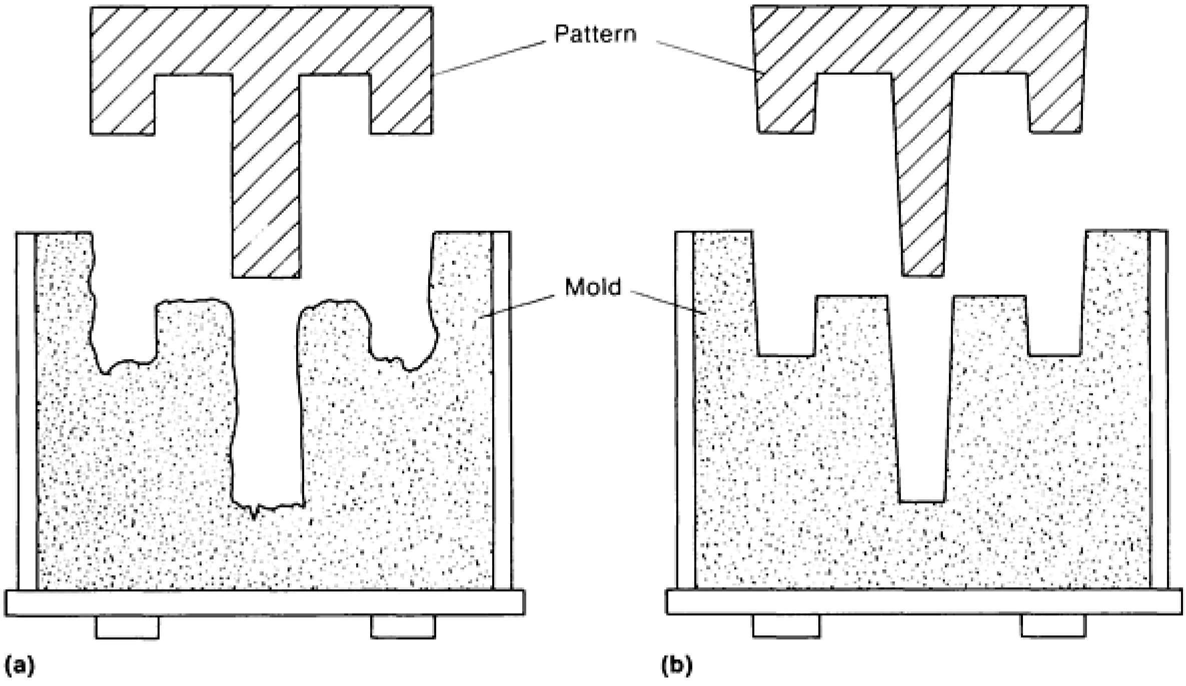

Fig. 26 Use of draft to facilitate withdrawal of the pattern from the mold material. (a) Lack of draft causes damage to the mold when the pattern is removed. (b) Ample draft allows easy pattern removal.

Because the pattern is to be withdrawn straight out of the mold, no protrusions that restrict this movement can be allowed in the construction of the pattern. If the geometry of the part requires such protrusions, there are only two alternatives for the casting engineer:

- Use a loose piece that remains in the mold or core after the pattern is drawn and then is removed separately

- Provide a portion of the pattern that creates a cavity for the setting of a core to create the geometry

The first alternative has limitations in that sufficient room and access to remove the loose pieces must exist. Loose pieces can be used only in moderately low volume casting production because they limit productivity in high production. Furthermore, because of the added handwork and potential for mold breakage during extraction, the use of loose pieces can be expected to increase casting costs even in low production. The second alternative involves the addition of a core and therefore also increases casting costs. The problem and some proposed solutions to undercuts are shown in Fig. 27.

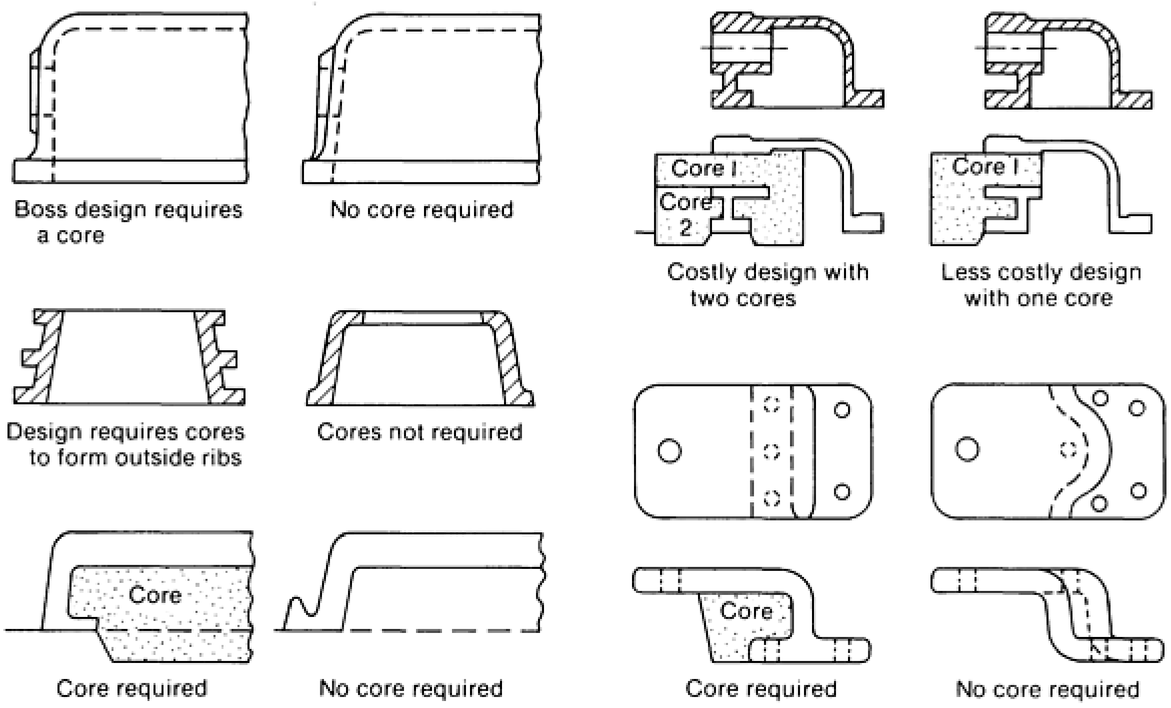

Fig. 27 Restrictions to pattern removal, and some potential solutions.

Finally, because part geometry can require more complex patterns due to irregular parting lines, *the final rule for reducing casting costs is to design straight parting lines whenever possible*. This rule can be seen in practice in Fig. 28. Because much thicker patterns are required for offset parting lines, the cost of the pattern is also greater.

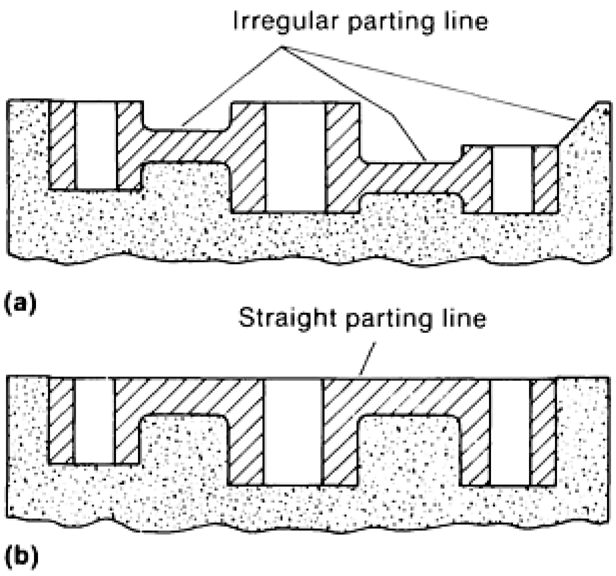

Fig. 28 Designing for a straight parting line to reduce pattern and casting costs. (a) Irregular parting line is a costly design. (b) Straight parting line is less expensive.

The factors that affect the resulting cost of castings and that have sufficient common traits to be independent of the casting process selected include:

- Requirements for surface finish and dimensional tolerances
- The number of castings to be produced
- The material selected for the casting
- The pattern material selected
- Any special or unusual testing/inspection or property requirements
- The casting design
- The casting process selected

Although casting costs are affected by these seven points, casting cost is only one element in the equation that determines the shipping dock cost of the final part headed to the consumer. If subsequent costs, for example, in machining, can be decreased by purchasing a more expensive casting, then the customer must weigh the potential cost savings against the cost of a less expensive casting.

The way in which consideration of casting and pattern costs alone can lead to false economies can be easily demonstrated by an example of the manufacture of a simple cube. The choice of parting line is usually not even considered by a casting customer, but is left to the quoting foundry. Because of this, many casting customers miss opportunities for innovative engineering solutions to shipping dock cost reduction.

For the cube example, there is a need to have the opposite sides of each face of the cube parallel and at right angles to one another. However, the need for draft angles on the tooling to allow removal of the pattern is in opposition to this. If this requirement is not conveyed to the casting supplier, he will undoubtedly quote the pattern equipment with a parting line as shown in Fig. 29(a). This parting line will be chosen by a casting supplier since it will produce the least costly pattern because it is the simplest pattern to make. Casting quotes are often rejected because of pattern prices; therefore, the casting supplier will generally opt for the lowest cost pattern.

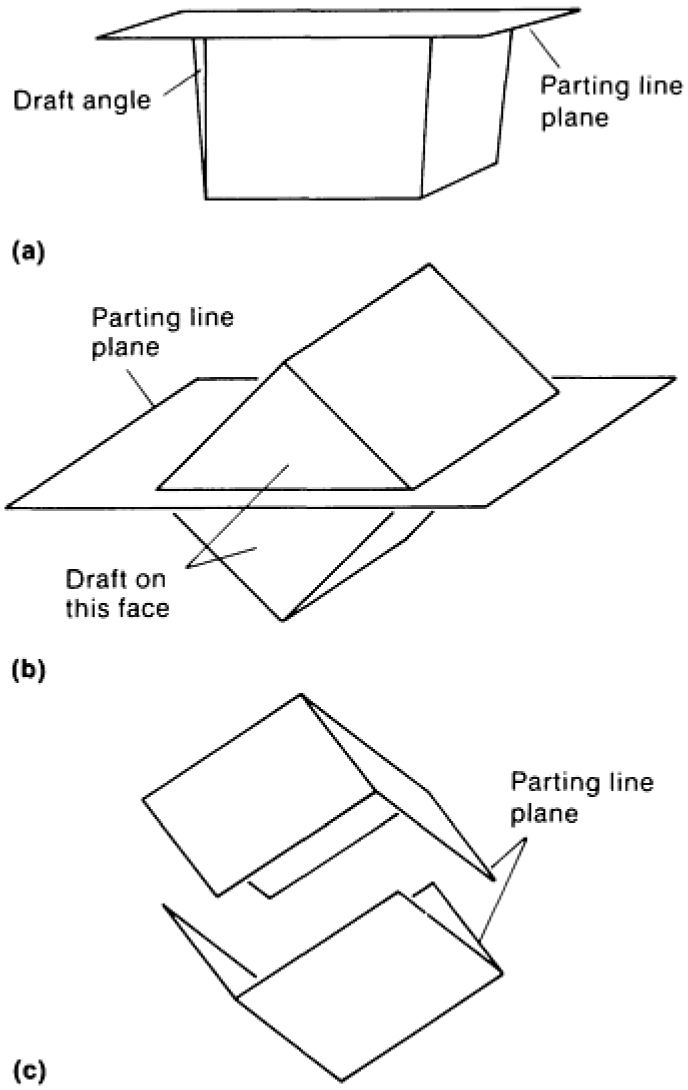

Fig. 29 Parting line options for a cube that must have as many sides as possible parallel and at 90° to each other. (a) Cube parted with four drafted sides is the least expensive option but does not meet design requirements. (b) Parting along the diagonal is a moderate-cost solution that results in four faces in compliance with design requirements. (c) Irregular parting is the most costly option, but is the only one that allows all sides to be parallel and at 90° to each other.

This choice of parting line will produce a cube in which only two of the opposing sides will be parallel to each other. A different parting that results in a slightly more expensive pattern is one in which the diagonal of two sides of the cube is used as the parting line (Fig. 29b). This would produce a part in which four of the opposing sides of the cube are parallel and at right angles to one another. However, the complicated parting line shown in Fig. 29(c) eliminates the need for draft on the tooling. Thus, all six sides of the cube can be made parallel to their opposing sides, and all of the sides will be at right angles to each other. This will be the most expensive pattern because of the complexity of the geometry involved. However, based on the requirement for parallel sides, it is the least costly method of producing the required shape.

The parting line should be considered in the design phase of a casting because of its importance in the final cost of the part. If it is not specified on the drawing, it should be requested to be returned with any casting quote; only in this way can the customer be assured of comparing equivalent manufacturing methods on the returned quotes. The customer should also request information on cores and other related production tooling in a quote. Only with this information can the best alternative be found for very low shipping dock cost. Without such information, the potential of various tooling designs cannot be determined, let alone used to develop a unique manufacturing approach to reduce the shipping dock cost. However, foundries usually consider such information to be proprietary.

If such manufacturing tooling design is of importance to the shipping dock cost of the final component, then it should be specified by the casting customer. This approach is virtually nonexistent in the industrial design of casting components, but it is essential if truly low cost component design is to be achieved.

Dimensional Tolerances and Allowances

Daniel E. Groteke, Metcast Associates, Inc.

Introduction

NO TWO MANUFACTURED PARTS are ever exactly alike, regardless of the process by which they are made. For example, castings made with supposedly identical processing in the same foundry will differ slightly from one another in terms of dimensions. This article will discuss the nature and causes of as-cast dimensional variations and the consequences of these variations in relation to tolerances.

Even more dramatic differences in dimensional reproducibility are seen when two casting sources manufacture the same casting. This is true even if both sources are using the same tooling to manufacture the shape, and it is a reflection of the total process capability of the source. The major variables contributing to the dimensional spread will be discussed in detail for each process method, and although they have some commonality among casting methods, the impact on the final shape can vary greatly, depending on the level of planning and process control exercised. It is acknowledged that the designer cannot exercise total control over the processing variables that cause dimensional variations, but an awareness of their existence and an understanding of their nature will assist him in specifying economically attainable tolerances.

An engineering decision to select a manufacturing process for the fabrication of a particular component involves many factors, including the quantity requirements, available processes, choice of materials, contact with qualified vendors, secondary operations after the initial fabrication, final component delivery schedules, and the basic manufacturing and economic decisions dealing with anticipated component product life. Because the cost effectiveness of a product is of primary concern, the designer is rarely handed a piece of blank drafting paper with a completely free choice of processes to produce any given component. Instead, the choices are limited to a relatively narrow spectrum by the existing corporate facilities of the employer, relations with vendors, production timetables and deadlines, and targeted manufacturing costs.

Therefore, unless a completely new product line is being considered for design and manufacture, general decisions have been made for the designer before the first line is drawn to define the shape of the component. This should not be thought of as an oppressive limitation on product design, because all processes and materials, including the traditional casting processes, are in a constant state of flux in order to improve their competitive positions and to expand their markets. Many previous assumptions about the process capability of any particular casting method should be challenged, whether on the basis of properties obtained in the final shape or even the dimensional reproducibility of any feature. Factors influencing these considerations include the availability of precision tooling, automation of operations to eliminate cost and human factors in production, improvements in materials, and stabilization of processes through statistical process control. Another significant factor is the attitude of the personnel in the producing organization and their interest in working with the designer to maximize process potential while emphasizing cost reduction for the final product configuration.

It is especially important to recognize that achieving the lowest possible cost in the final shape (while meeting function, service conditions, and product life requirements) is the ultimate goal, and not the lowest cost in any initial manufacturing step. Sacrifices can be made in casting cost if they will be reflected as lower finished component prices. For example, additional cores, inspection, or gaging operations; more careful grinding and finishing; and so on, can all be easily justified if they will eliminate or reduce subsequent machining or finishing operations.

Process Variables

To determine the specific casting method that will be used to produce the part to customer specifications, the engineer must consider such process variables as tolerance requirements, process capability, and casting distortion attributable to both metal solidification and mold restraint.

Tolerance Requirements

The engineer is always advised to allow the most generous tolerances consistent with the proper functioning of the part. Normally, the dimensions and tolerances specified will represent a compromise between the function of the casting and the capability of the process selected. The goal of the designer and foundry staff should be to bring the casting as close as possible to a near-net shape as the limitations of function and process will allow.

If the function of a casting permits the assignment of dimensional tolerances that are normal with respect to the capabilities of the process by which the casting is to be made, cost and delivery will not be adversely affected by the attainment of such tolerances. If the tolerances chosen are not realistically matched to the casting process, higher costs and delivery delays will almost certainly be the result. The producing foundry will experience higher scrap in the manufacture of the shape or will necessarily add gaging and straightening operations to provide castings that meet the requirements. In extreme cases, a casting may not be producible in the initial foundry chosen to the close tolerances assigned. This will require selecting another foundry as vendor of the part, with all of the attendant delays and possible retooling costs.

It should be noted that many of these problems can be avoided by a free exchange of information with the casting source. If the foundry engineers are aware of the performance criteria for the final shape and the manufacturing steps or operations that are required to bring it to that stage, it is possible that the total cost of the final product can be significantly reduced if the full capabilities of the process method are utilized. This can be especially true if the casting source is challenged to produce a shape that meets the criterion of maximum economy for the level of function provided, and not merely the lowest cost casting. With the enhanced process capability of all casting methods, many users are finding that a small additional investment in the price of the cast shape can minimize secondary processing expense and result in a lower cost final component.

An example of the potential savings is illustrated in Fig. 1, which shows bronze end cover casting used on a chemical reactor. The casting requires a series of flange mounting holes machined/cast around the outer circumference to assemble the cover to the main body of the reactor. When faced with the decision to machine the holes on a numerical control (NC) setup or to attempt to cast them to size using green sand cores formed directly in the molding operation, the engineers had an easy choice. The savings associated with casting the holes and eliminating a turning operation on the outside diameter are listed in Table 1.

Table 1 Cost differentials in bronze end cover

Item	**Machined casting**	Cored casting
Metal	$61.09	**$57.75**
Melting expense	6.80	**5.77**
Machining	8.75	**. . .**
Cleaning room	. . .	**2.08**
Scrap/rework	. . .	**0.60**
Total	$76.64	$66.20

Cost savings of cored casting over machined casting = $10.44

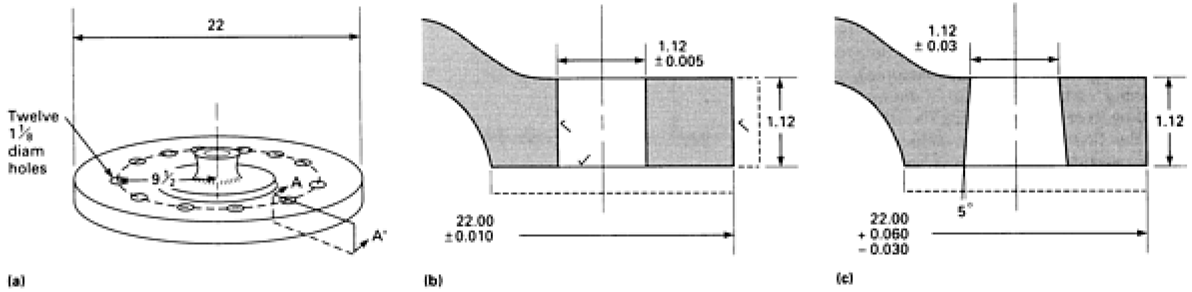

Fig. 1 Advantages of producing a commercial near-net shape casting of a bronze end cover used on a chemical reactor. The finished piece (a) is 559 mm (22 in.) in diameter. By eliminating the turning operation needed to form the center hub, as well as the drilling operation to form the 12 holes in the machined version (b), the as-cast version of the casting (c) was made more cost effective. Both the cross sections in (b) and (c) were taken at A-A'. Dimensions given in inches.

Process Capability

One mistake frequently made by purchasing departments charged with the narrow responsibility of securing parts at the lowest unit cost is the assumption that all casting operations are equal in a generic group (for example, sand foundries). Nothing could be further from reality than this assumption, with extreme differences existing between casting sources and even within molding operations/lines at the same source.

An analogy would be to assume that the process capability of a 1940 machine tool is equal to a current piece of NC equipment able to perform the same function. Even presuming that the level of maintenance is such that the machines are

performing at their new capability, it is extremely doubtful that the tolerance potential of the two machine tools would be even close, much less equal.

On the same basis, foundry equipment built during the same time periods can be expected to have similar ranges of process capability and are certainly not equal. The expected tolerances that can be held economically in a sand casting vary dramatically depending on the molding process used.

Green sand floor molding, traditionally the process chosen for the low-volume manufacture of castings, will normally use an unmounted, loose wood pattern with very limited accuracy. Sand is packed around the pattern by hand or with an air rammer, and the pattern is withdrawn to form the cavity for the molten metal. Much of the tolerance potential of the process is lost by molder operations that fall into the category of art rather than science. Examples include variations in density of the hand-rammed mold (which can yield and swell when molten metal is poured into the cavity) to the need to manually rap the pattern to loosen it in the sand before withdrawing it. All of these factors contribute to a great loss of tolerance control in the final shape.

The more modern foundries will frequently use more automated equipment to minimize the labor/skill elements in the preparation of a mold. Machines perform the many tasks necessary to prepare the sand mass to receive metal, but the sequence and method of performing individual steps in the molding operation can vary widely. All of these steps will influence the ultimate tolerance capability of the molding process, as will the compatibility of the part design to the actual molding equipment selected. Depending on the chosen method of filling the mold preform before compaction and the means available to achieve compaction, the tolerance capability of the equipment can vary widely for any one type of casting. A flat casting can be manufactured to very close dimensional tolerances on one type of molding machine. This same machine might not be able to achieve equal hardness in the mold mass for a part with deep pockets or changes in elevation and will thus sacrifice much of the tolerance capability gained.

The problem is very similar to the necessity for machine capability studies of machining centers. If the maximum advantage is to be developed from the casting process, it is necessary to understand the limitations of the method chosen. If this understanding is developed and if a spirit of cooperation exists between the casting supplier and user, then significant economies may be within reach. The magnitude of these economies become apparent when it is realized that the conversion of parts from a low-pressure squeeze molding method to a high-pressure automatic molding operation will frequently produce a reduction in finished casting weight that might approach 3 or even 5%.

Casting Distortion

Distortion Induced by Metal Solidification. One problem common to all casting processes, and potentially a large factor in dimensional tolerance control, is casting distortion. When metal masses solidify and cool to room temperature, depending on process control and manufacturing methods, very high stresses can be generated. These stresses are the result of thermal differences that can be created during the solidification or cooling of unequal section thicknesses or the resistance to contraction offered by unyielding mold sections.

The stresses can take many forms:

- They may be hidden and remain in the form of residual stresses in the cast shape (with a high potential for premature failure in service)
- They may be partially relieved in subsequent fabrication or machining operations, with a resultant change in dimensions or flatness of the casting as a new balance is reached with the remaining residual stresses
- They can reach a magnitude during solidification or cooling that results in hot tearing or cracking of the casting
- Although the design of the casting is a major factor in the formation of these stresses (and is addressed in the article "Casting Design" in this Volume), processing variables can play a major role in adding to or even reducing the stress level in the final shape. The achievement of low residual stress levels is the best guarantee that dimensional accuracy will not be affected by subsequent processing

The existence of residual stresses has long been recognized by users of castings, and a variety of methods have been adopted to lessen their effects. One of the first techniques was simply to allow the poured casting to remain in the mold

for a longer time and to slow cool through the critical temperature ranges to develop a form of stress relief. This was not sufficient for manufacturers of large machine tools, who found that the machining of their large gray iron cast machine beds immediately after casting frequently resulted in distortion and out-of-flat conditions on the frames. They discovered that the problem could be alleviated considerably by seasoning the casting before machining or by allowing it to weather in a storage yard for 1 to 3 years. Daily temperature cycles and seasonal changes produced enough stress relief in the cast shapes to minimize subsequent distortion upon machining.

Current manufacturing practices using automated molding lines (with very short holding times in the mold) and just-in-time inventory practices do not permit the luxury of leisurely processing. More modern techniques rely on thermal treatments at a temperature chosen to allow plastic deformation of the shape, thus relieving the stresses. Of course, other detrimental metallurgical effects can be created if the temperature and processing are not selected and handled with extreme caution. These can include a loss of strength through an annealing effect or the formation of undesirable microstructures--for example, grain-boundary carbides in stainless steel and the accompanying loss of corrosion resistance. Thermal treatments must also be controlled carefully on both the heating and cooling cycles, or the stress level in the casting may be added to rather than reduced. An alternative to thermal treatment relies on a mechanical relief of the stresses through high-frequency vibration. Depending on the techniques used, the nonthermal treatments may be less effective, but are simpler and less costly to perform.

From the point of view of the casting designer or foundry engineer, it is important to understand how the residual stresses are formed and what options might be available to minimize their impact on the final shape. These stresses, which are thermal in origin, are the result of temperature differences in the product that occur during solidification or subsequent cooling. The thermal differences, regardless of their source, can induce plastic deformation of the shape and will be reflected as elevated residual stresses when the casting is at constant temperature. Depending on the area of the casting, the stresses may be either tensile or compressive in nature and will be in balance. Achieving this balance is one of the sources of initial casting distortion, and the dimensional errors may be increased if the stress balance is altered by stock removal during machining.

The mode of formation of the stresses can be better understood by consideration of Fig. 2, which shows a simple shape of nonuniform section thickness. When metal is poured into the mold cavity and solidification begins, it will follow the rules described in the article "Casting Design" in this Volume. The heavier section (A) has more mass and heat content than the light section (B) and will cool more slowly (maintain a higher temperature) than the lighter section. This temperature differential, ΔT, is the source of all stresses (Fig. 2b).

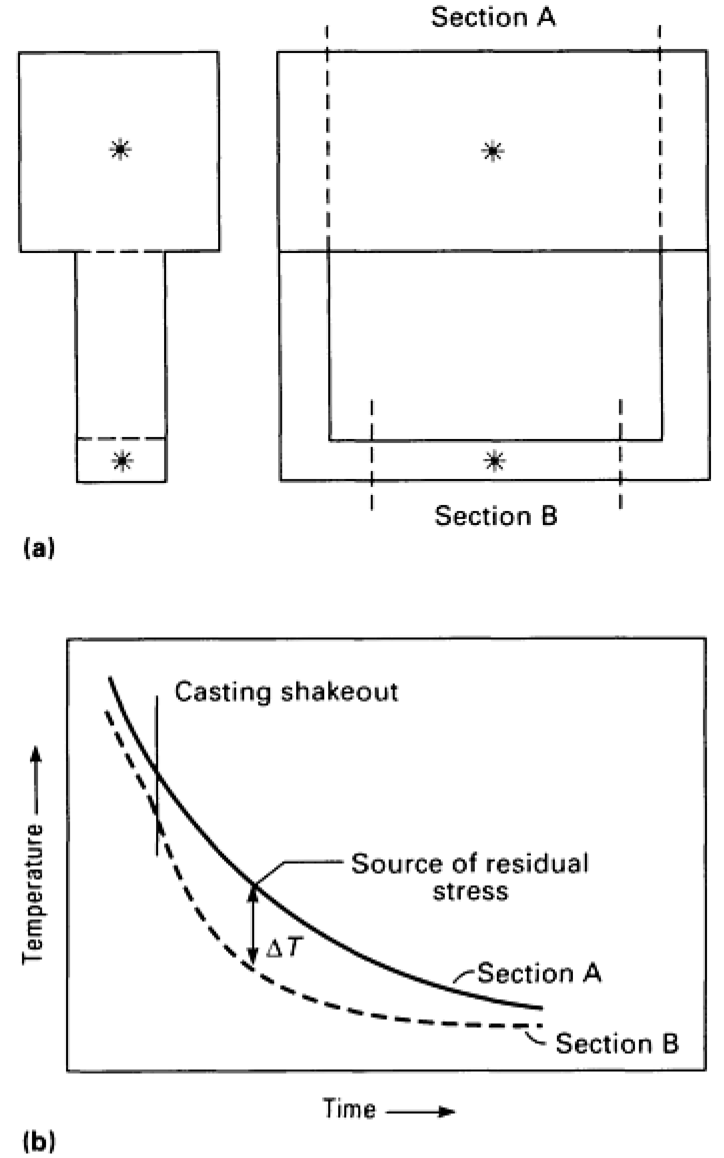

Fig. 2 Effect of casting mass on cooling rate. (a) Side and front views of a nonuniform section thickness having a major difference in section moduli; thermocouple location is indicated by *. (b) Time-temperature plot showing that temperature variation, ΔT, between the two sections is the source of deformation and residual stress buildup.

During the cooling process, Section B is contracting at a greater rate than Section A and is placing the material in Section A in compression. If the temperature differential is sufficiently high, the stresses exceed the strength of the material and plastic deformation occurs. Section A is then slightly shorter than B, and when the temperature differential no longer exists, Section A will be placed in tension. The stresses are always in balance in a shape, and the tensile stresses in A are offset by an equal compressive stress in Section B. If the compressive stress is greater than the strength of the material, the stresses will be relieved by distortion, and the high level of compressive stresses will be manifested by the familiar oil canning.

The residual tensile stresses in the heavy section can be high enough to crack the casting during cooling, or they may be increased by subsequent machining or handling. This is frequently the cause of seemingly inexplicable cracking that occurs during postcasting operations on brittle materials such as cast iron.

It is important to recognize that the cause of the stress and distortion is the temperature differential, ΔT, that can exist upon cooling, and not the actual section thickness itself. This means that castings with uniform sections but with distributions of concentrated mass that cool differentially may also be susceptible to high levels of stress or distortion.

Some typical shapes with this sensitivity are shown in Fig. 3. The solution lies in finding a way to reduce ΔT, thus proportionally reducing both stresses and distortion. Foundry engineers have found a variety of innovative methods of achieving uniform cooling, including the use of chills, rapid shakeout and selective forced cooling, or removing sand from some areas of the casting and retaining it on other surfaces.

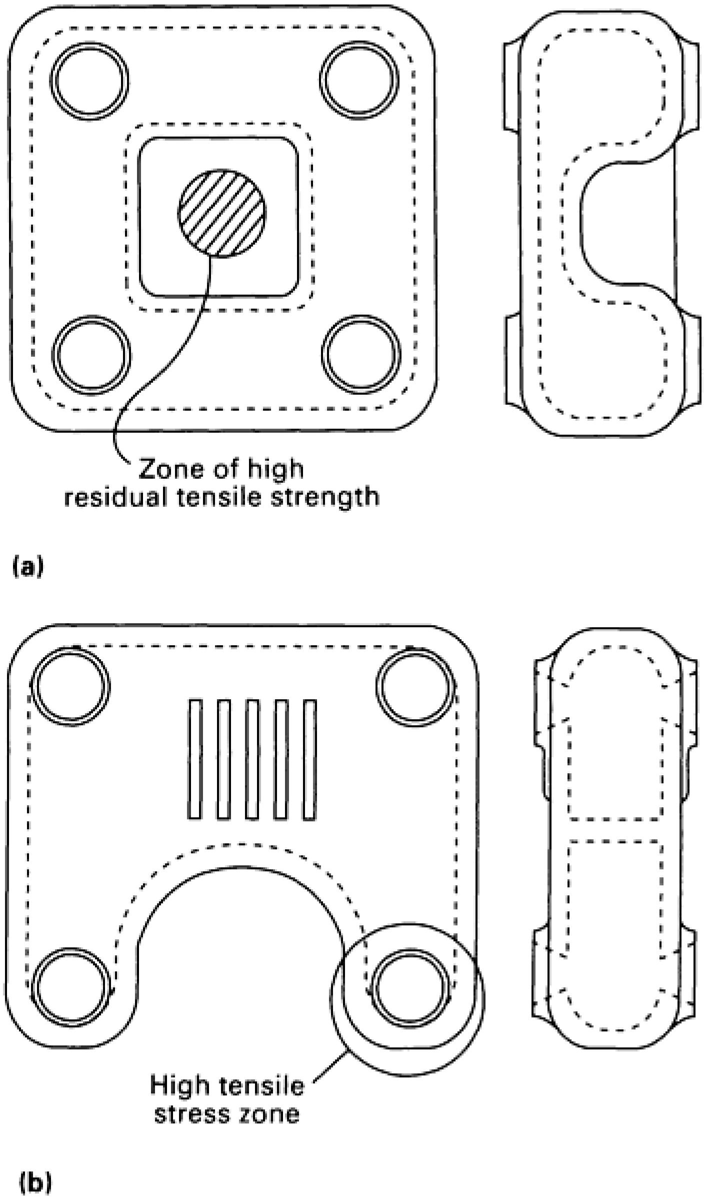

Fig. 3 Uniform section casting configurations yielding zones of high residual tensile stress. (a) Stresses concentrated in central interior of casting. (b) Stresses concentrated on outer projections of casting.

Distortion Due to Mold Restraint. A second major cause of casting distortion, particularly in fragile castings, is the restraint imposed by the mold as the casting cools and contracts. In its most severe form, this type of distortion is difficult to eliminate except by casting redesign or by adding tie bars to minimize the free movement of unrestrained sections. The condition can also lead to an even more serious problem if the casting is being manufactured in an alloy that is hot short. With these alloy systems, random cracking can occur that may go undetected until field failures result.

The sand casting shown in Fig. 4 was made without difficulty with regard to soundness or filling of the thin sections. Significant distortion was encountered, however, when the casting cooled in the sand and was restrained by the relatively solid mass of sand between the flanges. This unyielding mass caused the two vertical flanges to be bent outward as the bottom plate cooled and contracted. Two options in design are shown in Fig. 4(b) and 4(c), with the preferred method incorporating the tie bar. A third choice for a solution would not involve a change in the casting itself but rather a change

in the sand mold. It has been found that the sand mass between the two flanges can be relieved so that it will yield under the shrinkage stresses. This is accomplished by adding a block to the pattern so that a hollow relief cavity is formed between the flanges (Fig. 4d). This practice reduces the effective compressive strength of the molding media between the flanges and allows the sand mass to collapse during shrinkage of the casting, thus minimizing the imposed restraint.

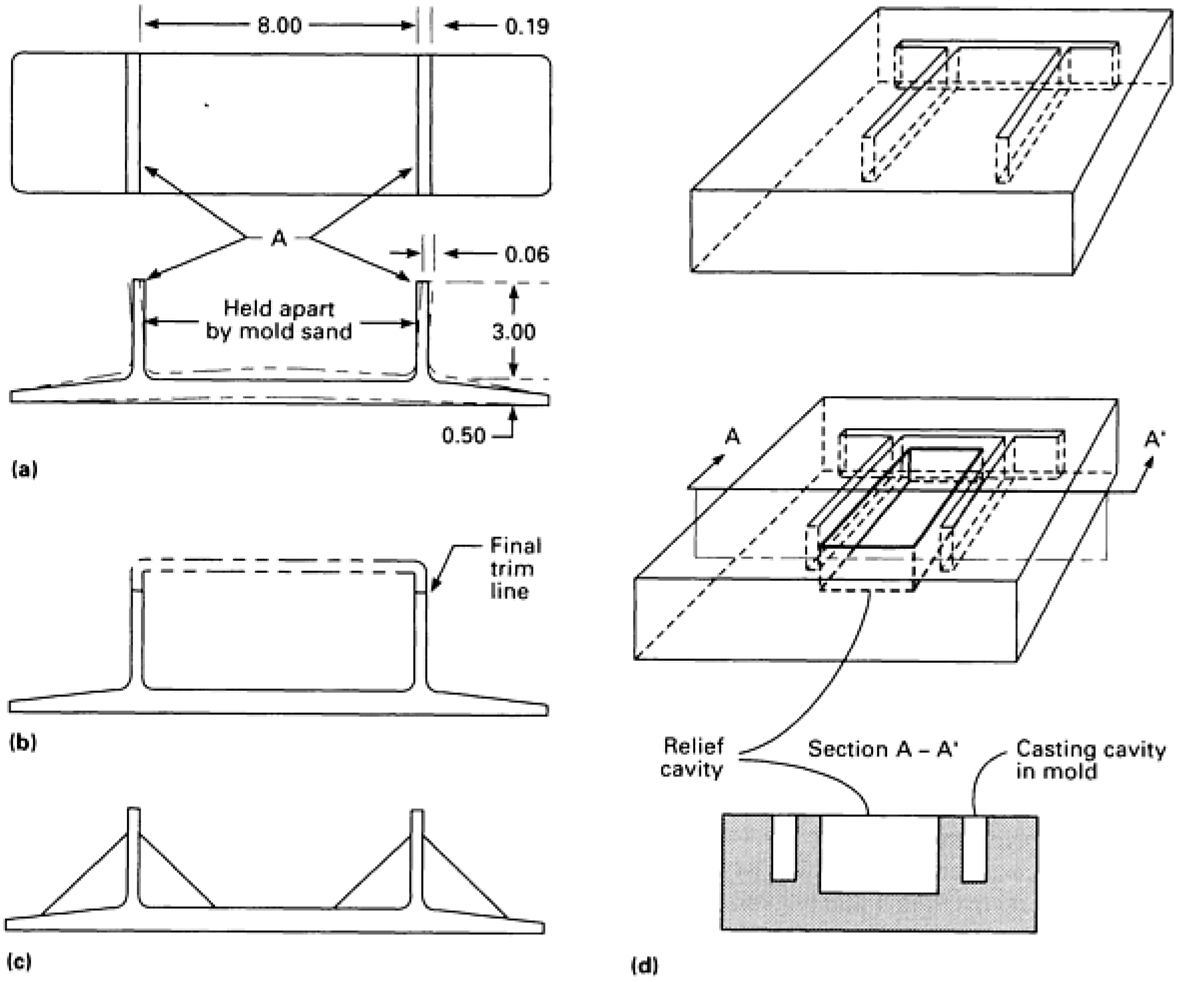

Fig. 4 Preventing distortion in a casting caused by mold restraint. The original design, shown in top and front views in (a), was altered to three possible preventative designs, as follows. (b) Preferred method incorporating a tie bar. (c) Less effective method than that shown in (b). (d) Open cavity created in the molding media to relieve restraint upon flanges during casting solidification by allowing solid sand mass to collapse during shrinkage and minimize restraint. Dimensions given in inches.

An example of a casting containing the design potential for hot tears is shown in Fig. 5. This shape was being manufactured in 535.0 aluminum alloy as a permanent mold casting. If the casting and molding sequences were not carefully controlled with respect to the time the mold was opened after pouring, the casting would develop hot tears in the locations shown. The problem was resolved by establishing very restrictive controls on mold temperature, pouring temperature, and mold opening time following the end of the pouring operation. Even with these controls, the scrap frequently exceeded 10% of the pieces poured.

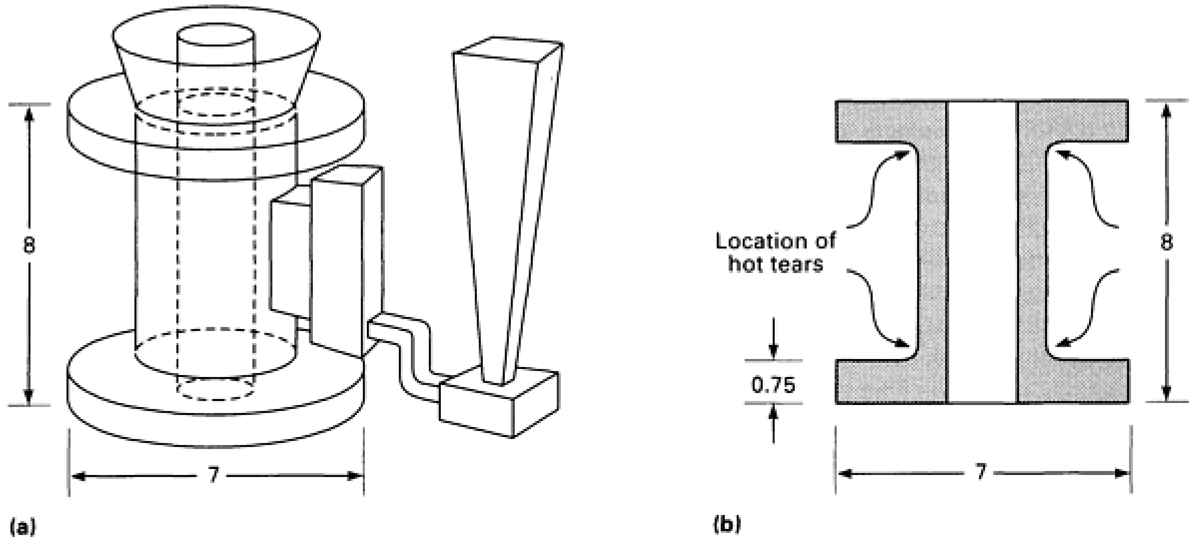

Fig. 5 Permanent mold casting of 535.0 aluminum alloy that is prone to hot tear sensitivity. (a) Casting shown with gate-riser system attached. (b) Casting with gate-riser system removed showing location of hot tears. Dimensions given in inches.

Sand Castings

As noted previously, there are many processes used to mold castings in an aggregate media. Typically, sand castings are defined as castings that are molded in an aggregate media, which may be bonded with a variety of different binders. These may range from clay and water mixtures (green sand castings) to chemically bonded sand/resin mixtures that harden around the pattern. Discussion of these processes for making the sand mass rigid is beyond the scope of this article, but may be found in the Section "Molding and Casting Processes" in this Volume. It is sufficient to recognize that the molding method chosen can greatly affect the accuracy of the final product.

Regardless of the final molding method selected to fabricate the sand casting, the accuracy of the shape will not be any better than the pattern equipment used to form the cavity. The better the casting process, the more faithful the dimensional reproduction of the mold cavity created by the pattern equipment and the more accurate the final shape produced. It is at this point in the manufacturing sequence that tolerance decisions made by the designer first come into play. If low production is expected and tooling costs are to be minimized, the assignment of wide tolerances will allow the use of loose (unmounted) wood patterns to fabricate the casting. As the anticipated production run lengthens, tooling with a longer life is required, and more restrictive casting tolerances may be specified without greatly influencing casting prices or lead times.

The types of patterns used may range from unmounted, loose wood patterns through mounted wood patterns, impressions that have been replicated in a plaster molding operation and cast on an aluminum match plate, impressions machined from solid and replicated in plastic materials before mounting on a metal plate, through metal impressions that have all been duplicated by an accurate machining process and then mounted on metal plates, and finally to multiple impressions machined from a solid blank of material with the operations and dimensions controlled by direct transfer of computer-aided design and manufacture (CAD-CAM) data. In general, increased accuracy will follow through each of the above stages of pattern equipment options, and the costs progressively increase as well.

The advent of CAD-CAM processing of pattern equipment and core boxes promises to revolutionize the industry as the methods receive wider application and use. Until recently, increased accuracy in pattern equipment went hand in hand with increased cost. If multiple cavities are needed and can be produced to help amortize the programming costs, the final tooling costs using CAD/CAM may be reduced by approximately 50% over competing replication processes. Further, the accuracy of reproduction is such that the designed casting wall thickness can be taken to the minimum for the process without fear that tooling errors will increase scrap for misruns or incomplete fills. Reports of savings of up to 10% on the weight of thin-wall castings are common in the literature when the tooling processes are properly applied and utilized.

Production Variables Influencing Dimensions

The manufacture of sand castings is influenced by a number of variables that will have a great impact on the final dimensions of a cast part. Some of these variables are common to other casting processes, but many are unique to the molding method. Metal contraction, mold influences, and metal variables are described below.

Metal Contraction. Most alloys undergo a large reduction in volume during the change from the molten state to the form of a solid casting at room temperature. In aluminum alloys, the transition may be as much as 10%, requiring careful planning on the part of the patternmaker and foundry engineer to ensure the production of a dimensionally accurate casting with the required integrity.

Average values for the contraction of each metal are known and can be built into the pattern construction. The skill of the patternmaker enters into the equation when it becomes necessary to estimate where nonstandard shrinkage allowances are required because of mold restraint imposed by external gating systems, rigid cores, chills to influence directional solidification, and so on. The usual practice is to refine the gating and riser system until a sound casting meeting all of the quality requirements is produced. At this point, adjustments are made to the pattern equipment and locating surfaces to bring the final shape into the profile required by the casting designer. These adjustments are, by necessity, a trial-and-error process that can be greatly complicated by multiple pattern impressions and core box cavities. If the true potential of the process is to be realized, the adjustments are an absolute necessity.

Mold Influences. The packed density of the mold aggregate is a major factor in maintaining uniform dimensions in the final casting. If variations in density, as reflected by mold hardness, are allowed to occur, the molten metal mass will force the mold surface to yield, and inconsistent dimensions will result. The magnitude of the problem is a function of the specific gravity and temperature of the alloy being poured, with steel castings showing the greatest variation and magnesium showing the least of the common alloys.

A second problem is to ensure that the mold assembly maintains the relative position of each component during closing, handling between molding and pouring stations, and the entry of molten metal. If the match between mold sections is not maintained, it will be reflected as a shift in the final casting, as shown in Fig. 6. The only effective method of preventing this error is to pay constant attention to careful handling and maintenance practices in the foundry. It is suggested that the designer anticipate the problem, tolerance the part accordingly, and specify a parting line that will minimize the impact upon the finished item.

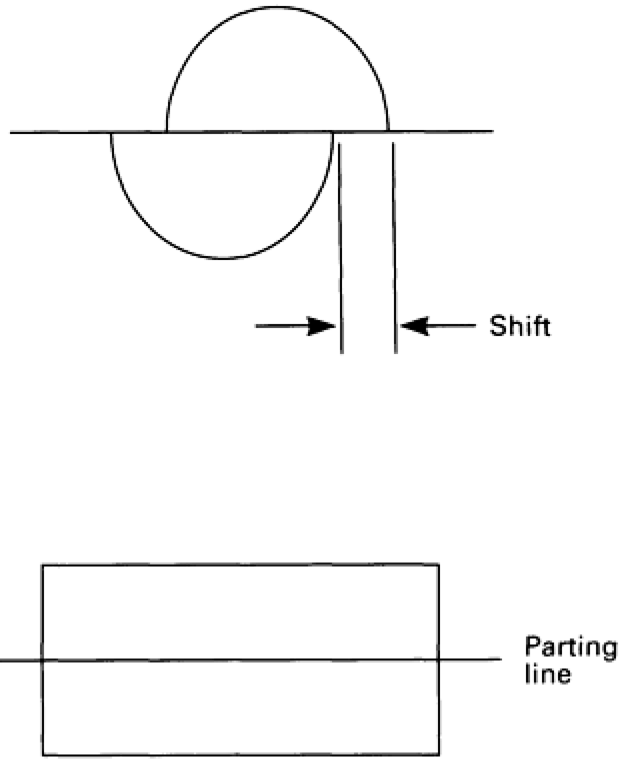

Fig. 6 Patterns in the two mold halves--the cope and the drag--must be aligned to prevent shift (a) and misalignment (b) of parting line.

Cores may be considered a second mold component in the assembly, and they will introduce an additional element of variation. Again, depending on the nature and condition of the core equipment, the impact on the total tolerance range of the casting will be a function of the core manufacturing process as well as the way the core is positioned and located in the mold assembly. If multiple cores are used in the mold and are prefabricated into subassemblies, the potential does exist for careful gaging and even dimensional corrections by selective stock removal.

Metal Variables. As with all other elements of process control, those dealing with the alloy, its composition, its temperature, and the practices used to introduce the metal into the mold can have a large influence on the dimensions of the final casting. The tolerance potential of each major alloy group can vary significantly for any one molding method. This is illustrated in Fig. 7, which shows the normal expected linear deviation from blueprint dimensions for steel and malleable castings made in green sand. Although the reported variation is large, it must again be remembered that it represents a data base from a family of molding operations and should not be construed as an average capability for the process or alloy family.

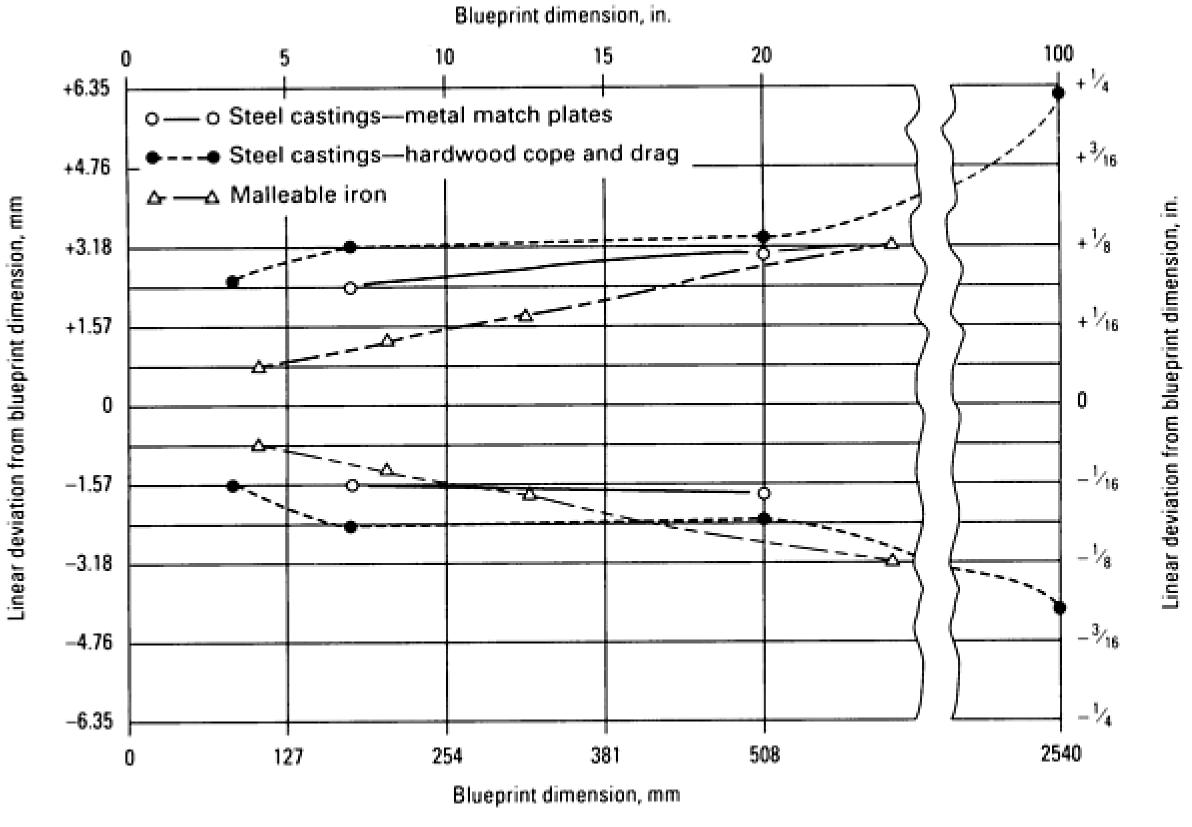

Fig. 7 Normal expected linear deviation from blueprint dimensions of steel and malleable castings made from green molding sand. Source: Ref 1.

Table 2 lists a second set of typical noncritical tolerances for steels and castings that has some significant differences. If general tolerances are sought for an alloy family, it is suggested that the industry group association producing that alloy be solicited for their recommendations. An example of the data that might be provided is the list of 18 engineering standards published by the Aluminum Association for sand and permanent mold casting or a similar group published by the American Die Casting Institute (ADCI). The best source of information concerning tolerances is the prospective production foundry under consideration as a final source for the casting. There is no single source that can better define the capability of their processes and controls than the operation responsible for manufacturing the casting.

Table 2 Typical noncritical tolerances for steel sand castings

Dimension		Typical tolerances							
		Across parting line				**Between points formed by core and mold**		Between points in one part of mold	
		Horizontal		**Vertical**					
mm	**in**	**± mm**	**± in.**	**± mm**	**± in.**	**± mm**	**± in.**	**± mm**	± in.
25-178	1-7	1.5	0.06	1.3	0.05	1.3	0.05	0.8	**0.03**
203-305	8-12	1.8	0.07	1.5	0.06	1.5	0.06	1.0	**0.04**
330-406	13-16	2.0	0.08	1.8	0.07	1.8	0.07	1.3	**0.05**

Beyond the overall tolerance limitations for an alloy family, there are many factors in the processing of the molten material that can influence the final dimensions. A partial list would include:

- Subtle changes in alloy chemistry that can produce a major change in the linear shrinkage of the material (for example, trace elements in iron-base materials that can induce the formation of white iron structures in an otherwise gray iron casting)
- Variations in pouring temperature or metal cleanliness that would cause nonstandard solidification, feeding, or casting density changes
- Improper clamping or weighting of the mold mass before pouring. The metallostatic head associated with even nominal mold heights can exert very large hydraulic lifting forces if the projected area of the casting is large or if the mold is not tightly sealed. This is one of the sources for variation in dimensions measured across parting lines

No-Bake Molds

No-bake molding practices are described in detail in the article "Resin Binder Processes" in this Volume. The technology offers a significant improvement in dimensional tolerance control because of the rigidity of the aggregate mass, which is normally hardened in place around the pattern equipment. The strength conferred by the chemical binders helps prevent distortion of the aggregate mass when metal is poured into the mold and has the potential to offer more uniform castings when compared over the duration of a production run. This has frequently been evidenced by a weight reduction in castings converted from green sand practices to no-bake. Depending on the level of control exercised over the green sand, the weight reduction can exceed 5% and can produce financial savings that will more than cover the cost of the resins and the disposal/reclamation of the sand materials.

The increased strength of the mold mass does create a different set of problems in that casting restraint on solidification is frequently higher. In addition to lower collapsibility in the media, castings molded by this method are frequently shaken

out of the molds at near room temperature, which means that the shape is under restraint over a much longer temperature interval than even die casting or permanent mold practices. These conditions would suggest that shrinkage allowances and dimensions would require verification if the pattern equipment was not constructed with the anticipation of use in no-bake molding.

A second problem when using green sand pattern equipment for no-bake processes is that dimensional control across the parting line may suffer if the pattern platens are not flat and true. The rigid mold mass will replicate the pattern plane, and if the surfaces are not flat, the mass will not have a tight closure. Again, the dimensional accuracy of the process is largely influenced by the quality of the pattern equipment.

One major advantage of the process is that the molds are not friable in the cured state and degrade very slowly in ambient atmospheres. This feature allows an almost unlimited time for mold assembly, careful gaging of core assemblies, venting, surface preparation, treatment of chills, spot repairs, and so on, before mold closure. All of the above can contribute to greater dimensional control in the final product and can minimize scrap during production.

Die Casting

This family of processes encompasses all metal casting operations done under high pressure, including conventional die casting, the Acurad process, and squeeze casting. (Acurad, an acronym for accurate, rapid, and dense, designates a proprietary die casting method developed to eliminate some of the casting quality problems associated with high-pressure castings.)

All die castings can be made to a very high level of accuracy if the production shop exercises the proper control of processes and tooling. For example, zinc castings are routinely manufactured with wall thicknesses as thin as 0.51 mm (0.020 in.) and cast-in-place hole tolerances as tight as ±0.015 mm (±0.0006 in.).

These levels of accuracy can be achieved only with precision tooling and absolute process control over all aspects of the operation. The controls start with the alloy composition and extend through the metal pouring temperature, die temperatures, injection parameters, die lock-up, cycle time, and all of the other factors that control casting quality. The resultant shapes will have an excellent finish, a high degree of dimensional uniformity from piece to piece, adequate mechanical properties for most applications, and a moderate price.

Internal porosity can be reduced through careful control of casting conditions during injection in order to obtain a sound, fine-grain surface layer. This is vital for castings destined for surface treatments such as plating, enameling, and anodizing.

The processes are not without limitations, which for the most part center around the relatively high tooling cost, long lead times for die construction, and limitations on shapes that are readily castable with straight core pulls. Although widely publicized as a method for forming ferrous materials, most commercial applications are limited to the nonferrous alloys of zinc, aluminum, magnesium, and copper. Future developments are expected to include the wider use of expendable cores, the fabrication of larger shapes with thinner walls, improved die materials with longer lives, and the production of composite shapes reinforced with carbon, silicon carbide, or refractory filaments.

With die castings, as with any precision casting process, the challenge to the designer is to determine where close tolerances are required as well as where they are not required. The potential for net shape production is very high, but the abuse of specifying overly restrictive tolerances will add greatly to lead time and cost in the final casting.

Normal commercial limits for die castings are defined in standards published by ADCI. These standards cover values consistent with speed, uninterrupted production, reasonable die and tool life, and moderate maintenance practice. In most cases, they are capable of being improved upon by an individual die caster, often at little or no increase in cost. Examples of the standards are given below. For as-cast components, linear dimensional tolerances are (ADCI-E1-61):

Tolerance	**Critical dimensions,**	Noncritical dimensions, mm

	mm (in.)	(in.)
Basic tolerance up to 25 mm (1 in.)	±0.10 (±0.004)	**±0.25 (±0.010)**
Additional tolerance for each additional mm (in.)		
>25-305 mm (1-12 in.)	±0.038 (±0.0015)	**±0.051 (±0.002)**
>305 mm (12 in.)	**±0.025 (±0.001)**	**±0.025 (±0.001)**

Note: Tolerances must be modified if dimension is affected by parting line or moving die part.

Source: Ref 2

Parting line tolerances, based on a single-cavity die, are (ADCI-E2-61):

Projected area of casting, mm^2 ($in.^2$)	Parting line tolerances, mm (in.)
Up to 32,000 (50)	**±0.13 (±0.005)**
32,000-64,000 (50-100)	**±0.20 (±0.008)**
64,000-129,000 (100-200)	**±0.30 (±0.012)**
129,000-194,000 (200-300)	**±0.38 (±0.015)**

Note: Tolerances to be added to linear tolerances specified in above Table. Source Ref 2

Part tolerances of the moving die part are as follows (ADCI-E3 61):

Projected area of die casting portion[a], mm^2 ($in.^2$)	Part tolerances, mm (in.)
6400 (10)	**±0.13 (±0.005)**
6400-12,900 (10-20)	**±0.20 (±0.008)**

12,900-32,300 (20-50)	**±0.30 (±0.012)**
32,300-64,500 (50-100)	**±0.38 (±0.015)**

Note: Moving die part tolerances, in addition to linear dimensions and parting line tolerances, must be provided when moving die part affects a linear dimension.

Source: Ref 2

(a) Projected area is area (in mm^2 or $in.^2$) of that portion of casting affected by moving die part.

Permanent Mold Castings

Permanent mold processes are widely used for all alloy systems except steel and superalloys. These processes encompass conventional gravity die casting, low-pressure casting operations, slush casting, and some special purpose processes that offer advantages in the production of specific end products. The processes may be readily automated, offer the potential of much better tolerance control than is possible with some sand casting operations, are considerably more flexible than die casting in terms of the size and shape of parts that can be fabricated, and can be tooled at much lower cost than parts made with die casting methods.

The tolerance potential for the processes is somewhat comparable to die casting in that a high percentage of the castings are made in all metal tooling. Although casting detail may not be as fine, because of the lower fill and injection pressures, the tooling need not be as sturdy to contain the injection process. Also, with the absence of high injection stresses, the die materials are chosen for their conductivity, availability, and low cost rather than their ability to withstand the shock loading stresses at the elevated temperatures that are common in die casting. The more tolerant process conditions encourage the use of gray iron molds, which are frequently cast to near-final dimensions to minimize machining and tool construction expense.

Permanent mold casting is used for the volume manufacture of castings with methods that are highly automated. Many mold installations are currently operating with all elements of the molding operation being performed automatically. The operator is an observer and an inspector and does not participate in any actual casting functions. Internal cores of increasing complexity are stripped from the castings automatically and then reassembled to pour the next shape. This permits a high level of accuracy, and many piston castings are being produced with 0.38 mm (0.015 in.) finish stock on some machined surfaces.

As with the other casting processes, the dimensional capability of permanent mold casting is largely limited by the accuracy of the dies used. Tooling wear and erosion are more serious problems than with other processes because of the need to interrupt production periodically to remove drags (cast metal adhering to the die in areas of low draft) and to renew the mold coatings used to protect the molds. The coatings are also a source of dimensional variation in that their thickness and composition are frequently changed to modify solidification patterns in the mold. By design, some areas of the mold can be operated with very thin coatings that are more lubricating than insulating. Other areas can be covered with multiple layers of insulating materials with thicknesses to 0.76 mm (0.030 in.). Because the coatings are refractory, they have an expansion coefficient that is different from that of the metal base, and they will spall and chip if uniform mold temperatures are not maintained. When this occurs, the coating must be removed down to the base material and renewed.

This removal and cleaning process is the source of most dimensional change over the service life of a permanent mold. The coatings are usually formulated with a sodium silicate base to promote adhesion, and they become very hard in service. Removal is accomplished by a light sandblasting or wire brushing of the entire mold cavity. This process also

wears away a portion of the base material, enlarging the mold cavity with each cleaning cycle until it eventually becomes unserviceable.

An example of the effect of tool wear on component weight is given in Fig. 8, which shows the change in casting weight of an aluminum engine manifold casting. The die was reconditioned several times during the period, but this repair was limited to the die faces rather than the total cavity. This is an area in which the new tooling and repair processes offered by CAD/CAM systems are expected to develop a large savings. Large automotive casting shops are scheduling a complete reconditioning of the die face and cavity on some dies as frequently as every 15,000 cycles. This expense is justified by the reduction in average casting weight produced, which is reported to save over 7% of the total metal required to make the parts. In addition, because the wall thickness can be accurately defined and controlled, new tools are manufactured to the bottom tolerance limit for wall thickness. An automotive gear-case designed in this manner led to a savings of 10% of the casting weight.

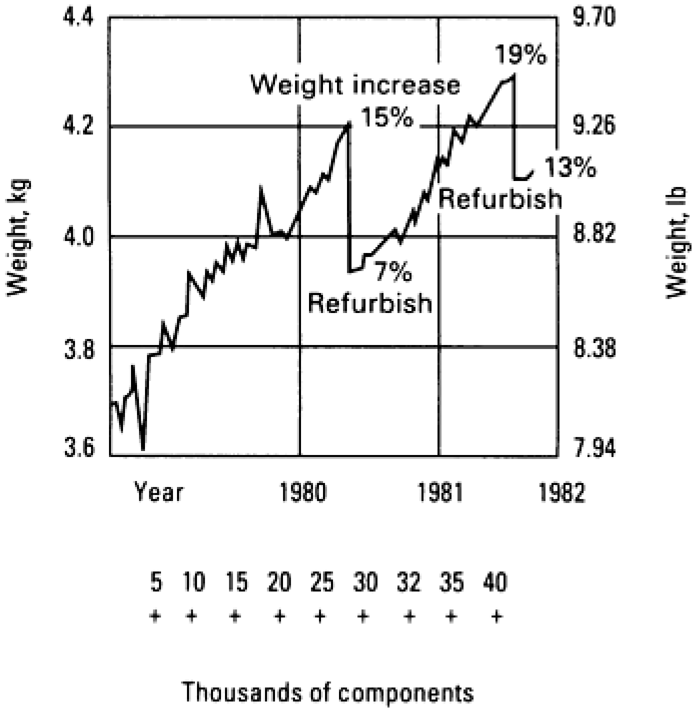

Fig. 8 Effect of mold wear on casting weight. The weight of the casting, an aluminum engine inlet manifold component, increases over the life of the mold. Source: Ref 3.

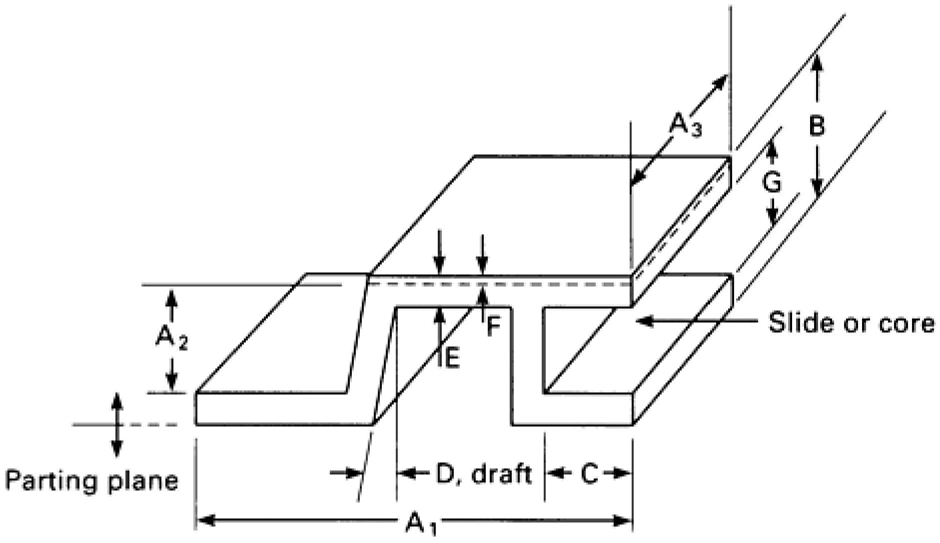
General casting tolerances are again available from the producing foundries and industry associations. An example of those published for aluminum permanent mold castings is shown in Fig. 9. As with all standards of this type, they are intended to establish the individual requirements involved in producing a usable, unmachined casting consistent with normal production practices, reproducibility, reasonable mold or pattern life, maintenance costs, and so on. Consultation with the foundry is strongly recommended.



Minimum diameter of cored holes 9.53 mm (0.375 in.)

Between two points in the same part of the mold; not affected by parting plane or core

Specified dimension		Tolerance	
mm	**in.**	**mm**	in.
≤25	≤1	±0.38	**±0.015**
>25	**>1**	**0.38 ± 0.002 mm/mm over 25 mm**	**0.015 ± 0.002 in./in. over 1 in.**

Flatness tolerance, as-cast

Flatness tolerance, the total allowable deviation from a plane, consists of the total distance between two parallel planes embracing the entire tolerated surface.

Greatest dimension[(a)]		Tolerance, permanent and semipermanent mold	
mm	**in.**	**mm**	in.
0-152	0-6	Within 0.51	**Within 0.020**
Each additional mm (in.)[(b)]		**0.003 mm/mm**	**0.003 in./in.**

(a) Section diameter or diagonal.

(b) For castings over 610 mm (24 in.), consult foundry.

Across parting plane; A-type dimension plus below

Projected area of casting, $A_1 \cdot A_3 = X$		Additional tolerance for parting plane	
mm²	**in.²**	**mm**	in.
$X \leq 6450$	$X \leq 10$	±0.25	**±0.010**
$6450 < X \leq 31{,}600$	$10 < X \leq 49$	±0.38	**±0.015**
$32{,}300 < X \leq 63{,}900$	$50 < X \leq 99$	±0.51	**±0.020**
$64{,}500 < X \leq 161{,}000$	$100 < X \leq 249$	±0.64	**±0.025**
$161{,}000 < X \leq 323{,}000$	**$250 < X \leq 500$**	**±0.76**	**±0.030**

Affected by moving parts; A-type dimension plus below

Projected area of casting affected by moving part, $A_3 \cdot G = YA_1 \cdot A_3 = X$		Additional tolerance			
		Metal core or mold		Sand core	
mm²	**in.²**	**mm**	**in.**	**mm**	in.
$Y \leq 6450$	$Y \leq 10$	±0.25	±0.010	±0.38	**±0.015**
$6450 < Y \leq 31{,}600$	$10 < Y \leq 49$	±0.38	±0.015	±0.64	**±0.025**
$32{,}300 < Y \leq 63{,}900$	$50 < Y \leq 99$	±0.38	±0.015	±0.76	**±0.030**
$64{,}500 < Y \leq 322{,}000$	$100 < Y \leq 499$	±0.56	±0.022	±1.02	**±0.040**
$323{,}000 < Y \leq 645{,}000$	$500 < Y \leq 1000$	±0.81	±0.032	±1.52	**±0.060**

Allowance for finish

Maximum dimension, *x*		Nominal allowance			
		Metal core or mold		Sand core

4. Standards for Aluminum Sand and Permanent Mold Castings, Aluminum Association, Inc., Washington, D.C.

Investment Castings

One of the casting processes that offer the most hope for near-net shape production is the ceramic mold production of investment cast shapes. These are made in virtually all castable alloys and in a size range from a fraction of a kilogram up to 45 kg (100 lb), and larger. Wall sections as thin as 0.76 mm (0.030 in.) can be cast with the precision process, and intricate coring and detail can be incorporated into production castings that cannot even be approached by other casting methods.

The tolerance capability of the process is limited by many of the same factors that influence other casting methods. Changes in tooling to correct for dimensional variation are sometimes costly, but once made, the reproducibility is excellent because the process lends itself to automation and very restrictive process control.

As with any process, costs are increased when tighter tolerances than required are specified. Typical investment casting tolerances are listed in Table 3, and with the cooperation of the producing foundry, it may be possible to improve these tolerances substantially.

Table 3 Typical linear tolerances in investment castings

Dimension		Normal tolerance	
mm	**in.**	**mm**	in.
Up to 13	Up to $\frac{1}{2}$	±0.13	**±0.005**
Up to 25	Up to 1	±0.25	**±0.010**

Up to 50	Up to 2	±0.33	**±0.013**
Up to 75	Up to 3	±0.41	**±0.016**
Up to 102	Up to 4	±0.48	**±0.019**
Up to 127	Up to 5	±0.56	**±0.022**
Up to 152	Up to 6	±0.63	**±0.025**
Up to 178	Up to 7	±0.71	**±0.028**
Maximum variation	**Maximum variation**	**±1.02**	**±0.040**

Source: Ref 5

One of the features of the process that is rapidly gaining acceptance and new markets for castings is the ability to assemble individual wax preforms into larger shapes with a high degree of complexity. This minimizes tooling costs and makes the process capable of making almost any shape and configuration. When coupled with precise gaging operations, the assemblies can result in final cast shapes that are without equal in design flexibility and tight tolerances.

Newly available waxlike materials offer the capability of direct machining to the final shape for prototypes, followed by assembly of the shape into an investment mold for subsequent casting. The waxlike material is completely heat disposable and offers the same tolerance capability of production tooling for the final investment casting.

Evaporative Foam Castings

This process offers much in the way of potential cost reductions in manufacturing cast shapes with a requirement for internal shapes that would normally be formed with separate cores. Through paste-up practices that are similar to investment casting methods, individual foam shapes can be built up to very complex assemblies that will result in a casting that is an accurate replica of the foam.

The process does require metal tooling for production of the foam preshapes, and again, the final casting will only be as accurate as the initial tool. The manufacture of the intermediate foam pattern does introduce an additional set of variables that can influence casting dimensions. The density of the foam shape must be closely controlled, as well as the paste-up, coating with washes, sand compaction in the mold while avoiding distortion of the foam shape, and pouring.

Users of the processes claim that it is possible to manufacture shapes that cannot be cast by another method and that very tight tolerances can be held upon selected dimensions. The process is very sensitive to manufacturing techniques, and the accuracy has been found to vary directly with the amount of process control that is exercised.

Shell Molded Castings

Castings made by the shell molding process are generally more accurate dimensionally than some of the sand casting processes, although high-pressure sand molding has often been found to approximate the casting accuracy of shell molded

casting. Problems encountered in shell casting manufacture are similar to those encountered in sand molding, and variables that influence tolerance capability are common to both processes.

The tolerance capability of shell molded castings is directly related to the size of the casting; small castings are capable of holding much tighter tolerances than the larger shapes. In part, this can be traced to variations induced by the use of heated patterns and the difficulty encountered in anticipating the contraction of the phenolic bonded shell when it cools to room temperature. Pattern adjustments can minimize these discrepancies, but they are still a source of variation.

The second difficulty encountered in the manufacture of large shapes is the deflection and distortion that can occur when high-melting alloys are poured into the resin bonded molds. This can be a significant source of dimensional change and will vary across the cross section of the casting, depending on the support and restraint provided by the backup material. The magnitude of the problem is reduced if low-density nonferrous alloys are used with lower melting temperatures.

Table 4 lists typical tolerance relations for shell molded steel castings in two directions of measurement. The improved accuracy of shell molded castings relative to that of sand castings can be inferred by comparing Table 2 with Table 4. With the cooperation of the producing foundry, it is frequently possible to halve the projected tolerance, if required for a particular dimension.

Table 4 Typical tolerance relations for shell mold steel castings

Dimension		Typical tolerance			
		Across parting line		Between points in one part of mold	
mm	**in.**	**± mm**	**± in.**	**± mm**	± in.
25	1	0.51	0.020	0.25	**0.010**
50	2	0.51	0.020	0.25	**0.010**
75	3	0.64	0.025	0.38	**0.015**
102	4	0.64	0.025	0.38	**0.015**
127	5	0.76	0.030	0.51	**0.020**
152	6	0.76	0.030	0.51	**0.020**
178	7	0.76	0.030	0.51	**0.020**

508	**20**	**1.52**	**0.060**	**1.27**	**0.050**

Plaster Mold Castings

This process is normally judged to have a dimensional accuracy somewhere near the midpoint between shell molded and investment castings, but may be tooled and put into production at a considerably lower cost. The inert mold material has very high insulating qualities and, when coupled with a mild preheat and pressure assist on pouring, can produce thin-wall shapes with exceptional tolerances.

The process is frequently used to replicate patterns from low cost wood masters and will produce equipment that can approach the tolerances of machined metal impressions. Although the plaster cast aluminum impressions may sacrifice some dimensional accuracy, they are capable of being produced very economically. This feature makes the process the most popular method of tooling construction for medium-volume parts.

Another popular use of the process, again making use of the dimensional capabilities, is to prototype die casting designs. Thin-wall shapes can be evaluated and field tested before entering into the expense of constructing die cast tools.

Plaster mold castings are normally found to contain a minimum of warpage and distortion because of the very low cooling rates and high plasticity of the materials cast. Near-net shape castings are frequently produced with machining operations eliminated or minimized because of the accuracy of the cast shapes. Typical examples of these parts include impellers that have vane thicknesses down to 0.76 mm (0.030 in.) or large wave guides where the alignment of the sections is maintained within very close limits as-cast. Detailed information on plaster mold castings and the other molding and casting processes mentioned in this article is available in the Section "Molding and Casting Processes" in this Volume.

Casting Dimensioning and Tolerancing

Regardless of the process chosen to manufacture the casting, the practices used to dimension the part are critical to the ultimate utility and cost of production. Two conventional methods are normally available:

- *Coordinate tolerancing*, which incorporates conventional plus and minus allowances on all referenced

dimensions

- *Geometric dimensioning and tolerancing*, which designates the true position of features controlled from referenced datums

Coordinate Tolerancing. The antiquated coordinate tolerancing system, although still used in some design areas, has been a source of many misunderstandings among design engineers, patternmakers, and foundrymen. When used on complex drawings, the stack-up of tolerances often makes it impossible for the patternmaker to interpret the intentions of the designer without frequent consultations and discussions. These discussions are often held after the manufacture of prototype parts, resulting in delays and additional expense in retooling or correcting the cast shape to meet the intended function.

Geometric dimensioning and tolerancing is an international system of design language. It enables the true functional limits of the production variability of any part to be expressed in a drawing.

The development of international drafting standards for clearly specifying the acceptable limits of production variability has evolved worldwide over the last 40 years. The system these standards define, known as geometric dimensioning and tolerancing, provides a drafting language by which sophisticated design requirements can be clearly stated and uniformly understood. These relationships are expressed through international, standardized symbols that clearly define part geometry, without relying on lengthy and often misinterpreted notes or the subtleties of view interrelationships.

Engineering drawings conventionally have two aspects: views that show the shape of the object and dimensions that show size. Problems occur most frequently when describing the elements of size, resulting in costly errors in which design features do not fit mating assemblies, and so on. Problems can be avoided by using geometric dimensioning and tolerancing, as documented by the American National Standards Institute (ANSI) and the International Standards Organization (ISO). The system breaks down language barriers while adding precision and clarity to the engineering drafting language.

Characteristic Symbols. There are 13 basic geometric symbols that describe the relationships of design features to each other and the reference datum planes. These are presented in Table 5, and their use is described in detail in ANSI Y14.5M. An example of their use, when combined with descriptive terms, is shown in Fig. 10.

Table 5 Symbols used in geometric dimensioning and tolerancing

Type of feature	**Type of tolerance**	**Characteristic**	Symbol
Individual (no datum reference)	Form	Flatness	⏥
		Straightness	⏤
		Roundness	○
		Cylindricity	⌭
Individual or related	Profile	Profile of a line	⌒
		Profile of a surface	⌓

Related (datum reference required)	Orientation	Perpendicularity	⊥
		Angularity	∠
		Parallelism	∥
	Location	Position	⌖
		Concentricity	◎
	Runout	Circular	↗
		Total	⌰

Classification of Ferrous Casting Alloys

Doru M. Stefanescu, University of Alabama

Introduction

CAST IRONS AND STEELS (ferrous alloys) represent some of the most complex alloy systems. A wide variety of microstructures and resulting properties are possible, depending on composition, solidification conditions, and appropriate heat treatment. The intent of this article is to provide a classification system for ferrous alloys. Figures 1 and 2 classify cast irons and steels according to their commercial name or application and their structure. The articles that constitute this Section discuss key aspects for each alloy system. These include:

- Chemical composition
- Structure and property correlations
- Melting practice and melt treatment
- Specifics of foundry practice (pouring, gating, and risering)
- Heat treatment
- Applications

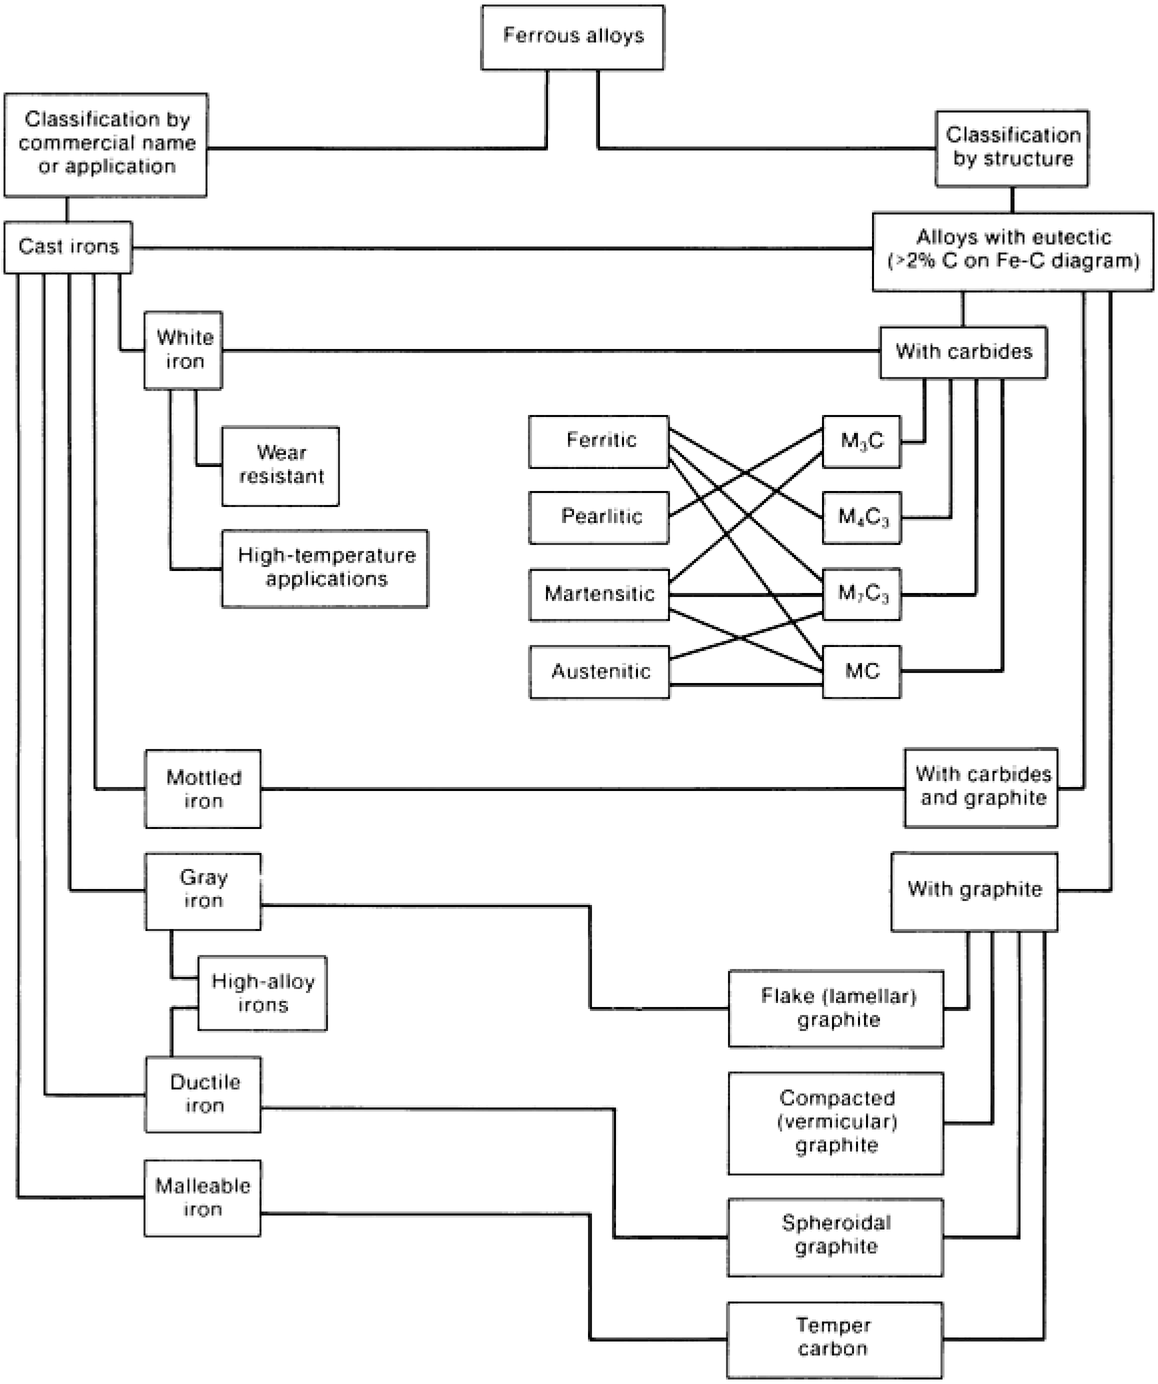

Fig. 1 Classification of cast irons

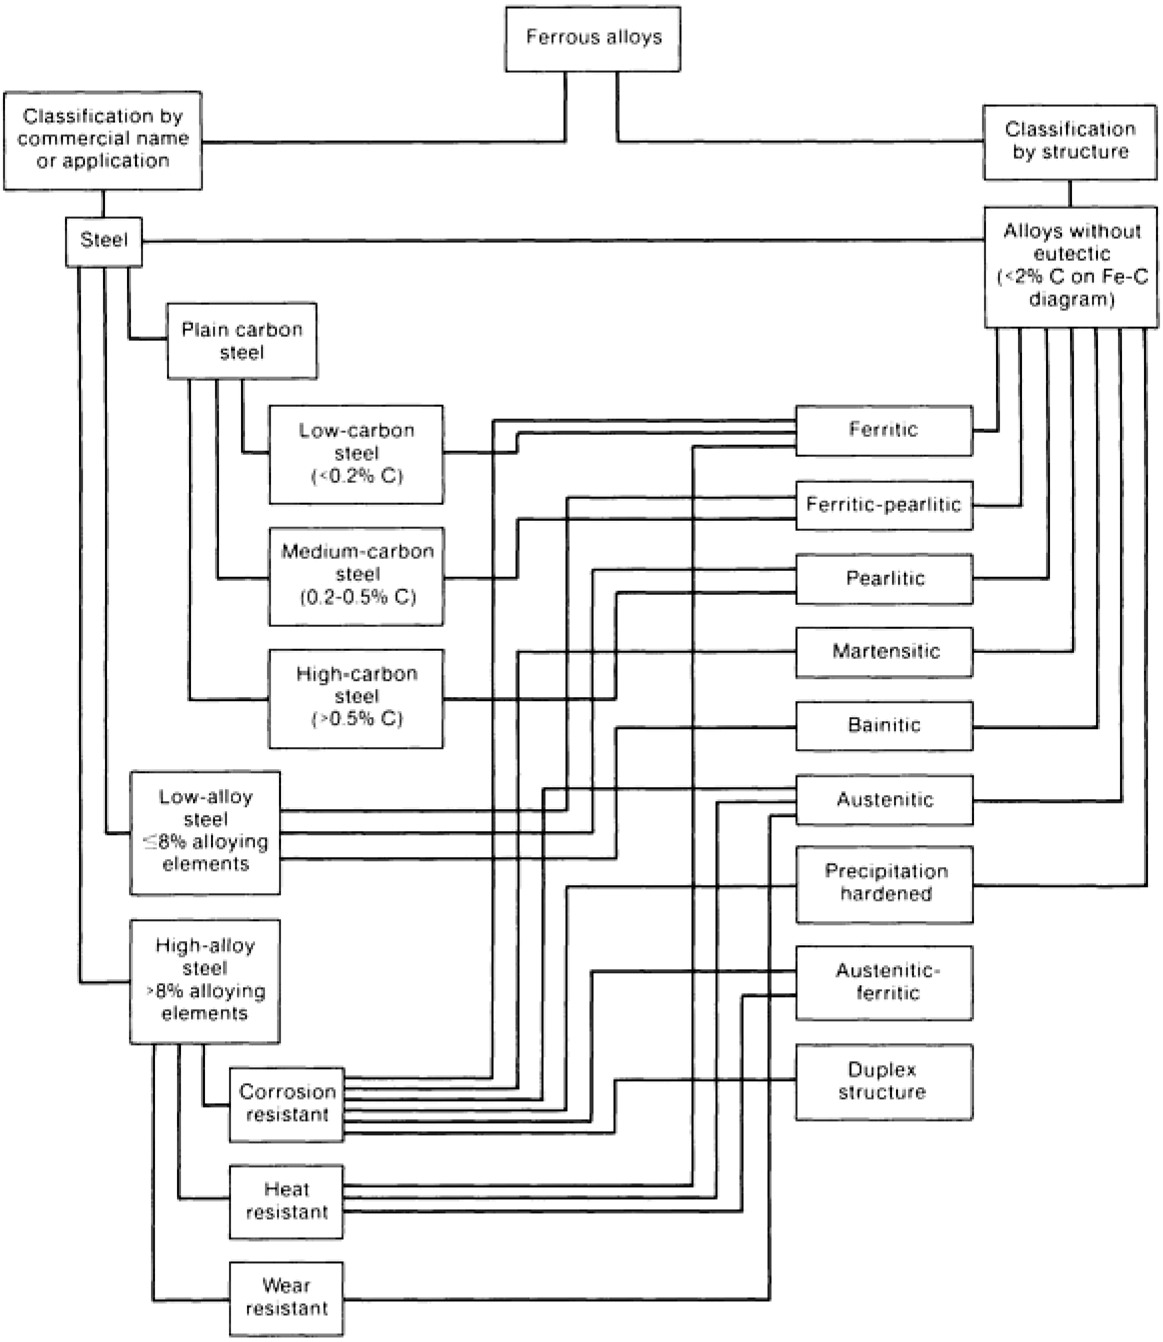

Fig. 2 Classification of steels

In addition to the contributions on cast irons and steels, an article on "Cast Alnico Alloys" is provided. These difficult-to-cast, precipitation-hardenable materials, which contain high amounts of aluminum, nickel, and cobalt as well as other alloying elements, are used for permanent magnetic applications.

Classification of Ferrous Casting Alloys

Doru M. Stefanescu, University of Alabama

Cast Irons

The term cast iron, like the term steel, identifies a large family of ferrous alloys. Cast irons are iron-carbon base alloys that solidify with a eutectic. They contain various amounts of Si, Mn, P, S, and trace elements such as Ti, Sb, and Sn. They may also contain various amounts of alloying elements. Wide variations in properties can be achieved by varying the balance between carbon and silicon, by alloying with various metallic or nonmetallic elements, and by varying melting, casting, and heat-treating practices.

The five basic types of cast iron are white iron, gray iron, mottled iron, ductile iron, and malleable iron (Fig. 1). White iron and gray iron derive their names from the appearance of their respective fracture surfaces: white iron exhibits a white, crystalline fracture surface, and gray iron exhibits a gray fracture surface with exceedingly tiny facets. Mottled iron falls between gray and white iron, with the fracture showing both gray and white zones. Ductile iron is so named because in the as-cast form it exhibits measurable ductility. By contrast, neither white nor gray iron exhibit significant ductility in a standard tensile test. Malleable iron is initially cast as white iron, then "malleablized," that is, heat treated to impart ductility to an otherwise exceedingly brittle material.

Two additional subdivisions of these five basic types include high-alloy graphitic irons and compacted graphite irons. The high-alloy graphitic irons, which are primarily used for applications requiring corrosion resistance or a combination of strength and oxidation resistance, are produced in both flake graphite (gray iron) and spheroidal graphite (ductile iron). Compacted graphite (CG) cast iron is characterized by graphite that is interconnected within eutectic cells, as is the flake graphite in gray iron. Compared with the graphite in gray iron, however, the graphite in CG iron is coarser and more rounded.

Steels

Steels can be classified on the basis of composition, such as carbon, low-alloy, and high-alloy steel (Fig. 2); microstructure, such as ferritic, austenitic, martensitic, and so forth; or product form, such as bar, plate, sheet, strip, tubing, or structural shape.

Common use has further subdivided these broad classifications. For example, carbon steels are often classified according to carbon content as low-, medium-, or high-carbon steels. Alloy steels are often classified according to the principal alloying element (or elements) present. Thus, there are nickel steels, chromium steels, chromium-vanadium steels, and so on.

Gray Iron

D.B. Craig, M.J. Hornung, and T.K. McCluhan, Elkem Metals Company

Introduction

THE TERM GRAY IRON refers to a broad class of ferrous casting alloys normally characterized by a microstructure of flake graphite in a ferrous matrix. Gray irons are in essence iron-carbon-silicon alloys containing small quantities of other elements. As a class, they vary widely in physical and mechanical properties.

The metallurgy of gray irons is extremely complex because of a wide variety of factors that influence their solidification and subsequent solid-state transformations. In spite of this complexity, gray irons have found wide acceptance based on a combination of outstanding castability, excellent machinability, economics, and unique properties.

Metallurgy

Crucial to understanding the production, properties, and applications of gray iron is an understanding of its metallurgy. While it is beyond the scope of this article to detail gray iron metallurgy, it is important to understand the metallurgical background of this group of ferrous casting alloys. The importance of composition and processing variables in product performance cannot be overemphasized.

Composition

For purposes of clarity and simplicity, the chemical analyses of gray iron can be broken down into three categories. The first category includes the major elements. In the second group are minor, normally low-level alloying elements that are critically related to gray iron solidification. Finally, there are a number of trace elements that affect the microstructure and/or properties of the material.

Major Elements. The three major elements in gray iron are carbon, silicon, and iron. Carbon and silicon levels found in commercial irons vary widely, as shown below:

Type of Iron	Total carbon, %	Silicon, %
Class 20	3.40-3.60	2.30-2.50
Class 30	3.10-3.30	2.10-2.30
Class 40	2.95-3.15	1.70-2.00
Class 50	2.70-3.00	1.70-2.00
Class 60	2.50-2.85	1.90-2.10

Primarily because of the development of ductile iron and some specialized grades of alloyed irons, most gray irons are produced with total carbon levels from 3.0 to 3.5%. Normal silicon levels vary from 1.8 to 2.4%.

Gray irons are normally viewed as iron-carbon-silicon ternary alloys. A section from the equilibrium phase diagram at 2.5% Si is shown in Fig. 1. As can be seen, the material exhibits eutectic solidification and is subject to a solid-state eutectoid transformation. These two factors dominate the metallurgy of gray iron.

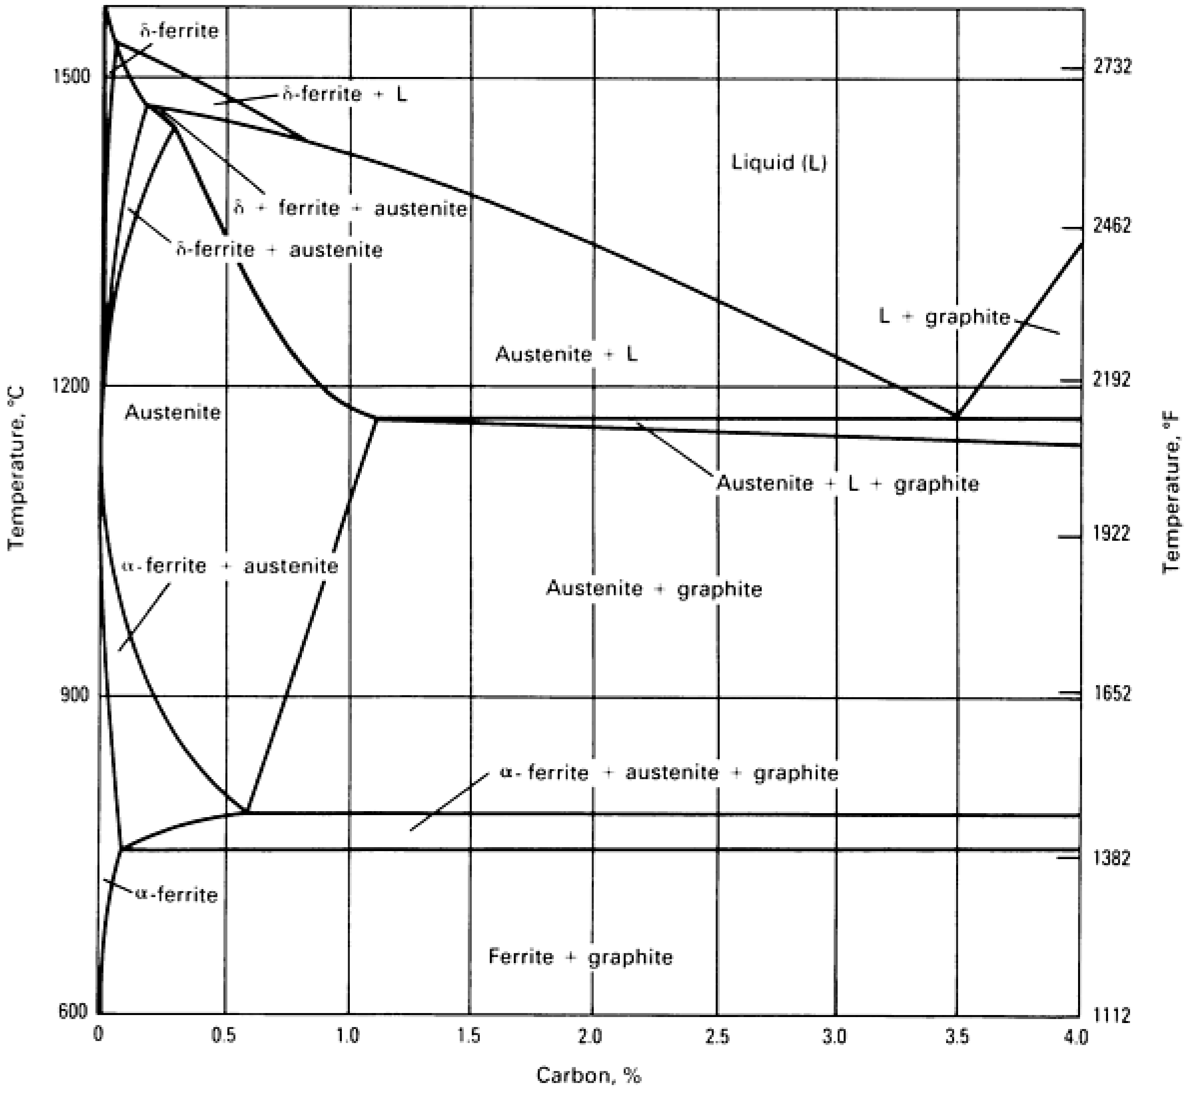

Fig. 1 Iron-carbon phase diagram at 2.5% Si. Source: Ref 1

Both carbon and silicon influence the nature of iron castings. It is therefore necessary to develop an approximation of their impact on solidification. This has been accomplished through development of the concept of carbon equivalence (CE). Using this approach, carbon equivalence is calculated as:

$$CE = \%C + \frac{\%Si}{3} \quad \textbf{(Eq 1)}$$

or more precisely, taking phosphorus into consideration:

$$CE = \%C + \frac{(\%Si + \%P)}{3} \quad \textbf{(Eq 2)}$$

Using Eq 1 and 2, it is possible to relate the effect of carbon, silicon, and phosphorus to the binary iron-carbon system. Irons with a carbon equivalent of 4.3 are considered to be of eutectic composition. Most gray irons are hypoeutectic (that is, CE < 4.3). Nearly all of the mechanical and physical properties of gray iron are closely related to CE value.

The minor elements in gray iron are phosphorus and the two interrelated elements manganese and sulfur. These elements, like carbon and silicon, are of significant importance in gray iron metallurgy. Control is required for product consistency. Absolute levels vary somewhat with application and foundry process variables.

Phosphorus is found in all gray irons. It is rarely added intentionally, but tends to come from pig iron or scrap. To some extent, it increases the fluidity of iron. Phosphorus forms a low-melting phosphide phase in gray iron that is commonly referred to as steadite. At high levels, it can promote shrinkage porosity, while very low levels can increase metal penetration into the mold (Ref 2, 3). As a result, most castings are produced with 0.02 to 0.10% P. In critical castings involving pressure tightness, it may be necessary to develop optimum levels for the application.

Sulfur levels in gray iron are very important and to some extent are an area of current technical controversy. Numerous investigators have shown that sulfur plays a significant role in the nucleation of graphite in gray iron. The impact of sulfur on cell counts and chill depth in gray iron can be seen in Fig. 2 for uninoculated and inoculated gray irons. This work indicates that sulfur levels in gray iron should be in the approximate range of 0.05 to 0.12% for optimum benefit.

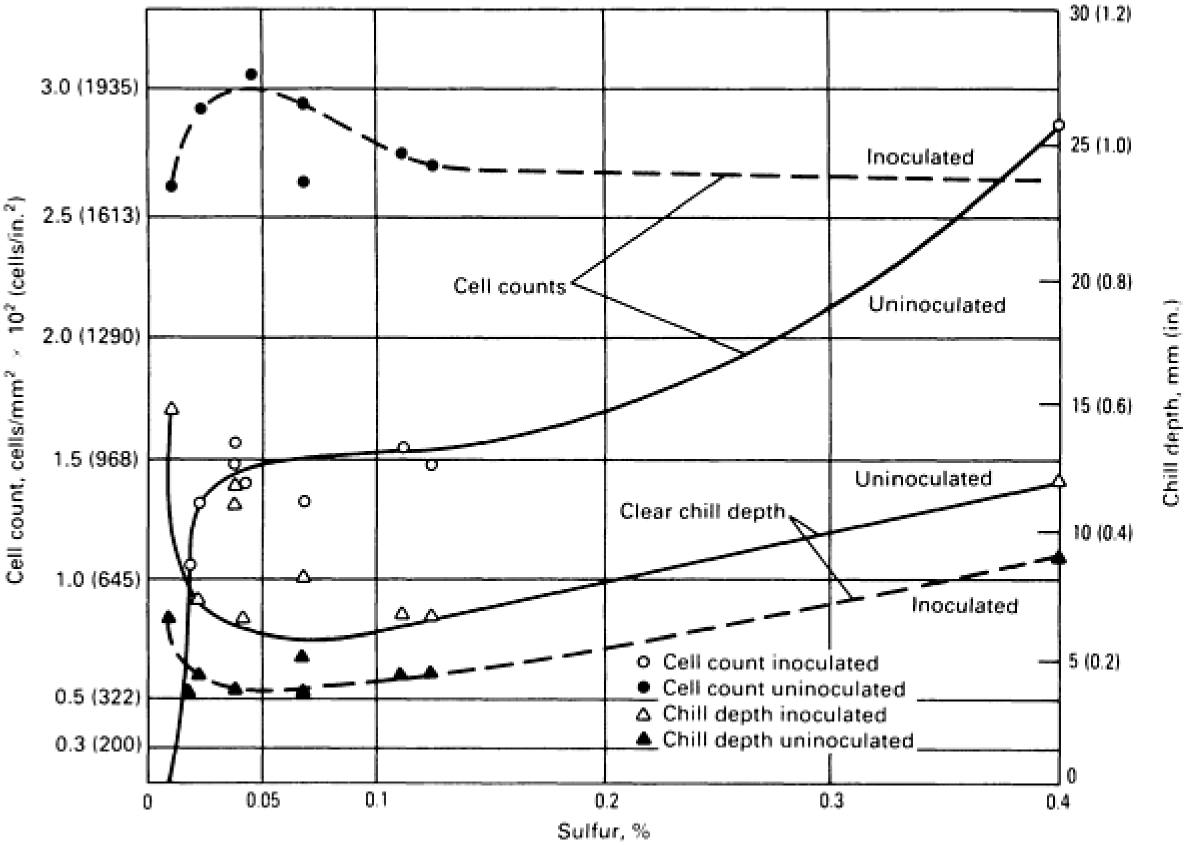

Fig. 2 Effect of sulfur on eutectic cell count and clear chill depth for inoculated and uninoculated gray irons. Source: Ref 4

It is important that the sulfur content of iron be balanced with manganese to promote the formation of manganese sulfides. This is normally accomplished by using Eq 3:

$$\%Mn \geq 1.7\% \, S + 0.3\% \quad \textbf{(Eq 3)}$$

Recent work has indicated that the 0.3% level may be reduced slightly; some foundries add only 0.2% excess manganese.

Trace Elements. In addition to these primary elements, there are a number of minor elements that affect the nature and properties of gray iron. Table 1, extracted in part from a tabulation by BCIRA, shows the effects of some trace elements

on gray iron as well as their possible sources. Depending on property requirements, many of these elements can be intentionally added to gray iron. For example, tin and copper are often added to promote pearlite.

Table 1 Effects, levels, and sources of some trace elements in gray iron

Element	**Trace level, %**	**Effects**	Sources
Aluminum	≤0.03	Promotes hydrogen pinhole defects, especially when using green sand molds and at levels above 0.005%. Neutralizes nitrogen	**Deliberate addition, ferrous alloys, inoculants, scrap contaminated with aluminum components**
Antimony	≤0.02	Promotes pearlite. Addition of 0.01% reduces the amount of ferrite sometimes found adjacent to cored surfaces.	**Vitreous enameled scrap, steel scrap, white metal bearing shells, deliberate addition**
Arsenic	≤0.05	Promotes pearlite. Addition of 0.05% reduces the amount of ferrite sometimes found adjacent to cored surfaces.	**Pig iron, steel scrap**
Bismuth	≤0.02	Promotes carbides and undesirable graphite forms that reduce tensile properties	**Deliberate addition, bismuth-containing molds and core coatings**
Boron	≤0.01	Promotes carbides, particularly in light-section parts. Effects become significant above about 0.001%.	**Deliberate addition, vitreous enameled scrap**
Chromium	≤0.2	Promotes chill in thin sections	**Alloy steel, chromium plate, some refined pig iron**
Copper	≤0.3	Trace amounts have no significant effect and can be ignored.	**Copper wire, nonferrous alloys, steel scrap, some refined pig iron**
Hydrogen	≤0.0004	Produces subsurface pinholes and (less often) fissures or gross blowing through a section. Mild chill promoter. Promotes inverse chill when insufficient manganese is present. Promotes coarse graphite	**Damp refractories, mold materials, and additions**
Lead	≤0.005	Results in Widmanstätten and "spiky" graphite, especially in heavy sections with high hydrogen. Can reduce tensile strength 50% at low levels (≥0.0004%). Promotes pearlite	**Some vitreous enamels, paints, free-cutting steels, nonferrous alloys, terne plate, white metal, solder, some pig irons**
Molybdenum	≤0.05	Promotes pearlite	**Some refined pig iron, steel scrap**
Nickel	≤0.01	Trace amounts have no major effect and can be ignored.	**Refined pig iron, steel scrap**
Nitrogen	≤0.02	Compacts graphite and increases strength. Promotes pearlite. Increases chill. Can cause pinhole and fissure defects. Can be neutralized by aluminum or titanium	**Coke, carburizers, mold and core binders, some ferroalloys, steel scrap**

Tellurium	≤ 0.003	Not usually found, but a potent carbide former	**Free-cutting brasses, mold and core coatings, deliberate addition**
Tin	≤ 0.15	Strong pearlite promoter; sometimes deliberately added to promote pearlitic structures	**Solder, steel scrap, nonferrous alloys, refined pig iron, deliberate addition**
Titanium	≤ 0.15	Promotes undercooled graphite. Promotes hydrogen pinholing when aluminum is present. Combines with nitrogen to neutralize its effects	**Some pig irons, steel scrap, some vitreous enamels and paints, deliberate addition**
Tungsten	≤ 0.05	Promotes pearlite	**Tool steel**
Vanadium	**≤ 0.08**	**Forms carbides; promotes pearlite**	**Steel scrap; some pig irons**

Solidification

Eutectic solidification and the accompanying transformations responsible for the development of the graphite and matrix structure of a cast iron are discussed in the article "Solidification of Eutectics" in this Volume. A review of these principles as they pertain to gray iron will be presented in the following paragraphs.

Most gray irons are hypoeutectic in nature (that is, CE < 4.3). The sequence of events associated with the solidification of hypoeutectic irons can be studied with the simplified version of the iron-carbon-silicon ternary phase diagram taken at 2% Si (Fig. 3).

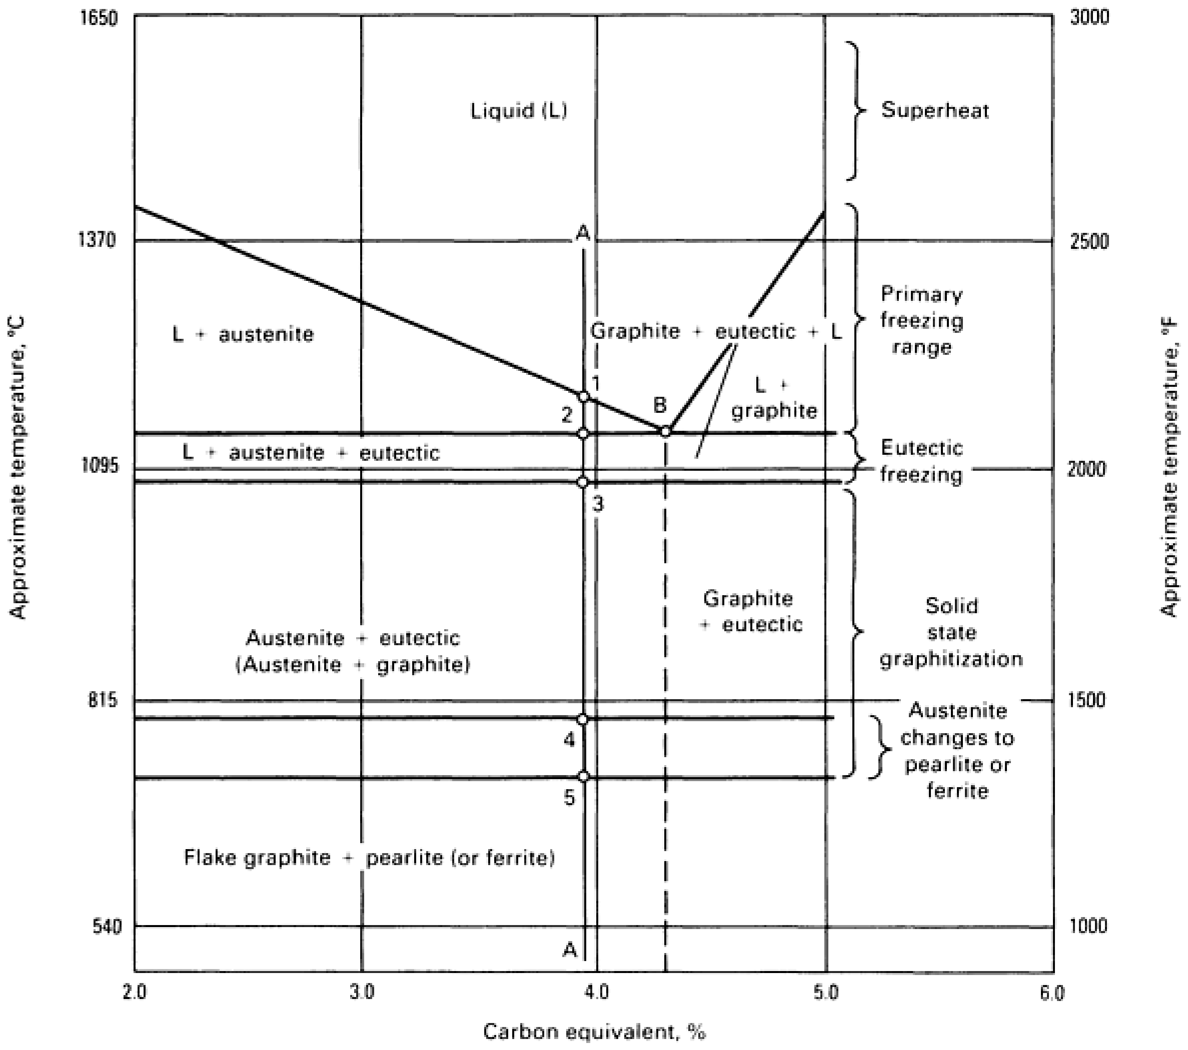

Fig. 3 Simplified iron-carbon-silicon phase diagram at 2% Si. Source: Ref 6

At temperatures above point 1 in Fig. 3, the iron is entirely molten. As the temperature is decreased and the liquidus line is crossed, primary freezing begins with the formation of proeutectic austenite dendrites. These dendrites grow and new dendrites form as the temperature drops through the primary freezing range, which is marked by points 1 and 2. Dendrite size is governed by the carbon equivalent of the iron and the solidification rate. Lower carbon equivalents produce large dendrites because the temperature interval between the liquidus and eutectic lines is greater for these irons than for those with a higher carbon equivalent. As expected, rapid cooling promotes a finer dendrite size.

During the formation of the austenite dendrites, carbon is rejected into the remaining liquid. The carbon content of the liquid increases until it reaches the eutectic composition of 4.3%. Once this composition is attained, the liquid transforms into two solids. This takes place between points 2 and 3. The type of solid formed depends on whether solidification is following the metastable or stable eutectic reaction. Iron carbide plus austenite form during the metastable reaction. Graphite plus austenite form during the stable reaction. When eutectic solidification is complete, no liquid metal remains, and any further reaction takes place in the solid state.

Although not shown in Fig. 3, in the temperature interval between the eutectic and eutectoid transformations, marked by points 3 and 4, the high-carbon austenite rejects carbon, which diffuses to the graphite flakes. This allows the austenite to acquire the composition needed for the eutectoid transformation, which, under equilibrium conditions, takes place between points 4 and 5. This transformation involves the decomposition of austenite into pearlite or pearlite plus ferrite, depending on such factors as the cooling rate and alloy content of the iron. In unalloyed gray irons, no significant changes in microstructure occur below the eutectoid transformation line.

Graphite Morphology

The mechanical and physical properties of gray iron are governed in part by the shape, size, amount, and distribution of the graphite flakes. A method for evaluating graphite flake distribution and size is given in ASTM A 247, and the metallography of cast irons is discussed in Ref 7, 8, 9.

There are five graphite flake distributions: A to E (Fig. 4). Type A graphite flakes are randomly distributed and oriented throughout the iron matrix. This type of graphite is found in irons that solidify with a minimum amount of undercooling, and type A is the structure desired if mechanical properties are to be optimized.

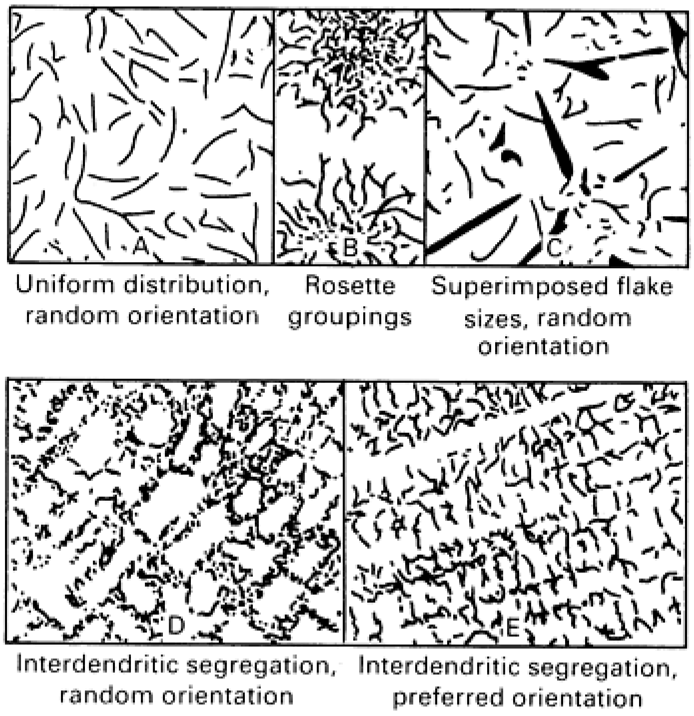

Fig. 4 Graphite distributions specified in ASTM A 247

Type B graphite is formed in irons of near-eutectic composition that solidify with a greater amount of undercooling than that associated with type A graphite. Rosettes containing fine graphite, which are characteristic of type B, precipitate at the start of eutectic solidification. The heat of fusion associated with their formation increases the temperature of the surrounding liquid, thus decreasing the undercooling and resulting in the formation of type A graphite.

Types D and E graphite form when the amount of undercooling is high but is not sufficient to cause carbide formation. Both types are found in interdendritic regions. Type D graphite is randomly distributed, while the type E flakes have a preferred orientation. The manner in which the plane of polish intersects the graphite flakes may be responsible for this difference in orientation. Elements such as titanium and aluminum have been found to promote undercooled graphite structures. The iron matrix associated with undercooled graphite is usually ferrite because formation of the fine, highly branched flakes reduces carbon diffusion distances and results in a low-carbon matrix. Because ferrite has a lower tensile strength than pearlite, there is a reduction in the anticipated strength of the iron. Examples of type A, B, and D graphite found in commercial irons are shown in Fig. 5.

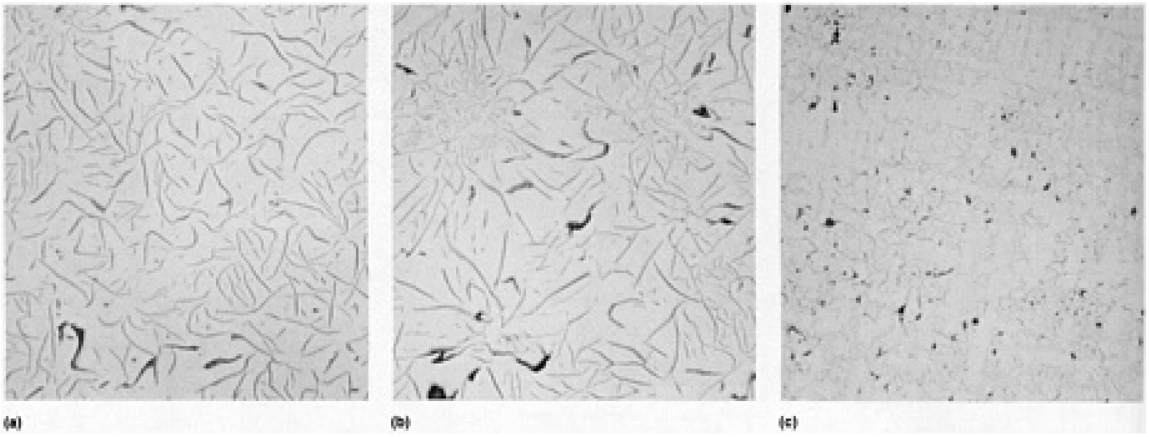

Fig. 5 Examples of type A (a), type B (b), and type D (c) graphite from foundry-produced gray irons. As-polished. 100×

Type C graphite occurs in hypereutectic irons, particularly those with a high carbon content. Type C graphite precipitates during the primary freezing of the iron. Kish graphite, as it is often called, appears as straight, coarse plates. It greatly

reduces the mechanical properties of the iron and produces a rough surface finish when machined. Type C graphite is, however, desirable in applications requiring a high degree of heat transfer.

Graphite flake sizes as categorized in ASTM A247 are shown in Fig. 6. Large flakes are associated with irons having high carbon equivalents and slow cooling rates. Strongly hypoeutectic irons and irons subjected to rapid solidification generally exhibit small, short flakes. The large flakes are desirable in applications requiring high thermal conductivity and damping capacity. Small flakes, because they disrupt the matrix to a lesser extent, are desired when maximum tensile properties and a fine, smooth surface finish are needed.

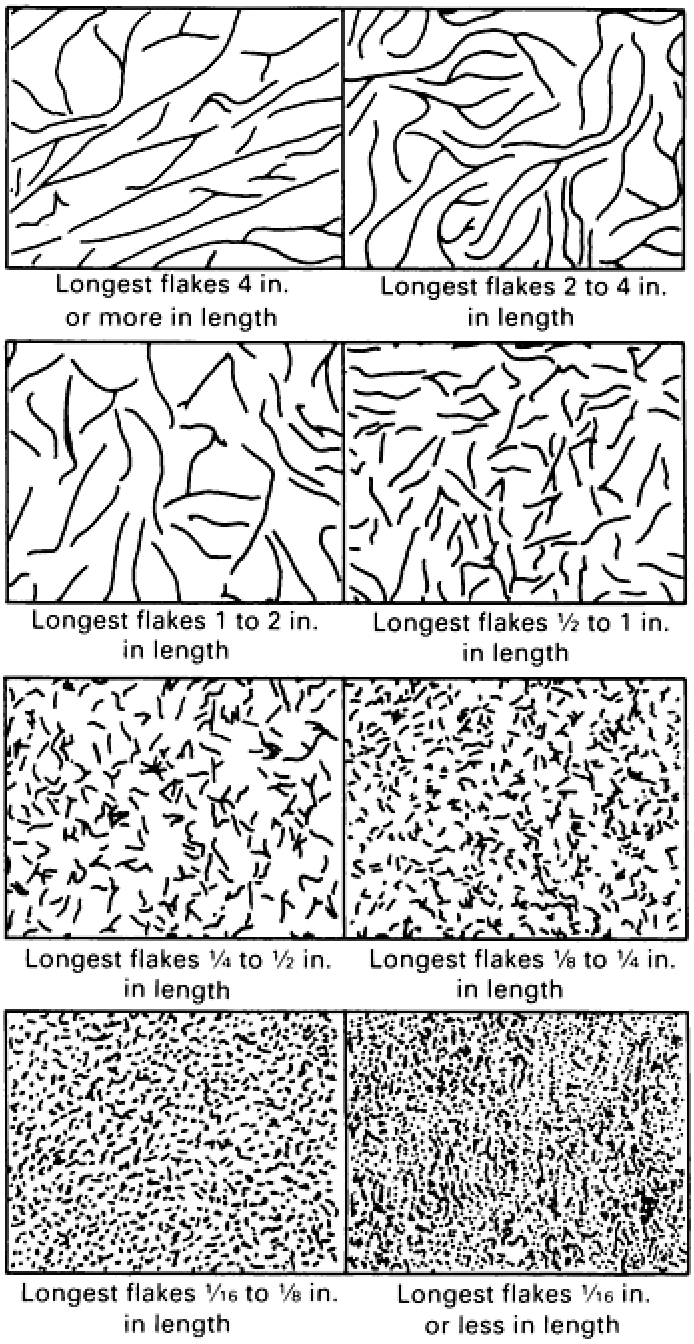

Fig. 6 Graphite flake sizes as specified in ASTM A 247

Matrix Structure

An etchant such as 2% nital is required to reveal the matrix phases in which the graphite flakes reside. Commonly found phases in cast iron are ferrite, cementite, and pearlite.

Ferrite is the soft, low-carbon α-iron phase that exhibits low tensile strength but high ductility. It is promoted by graphitizers such as silicon as well as slow cooling rates such as those found in heavy sections. As previously mentioned, ferrite is often found in conjunction with undercooled graphite (Fig. 7).

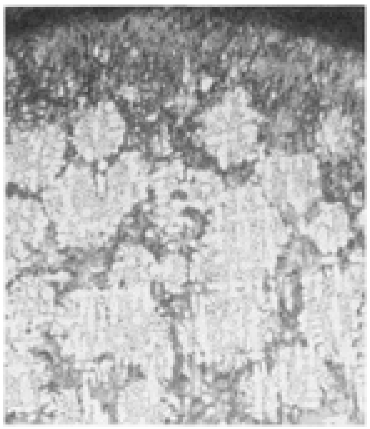

Fig. 7 Graphite and pearlite revealed by etching with 2% nital. The ferrite is found with undercooled graphite. 100×

Cementite, or eutectic carbide, is a hard, brittle intermetallic compound of iron and carbon. Its formation is favored in areas of a casting where rapid cooling takes place, such as in thin sections, at corners, and along the cast surface. Irons with low carbon equivalences, particularly those with low silicon contents, are likely to contain cementite. An example of eutectic carbide found in a mottled iron is shown in Fig. 8.

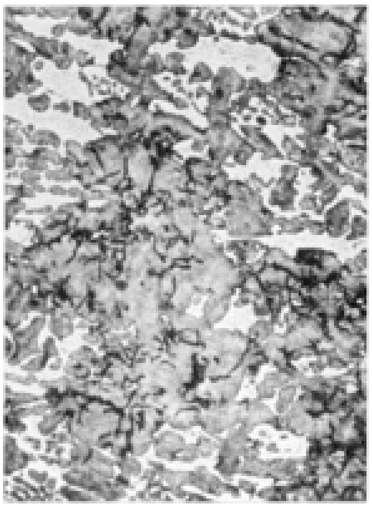

Fig. 8 Mottled cast iron etched using 4% picral. The white phase is eutectic carbide. 50×. Source: Ref 10

Pearlite is the eutectoid transformation product and in gray iron consists of lamellar plates of ferrite and cementite. It possesses higher hardness and tensile strength than ferrite but lower ductility. The hardness and tensile strength associated with pearlite depend primarily on the spacing of the plates. Higher values are found in pearlite with fine interlamellar spacing, which is associated with more rapid cooling rates or alloying. A comparison of tensile strength, ductility, and hardness values for these matrix phases is given below:

Phase	Tensile strength, MPa (ksi)	Elongation, %	Hardness, HB
Ferrite	272-290 (39.5-42)	61	**75**
Pearlite	862 (125)	10	**200**
Cementite	. . .	. . .	**550**

Source: Ref 6

Other microconstituents can also be formed in gray iron by changing the solidification rate or by adding alloying elements. Bainite can be produced by subjecting the iron to an isothermal heat treatment. Quenching the iron from the austenite region can induce martensite formation. Alloying elements such as nickel can be used to produce austenitic gray irons. Hardness values for various combinations of graphite and other matrix phases are given in Table 2.

Table 2 Hardness ranges for various combinations of gray iron microstructures

Microstructure	Hardness, HB
Ferrite + graphite	**110-140**
Pearlite + graphite	**200-260**
Pearlite + graphite + massive carbides	**300-450**
Bainite + graphite	**260-350**
Tempered martensite + graphite	**350-550**
Austenite + graphite	**140-160**

Source: Ref 11

Steadite, the iron-phosphide eutectic, is commonly found in gray irons with phosphorus contents in excess of the 0.02% level considered to be soluble in austenite. It has a low melting point (about 930 °C, or 1705 °F) and is typically the last constituent to solidify. This explains its presence at cell boundaries, where it can assume a concave triangle appearance (Fig. 9). Steadite, like iron carbides, can decrease the mechanical properties of the iron. Elements such as chromium and molybdenum can concentrate in the phosphide phase, thus increasing its volume (Ref 13).

Fig. 9 Steadite in gray cast iron. Etched using 2% nital. 400×. Source: Ref 12

Manganese sulfides are commonly found evenly distributed in the matrix of gray iron, as shown in Fig. 10. They are dove gray, geometrically shaped inclusions that are formed before final solidification. The presence of manganese sulfide is a result of deliberate additions of manganese to prevent the formation of brittle iron sulfides that would otherwise form at the grain boundaries. Sufficient manganese must be added to tie up the sulfur to prevent this from occurring. Equation 3 is used to determine the manganese needed to balance the sulfur. Additional manganese is sometimes added, and a general rule is to add three times as much manganese as there is sulfur to ensure neutralization.

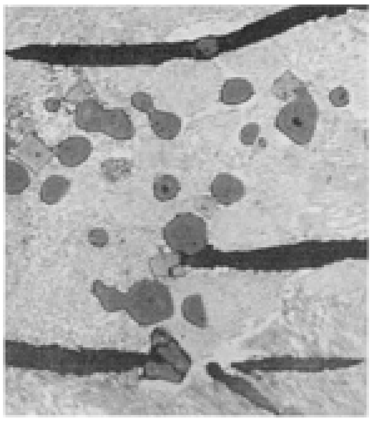

Fig. 10 Manganese sulfide (dark gray, rounded) and titanium carbonitride (light gray, angular) inclusions. Etched using 2% nital. 500×

Titanium carbides or titanium carbonitrides are often observed in gray iron. This is particularly true for irons to which deliberate titanium additions have been made to prevent the formation of nitrogen fissure defects. These inclusions are angular, often cubic in appearance, and are found throughout the matrix but are concentrated in the intercellular regions (Fig. 10). They usually possess an orange color when viewed under reflected light, but other colors, including blue-gray, violet, pink, and yellow, have been observed, depending on nitrogen content (Ref 14).

Section Sensitivity

The solidification of a gray iron casting is controlled by the composition and the cooling rate of the iron within the casting. Each variable has a considerable effect on solidification. However, once the iron is poured into the mold, the composition is fixed and, except for localized segregation, remains relatively homogeneous throughout the casting. Therefore, during solidification, the cooling rate becomes the controlling variable. The cooling rate influences the

microstructure from the inception of solidification until the iron passes through the eutectoid transformation. It is a controlling factor in the amount of carbon remaining in solution and therefore affects the resulting microstructure.

Cooling rate is influenced by a number of variables that include pouring temperature, pouring rate, volume of iron to be cooled, surface area of the iron, thermal conductivity of mold material, amount of mold material surrounding the casting, the number of castings in a mold, location of cores, and the position of gates and risers (Ref 15). Within a mold, a number of these variables will remain constant. However, as volume-to-surface-area ratio of the casting varies from section to section, so does the corresponding cooling rate. This variation in cooling rate results in a changing solidification pattern for each section, which can create a variation in mechanical properties within the casting. Therefore, the solidification of a gray iron casting is said to be section sensitive.

It is important for both the casting designer and the foundryman to recognize the section sensitivity of gray iron. The casting designer should indicate which mechanical properties are required in each section of a casting as well as which sections are critical. The foundryman can then select the iron composition that will develop the desired mechanical properties during solidification.

The effect of section thickness on the hardness of gray iron is illustrated in Fig. 11. A wedge-shaped bar with a taper of 10° was cast in a sand mold and sectioned near the center of the bar. Rockwell Hardness determinations were made progressively from the tip to the base of the wedge. The effect of increasing section size is shown by the change in hardness associated with the increasing width of the wedge.

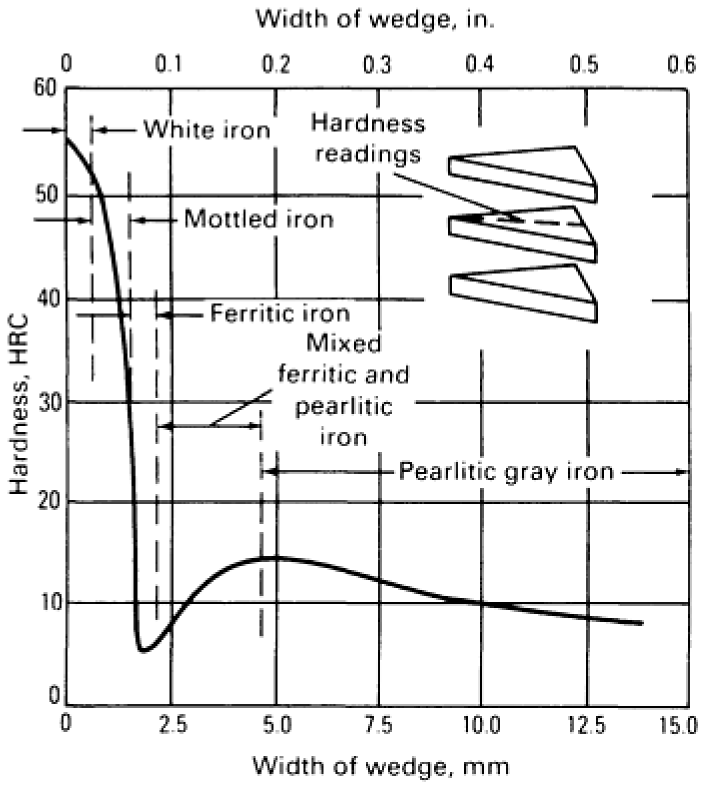

Fig. 11 Effect of section thickness on the hardness and microstructure of gray iron. Hardness readings were taken at increasing distance from the tip of a cast wedge (see inset). Iron composition was Fe-3.52C-2.55Si-1.01Mn-0.215P-0.086S.

The cooling rate is highest at the tip of the wedge. This results in the formation of white iron, a mixture of iron carbide and pearlite that is considerably harder than gray iron (Fig. 11). When the cooling rate has decreased sufficiently to allow the formation of some graphite, a mottled zone appears. This mottled zone, which is a mixture of gray and white iron, has a lower hardness than the white iron tip. As the width continues to increase, the white iron gradually disappears, and there is a corresponding drop in hardness. As the white iron disappears, the microstructure becomes a mixture of ferrite and type D graphite, resulting in the minimum hardness shown in Fig. 11. A further reduction in the cooling rate results in an increase in hardness as the microstructure shifts from type D to type A graphite and the matrix converts from ferrite to pearlite. As the cooling rate continues to decrease, the hardness is reduced because of a gradual conversion of the pearlite to ferrite and the formation of a coarser graphite structure.

Figure 11 shows the hardness profile for one composition of gray iron. A change in composition or foundry practice can shift this curve to the right or left; therefore, the wedge can be a useful indicator of the tendency of the iron to chill. By measuring the depth of chill in the wedge, the foundryman can monitor gray iron for variations in the foundry process.

The cooling rate influences the amount of time allowed for the diffusion of carbon from the austenite to the graphite and therefore determines the level of combined carbon retained in the iron. Slow cooling rates allow more time for carbon diffusion. As the amount of combined carbon decreases, the amount of ferrite increases, resulting in an overall reduction of the mechanical strength of the iron. Therefore, the cooling rate must be controlled until the critical sections of the casting pass through the eutectoid temperature to ensure that the desired mechanical properties have been achieved.

In ASTM A 48, gray iron is classified based on the tensile strength of the iron. The categories range from class 20 to class 60 (minimum tensile strength of 138 to 414 MPa, or 20 to 60 ksi, respectively) in a 30.5 mm (1.2 in.) test bar. Figure 12 shows the effect of varying section size on tensile strength for various classes of iron. Tensile strength decreases with increasing section size for all classes of gray iron. For example, an iron with a tensile strength of 310 MPa (45 ksi) in a 25 mm (1 in.) section will develop only 207 MPa (30 ksi) in a 76 mm (3 in.) section because of the decreased cooling rate associated with the larger section. This reduction in tensile strength is caused by the presence of larger graphite flakes and by a reduction in combined carbon. Decreasing combined carbon results in an increase in the amount of ferrite found as either a coarser pearlite spacing, or in the appearance of a ferrite phase.

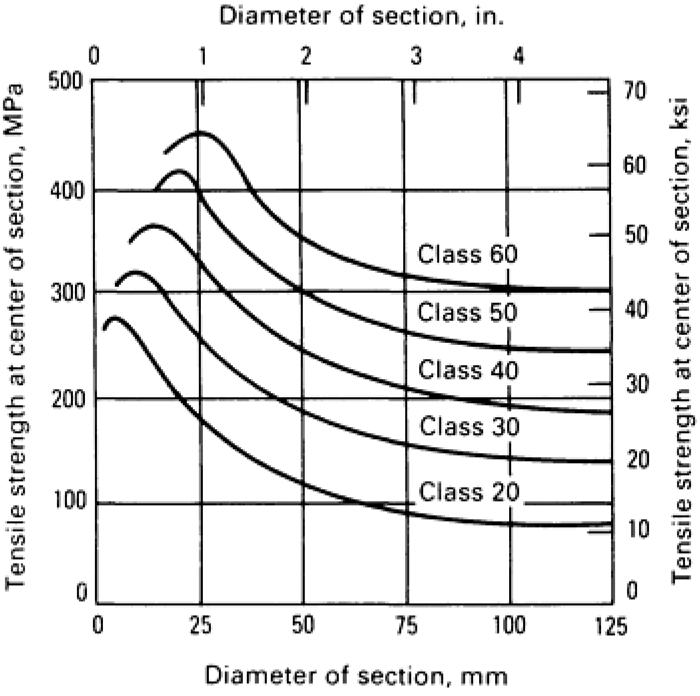

Fig. 12 Effect of section size on tensile strength of specimens cast from five classes of gray iron

It should be noted that the maximum strength of class 20 iron occurs at a smaller section size than class 60 iron. Each class has a minimum section size that can be cast without the formation of iron carbide; recommended minimum section sizes are listed in Table 3 for each class of unalloyed gray iron. It is important for both the foundryman and the designer to recognize that each class of iron has a minimum section size in which it can be cast without the presence of chill and that this minimum increases with higher classes of gray iron.

Table 3 Minimum recommended section sizes for unalloyed gray irons

Class	**Minimum section thickness**		Volume-to-surface-area ratio[(a)]	
	mm	**in.**	**mm**	in.
20	3.2	$\frac{1}{8}$	1.5	**0.06**
25	6.4	$\frac{1}{4}$	3.0	**0.12**

30	9.5	$\frac{3}{8}$	4.3	**0.17**
35	9.5	$\frac{3}{8}$	4.3	**0.17**
40	15.9	$\frac{5}{8}$	7.1	**0.28**
50	19.0	$\frac{3}{4}$	8.4	**0.33**
60	**25.4**	**1**	**10.7**	**0.42**

(a) Volume-to-surface-area ratios are for square plates.

Cooling rates are difficult to predict for complex shapes. However, the cooling rate for the casting can be approximated by comparing the various sections of the casting to the simplified shapes listed in Table 4. The volume-to-surface-area ratios have been calculated for these shapes and can be compared to the minimum volume-to-surface-area ratios for each class of iron listed in Table 3.

Table 4 Volume-to-surface-area ratios for bars and plates

Cast form and size	Volume-to-surface-area ratio	
	mm	in.
Bar 12.7 mm ($\frac{1}{2}$ in.) diam × 533 mm (21 in.) long	3.0	**0.12**
Bar 12.7 mm ($\frac{1}{2}$ in.) square × 533 mm (21 in.) long	3.0	**0.12**
Plate 6.4 mm ($\frac{1}{4}$ in.) × 305 × 305 mm (12 × 12 in.)	3.0	**0.12**
Bar 30.5 mm (1.2 in.) diam × 533 mm (21 in.)	7.4	**0.29**
Bar 30.5 mm (1.2 in.) square × 533 mm (21 in.)	7.4	**0.29**

Plate 15.9 mm ($\frac{5}{8}$ in.) × 305 × 305 mm (12 × 12 in.)	7.1	**0.28**
Bar 51 mm (2 in.) diam × 559 mm (22 in.)	12.2	**0.48**
Bar 51 mm (2 in.) square × 559 mm (22 in.)	12.2	**0.48**
Plate 28.6 mm ($1\frac{1}{8}$ in.) × 305 × 305 mm (12 × 12 in.)	11.9	**0.47**
Bar 102 mm (4 in.) diam × 457 mm (18 in.)	22.9	**0.90**
Bar 102 mm (4 in.) square × 457 mm (18 in.)	22.9	**0.90**
Plate 65 mm ($2\frac{9}{16}$ in.) × 305 × 305 mm (12 × 12 in.)	22.8	**0.90**
Bar 152 mm (6 in.) diam × 457 mm (18 in.)	32.7	**1.29**
Bar 152 mm (6 in.) square × 457 mm (18 in.)	32.7	**1.29**
Plate 114 mm ($4\frac{1}{2}$ in.) × 305 × 305 mm (12 × 12 in.)	**32.7**	**1.29**

The minimum section sizes were developed for plates and can vary depending on foundry practice and mass effects. Mass effects occur when a very large section of a casting cools very slowly and influences the cooling rate of nearby smaller sections.

Commercial foundries often use separately cast test bars to monitor the mechanical properties of the iron. Because gray iron is section sensitive, it is important for the foundry to select a test bar with a cooling rate similar to that of the controlling section of the casting. Specification ASTM A 48 covers five categories of test bars that represent various section sizes within a casting. Foundries typically select a test bar 30.5 mm (1.2 in.) in diameter to monitor the mechanical properties of gray iron. It is interesting to note that this 30.5 mm (1.2 in.) diam bar is used in determining the minimum tensile strength required for each class of iron. It is important that the designer not only designate which class of iron is required but also in which sections this strength is required, so that the foundryman can accurately control the mechanical properties of the casting.

Foundry Practice

Specific aspects of foundry practice for gray iron that will be discussed include melting, inoculation, alloying, pouring, and molding. Foundry practices for other cast irons are detailed in the articles "Ductile Iron," "Compacted Graphite Irons," "High-Alloy White Irons," "Malleable Iron," and "High-Alloy Graphitic Irons" in this Volume.

Melting

The essential purpose of melting is to produce molten iron of the desired composition and temperature. For gray iron, this can be accomplished with various types of melting equipment. Cupolas and induction furnaces tend to be the types most commonly found in the gray iron foundry. The cupola was traditionally the major source of molten iron. However, gradual acceptance of electric melting has reduced the dominance of the cupola. Gray iron can be melted with a single furnace or a combination of furnaces. Detailed information on the operating parameters of each furnace type can be found in the Section "Foundry Equipment and Processing" in this Volume.

Regardless of the type of furnace used, the basic melting process is a physical transformation from solid to liquid rather than a complex reduction or oxidation reaction. Therefore, the composition of all the materials charged into the furnace determines the composition of the slag/iron mixture. As mentioned previously, the composition of the iron will affect the resulting microstructure and mechanical properties. Therefore, control of the major, minor, and trace elements in the charge materials will ultimately influence the properties of the iron.

The cupola is a vertical steel shaft that can be refractory lined or water cooled, as shown in Fig. 13. It consists of a furnace hearth (or well), a melting zone, and an upper stack. The furnace hearth includes the bottom doors, the sand bed, and the iron trough. The tuyeres are located near the bottom of the melting zone, and the charging doors are located in the upper stack.

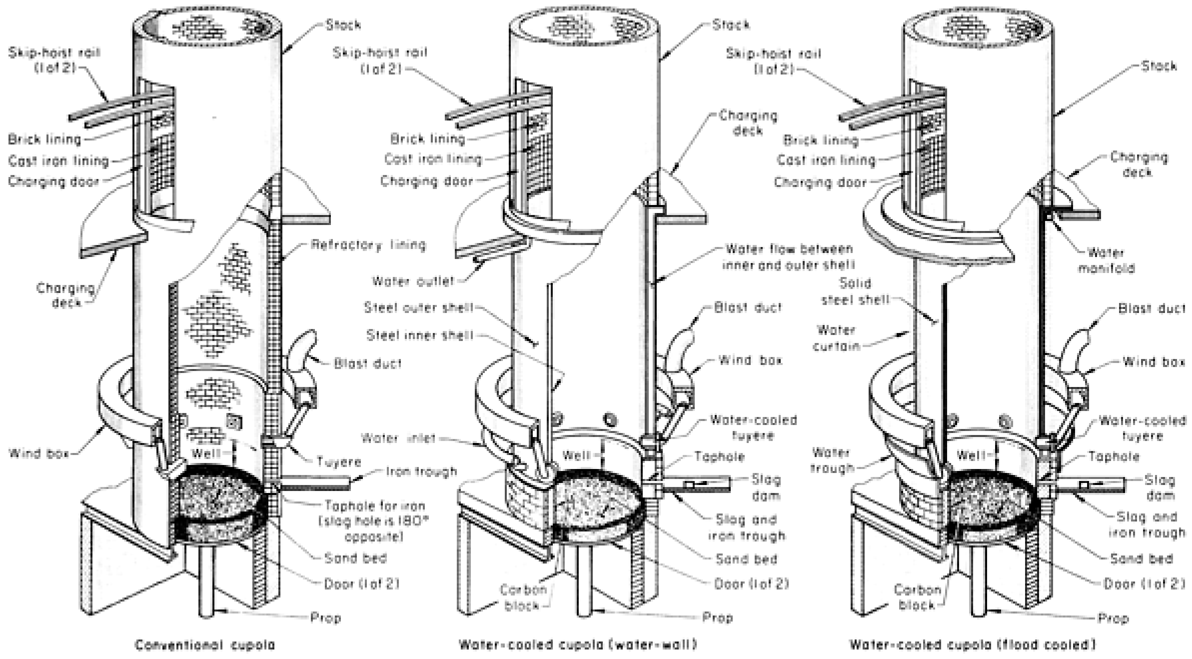

Fig. 13 Sectional views of conventional and water-cooled cupolas

The cupola is prepared for operation by closing the bottom doors and supporting them with a prop. A bed of rammed sand 150 to 200 mm (6 to 8 in.) thick is placed on the doors. The sand bed is sloped such that the molten iron and slag that collect on the bed flow toward the taphole, which is located at the edge of the sand bed. The hearth and the melting zone are filled with a coke bed to a level of approximately 1 to 1.5 m (40 to 60 in.) above the tuyere level. The coke bed is lit, and the shaft is filled with alternating layers of iron-bearing materials, coke, fluxes, and alloys. The shaft is filled to the bottom of the charging doors. The air supply or blast is turned on, causing a flow of air to impinge on the coke bed through the tuyeres. The coke burns, liberating heat that superheats a mixture of air and combustion products.

The hot gases from the combustion reaction rise through the stack, heating the charge materials. As the charge materials descend through the stack, the metallics and the fluxes begin to melt. Small iron droplets form and percolate down through the coke bed. The coke bed remains solid up to temperatures of approximately 2000 °C (3630 °F) and thus supports the charge. The iron droplets are superheated as they filter through the coke bed and collect in the hearth. The coke, which is charged in alternate layers with the metallic materials, replenishes that which is consumed during combustion. Therefore, melting is continuous as long as the air blast is on.

As the metal droplets cascade through the coke bed, their surfaces become carburized through contact with the coke. The iron also absorbs sulfur from the coke and oxidizes slightly in the region above the tuyeres. The oxidized iron is then reduced in the region below the tuyeres. Portions of the silicon and manganese alloys are also oxidized in the cupola. However, carbon reduces some of these oxides to their metallic form (Ref 16). Any oxides not reduced in the lower region of the furnace are entrained in the slag. The molten droplets collect within the hearth, and the iron and slag separate due to their different densities. Iron can be tapped from the cupola continuously or intermittently, depending on design.

Cupola slag is formed from coke ash and impurities arising from the charge, together with oxides of silicon, manganese, and other alloying elements (Ref 16). Cupola slag is usually acidic. Acidity is determined by the ratio of CaO to SiO_2 in the slag. Limestone is added to the cupola charge to control the acid/base ratio of the slag and to flux away the coke ash. This fluxing action intensifies the combustion and carburization action of the coke. The acid/base ratio of the slag affects the final composition of the gray iron. An increase in basicity reduces the final sulfur and increases the carbon in the iron. A decrease in silicon can accompany this increase in basicity because of increased oxidation losses. Therefore, control of the fluxing materials charged can influence the resulting composition of cupola-melted gray iron.

The composition of gray iron melted in a cupola depends on the composition of all materials charged and the degree of oxidation each element experiences during melting. The approximate gain or loss various charge constituents experience during the melting process is shown below:

Charge constituent	Loss or gain, % of weight charged
Silicon[(a)]	**-7 to 12**
Manganese[(a)]	**-10 to 20**
Ferrosilicon (lump)	**-10 to 15**
Ferromanganese (lump)	**-15 to 25**
Spiegeleisen	**-15 to 25**
Phosphorus	**+Trace**
Ferrochromium (lump)	**-10 to 20**
Nickel (shot or ingot)	**-2 to 5**
Copper[(b)]	**-2 to 5**
Alloys in briquets	**-5 to 10**
Sulfur	**+40 to 60**

(a) In pig iron or scrap.

(b) As shot or scrap with minimum thickness of 4.8 mm ($\frac{3}{16}$ in.)

The metallic charge composition is based on the estimated losses and the compositional requirements of the gray iron. Compositions for gray iron melted in a cupola will vary among foundries, and some experimentation is usually required to develop a charge composition.

Induction Melting. Commercial induction furnaces are classified as either coreless or channel induction based on the design feature used to induce energy into the metal. Melting is accomplished in an induction furnace through the conversion of an electrically induced magnetic field into heat within the metallic charge materials. The passing of a magnetic field through an electrically insulated metal generates electrical currents that are converted to heat due to

resistance within the metal. Melting occurs when sufficient energy has been induced into the metallic charge. A further influx of energy results in the superheating of the liquid metal. Controlled energy input gives excellent temperature control of the molten metal.

A coreless induction furnace (Fig. 14a) consists of a refractory-lined crucible encircled by a hollow copper coil. The copper coil is water cooled and is connected to a high-energy electrical source. The coil is commonly held in place by vertical iron bars that also act as magnetic yokes. The crucible is usually deeper than it is wide for good electrical coupling. The induction field creates a stirring action in the furnace crucible that is directly proportional to the energy input. A coreless induction furnace can melt as either a batch or semibatch unit. The semibatch unit requires about 50 to 85% of the molten iron remain in the crucible, while the batch method allows for complete removal of the molten iron prior to charging of the cold material. The excellent mixing due to the induced energy makes the coreless induction furnace an excellent primary melter that delivers iron with uniform chemical composition at the desired temperature.

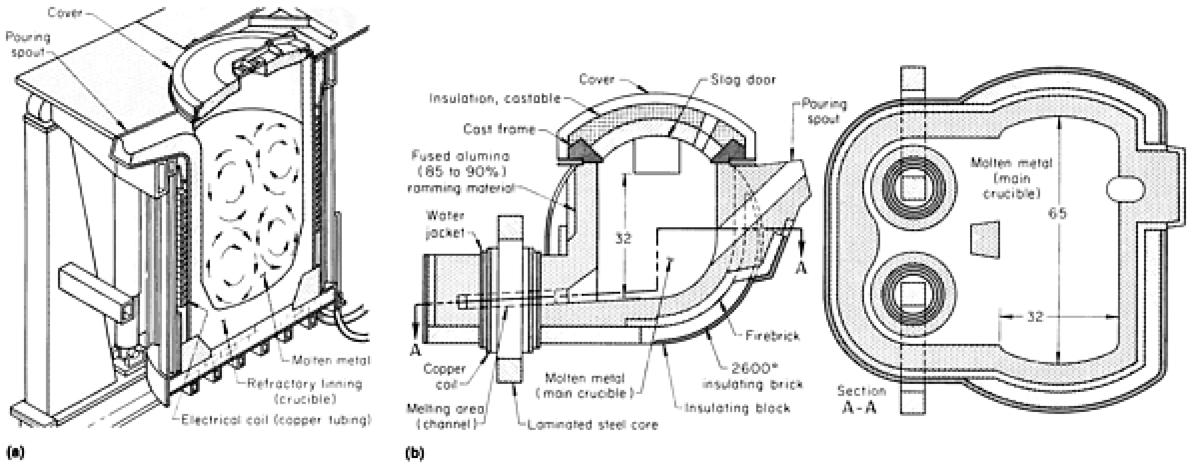

Fig. 14 Sectional views of coreless (a) and cored (b) induction furnaces. Dimensions given in inches

A channel induction furnace (Fig. 14b) consists of a refractory-lined metal reservoir connected to a refractory-lined transformer core. A small channel filled with molten iron acts as one leg of the transformer, and the electrical energy is induced into this channel of iron. The induced energy superheats and circulates the iron within the channel. The superheated iron is returned to the reservoir, where it mixes into the bath by convection, creating a gentle stirring action. A channel induction furnace is highly efficient electrically and generally operates on a low-frequency power supply. Due to the lower stirring action, a channel induction furnace is inefficient as a primary melting unit. Because of its design, this furnace requires a molten metal charge. The channel furnace is generally used in conjunction with another type of melting furnace as a duplexing unit. It is used to smooth out fluctuations in chemistry and temperature from the primary melter and to superheat the iron.

Compositional control of gray iron is greater in induction furnaces than cupolas because of the reduced oxidation losses during melting and the elimination of coke as fuel. The composition of the metallic charge materials is directly related to the final composition of the iron. Therefore, accurate weights and analysis of charge materials are required for good compositional control. Typical charge materials include steel scrap, cast iron scrap, foundry returns, ferrosilicon, and carbon. Pig iron is rarely used because of cost, although it does offer advantages in terms of purity. The type of scrap employed will depend on economics. The elimination of coke from the charge also reduces the sulfur absorbed by the iron; therefore, resulfurization is often desirable in electrically melted gray iron.

Inoculation

Inoculation is defined as the late addition of certain silicon alloys to molten iron to produce changes in graphite distribution, improvements in mechanical properties, and a reduction of the chilling tendency that are not explainable on the basis of composition change with respect to silicon (Ref 17). Graphite, added alone or in combination with ferrosilicon, will also produce these changes without significantly altering the chemistry of the iron. It is recognized that two irons with the same apparent composition can have dramatically different microstructures and properties if one is

inoculated and the other is not. A great deal of research has been dedicated to determining the mechanism behind inoculation (Ref 18, 19). Although many theories exist, no conclusions have been reached regarding possible mechanisms.

The purpose of an inoculant is to increase the number of nuclei in molten iron so that eutectic solidification, specifically graphite precipitation, can begin with a minimum amount of undercooling. When undercooling is minimized, there is a corresponding reduction in the tendency to form eutectic carbide or white iron, which is referred to as chill. Instead, a more uniform microstructure consisting of small type A graphite flakes is produced. These microstructural changes can result in improved machinability and mechanical properties.

Irons are inoculated for various reasons. The primary reason is to control chill in areas of castings that experience rapid solidification, such as in thin sections, at corners, and along edges. Tensile strength can be improved through inoculation. This is particularly true for the lower carbon equivalent irons, which are selected for applications requiring a higher tensile strength (tensile strength decreases as carbon equivalence increases) (Ref 20). Low carbon equivalent irons, however, are also the grades that are most susceptible to carbide formation. Inoculation helps overcome this problem by minimizing the chill-forming tendency of the iron, thus allowing low carbon equivalent irons to be poured in thin sections. Irons that are stored in holding furnaces or in pouring systems for an extended period of time are also more susceptible to chill formation. This susceptibility can be attributed to the reduction in nuclei in the melt that takes place during extended holding. This effect is accelerated if holding occurs at high temperatures. Melting method influences white iron formation; electric-melted irons are generally more prone to carbide formation than cupola-melted irons.

Types of Inoculants. Graphite- or ferrosilicon-base alloys can be used to inoculate gray iron. The graphite used must be highly crystalline to give the best effect. Examples of highly crystalline graphite include some naturally occurring graphite and graphite electrode scrap. Amorphous forms of carbon, such as metallurgical coke, petroleum coke, and carbon electrode scrap, are not suitable for inoculation. Graphite is rarely used by itself and is usually added in combination with a crushed ferrosilicon. Because inconsistent results have been obtained with graphite, careful addition methods and relatively higher temperatures are needed to ensure its complete solution. Graphite has been found to promote extremely high eutectic cell counts.

Ferrosilicon alloys are also used to treat gray iron. They are typically based on 50 or 75% ferrosilicon and act as carriers for the inoculating (reactive) elements, which include aluminum, barium, calcium, cerium or other rare earths, magnesium, strontium, titanium, and zirconium. The silicon in the alloys does not cause significant chill reduction unless added to a level that produces a marked increase in carbon equivalence. Because ferrosilicon dissolves readily, it helps to distribute the reactive elements uniformly throughout the melt. It is important to note that the reactive elements, in addition to reacting with iron, react readily with sulfur and oxygen. Their addition, therefore, can result in dross formation. The quantity of dross produced is directly proportional to the amount of reactive elements in the alloy. Compositions of some of the commercially available ferrosilicon inoculants are given in Table 5.

Table 5 Compositions of ferrosilicon inoculants for gray cast iron

Performance category of inoculant	Composition[(a)], %									
	Si	**Al**	**Ca**	**Ba**	**Ce**	**TRE[(b)]**	**Ti**	**Mn**	**Sr**	Others

(a) All compositions contain balance of iron.

(b) TRE, total rare earths

As indicated in Table 5, it is convenient to group inoculants into four performance categories: standard, intermediate, high potency, and stabilizing. The calcium-bearing alloys fall into the standard category. Improvement in chill reduction is obtained by pairing calcium with barium (Ref 21). This type of inoculant falls into the intermediate group. The strontium or calcium plus cerium alloys are the strongest chill reducers. Figure 15 shows the performance obtainable with these three inoculant groups. It also shows that as the amount of inoculant added increases, a reduction in chill is realized until a point of diminishing returns is reached. It is not correct to assume that if a little is good, a lot is better. Addition levels above those needed to control chill and produce the desired mechanical and microstructural changes result in higher costs and can lead to a variety of problems, including inclusion defects caused by inoculant dross, hydrogen pinholing, and shrinkage.

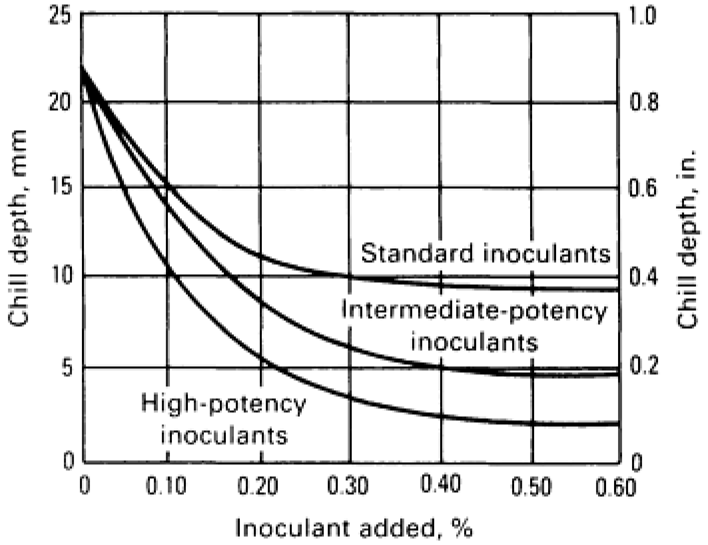

Fig. 15 General classification of inoculants showing chill reduction in iron with carbon equivalence of 4.0

Aluminum is found in all ferrosilicon inoculants in amounts that can vary considerably. This is because the effectiveness of aluminum in controlling chill in gray iron is still under debate. Because aluminum has been linked to hydrogen pinhole formation in castings produced in green sand molds, it is best to keep its level rather low.

Stabilizing inoculants are also available. They are designed to promote pearlite and at the same time provide graphitization during solidification. They are useful in producing high-strength castings with a minimum of chill, and they help to eliminate ferrite in thick sections (Ref 22). Stabilizing inoculants normally employ chromium as the pearlite stabilizer. Because these alloys can be difficult to dissolve, they are not suggested for mold addition.

Inoculant Evaluation. A variety of methods can be employed to evaluate the effectiveness of an inoculant. Because chill reduction is often of primary concern, one way to test an alloy is by pouring chill bars or wedges. The depth of chill produced in the treated iron can be compared to that of the base iron. Details of chill testing can be found in ASTM A 367.

Inoculation is known to increase the eutectic cell count of gray iron. Therefore, eutectic cell count can be used as an indication of the nucleation state of the melt. Samples for this type of evaluation are typically polished through 400-grit paper and then etched with Stead's Reagent (Ref 23). Results should be interpreted with caution because no standard relationship exists between cell count and chill depth. For example, strontium-bearing ferrosilicon inoculants reduce chill to very low levels without dramatically increasing the eutectic cell count.

Evaluation of the microstructure and mechanical properties provides information regarding the performance of an inoculant. The presence of type A graphite rather than carbides and undercooled graphite, along with attainment of the desired tensile properties, indicates that inoculation has been successful. Cooling curves can also be used to evaluate inoculant performance; the relative amount of undercooling can be used as an indicator of effectiveness.

Each technique of alloy evaluation has advantages and disadvantages. The use of a suitable combination of these techniques is suggested for obtaining an adequate assessment of inoculant performance in a particular base iron under a given set of foundry conditions.

Addition Methods. Ladle inoculation is a common method of treating gray iron. In this method, the alloy is added to the metal stream as it flows from the transfer ladle into the pouring ladle. A small heel of metal should be allowed to accumulate in the bottom of the ladle prior to the addition. This allows the inoculant to be mixed and evenly distributed in the iron. Addition of the alloy to the bottom of an empty ladle is not recommended, because this may cause sintering and a reduction in inoculant effectiveness. Problems can also arise if the alloy is added to a full ladle because the material can become entrapped in the slag layer that forms on the surface.

The amount of inoculant needed in this treatment normally varies between 0.15 and 0.4%, depending on the potency of the inoculant. If graphite alone is used, the addition level is about 0.1 to 0.2%. Excessive additions should be avoided for the reasons cited earlier. Inoculants for this method typically have a 6 or 12 mm ($\frac{1}{4}$ or $\frac{1}{2}$ in.) maximum size. Minimum size has not been found to be as critical, although excessive fines should be avoided because they can float on the surface and lose their effectiveness through oxidation. All additions should be weighed or measured accurately, and the use of proper metal temperatures ensures good dissolution. Minimizing the time between treatment and pouring helps avoid loss of the inoculating effect, which is known as fade.

The maximum effect of an inoculant is realized immediately after the alloy is dissolved in the metal. More than half of the effect of inoculation can be lost, because of fade, in the first 5 min after the addition. Complete loss can occur if the iron is held for 15 to 30 min (Ref 24). Although the composition of the iron does not change dramatically, an increase in chilling tendency occurs, along with an accompanying decrease in mechanical properties. All inoculants fade to some degree.

Methods that can help avoid or minimize the loss of the inoculation effect have been gaining acceptance. By adding inoculant late in the production process, the effect of time can be greatly reduced. Stream and mold inoculation are two late methods of iron treatment that are believed to promote more uniform quality from casting to casting.

Stream inoculation requires that the alloy be added to the stream of metal flowing from the pouring ladle into the mold. One of the electropneumatic devices used to sense when the metal flow starts and stops is shown schematically in Fig. 16. This device ensures that the alloy is dispensed in such a manner that the last metal entering the mold is treated similarly to the first metal. The same inoculants used to treat iron in the ladle can be used for stream inoculation, but less of a performance distinction has been observed among them. Graphite is not recommended, because of its relatively poor solution characteristics. A uniform and consistent size seems to be a very important factor in stream inoculation. Too large a size can cause plugging of the equipment and incomplete dissolution. A maximum particle size of 8 to 30 mesh and a minimum size of about 100 mesh are recommended. Addition levels range from 0.10 to 0.15%.

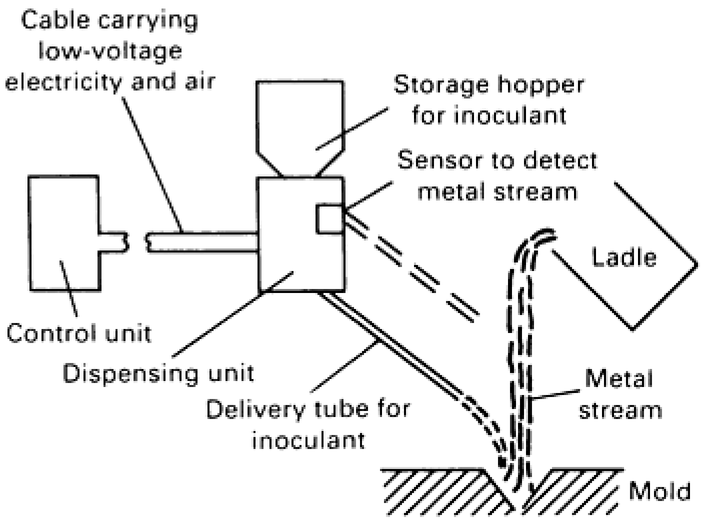

Fig. 16 Schematic showing the principle of stream inoculation. Source: Ref 25

Mold inoculation involves placement of the alloy in the mold, such as in pouring basins, at the base of the sprue or in suitable chambers in the runner system (Ref 26). Inoculants for this method can be crushed material, powder bonded into a pellet, or precast slugs or blocks. As in stream inoculation, alloy dissolution rate is an important factor. Crushed alloy is for this application typically 20 to 70 mesh in size, and the addition rate can be as little as 0.05%. The precast and bonded alloys are designed to dissolve at a controlled rate throughout the entire pouring cycle (Ref 27). Mold inoculation is often used as a supplement to ladle inoculation.

There are several advantages of late inoculation over ladle inoculation. As previously stated, fading is virtually eliminated, and because the castings are inoculated to the same extent, there is greater consistency in structure from casting to casting. It has also been observed that late inoculation is more successful in preventing carbide formation in thin sections, thus eliminating heat treatment.

Alloying

Alloying is used to a fairly large degree in the production of gray iron. Alloyed irons are discussed in the article "High-Alloy White Irons" in this Volume. However, it is important to recognize the minor alloying of gray iron that is conducted at levels below that considered in the category of alloyed irons.

In most cases, minor alloying of gray iron is done to increase strength and promote pearlite. The minor elements normally used in gray iron alloying are chromium, copper, nickel, molybdenum, and tin. Recently, beneficial effects of vanadium as an alloying element have also been demonstrated (Ref 28).

Chromium. Small chromium additions (up to about 0.5 to 0.75%) cause significant increases in the strength of gray iron. Chromium also promotes a pearlitic matrix and an associated increase in hardness. Chromium is a carbide promoter, and in light-sectioned castings or at heavy addition rates, it can cause chill formation. Chromium is normally added as a ferrochromium alloy. Care should be taken to ensure that the alloy is completely dissolved.

Copper also increases the tensile strength of gray iron by promoting a pearlitic matrix. Its effect is most pronounced at lower addition levels of 0.25% to 0.5%. At higher addition rates, its effects are not as dramatic. Copper has a mild graphitizing effect and therefore does not promote carbides in light sections. Copper should be added as high-purity material to avoid the introduction of tramp elements such as lead.

Nickel additions of up to 2% cause only a minor increase in the tensile strength of gray iron. Nickel does not promote the formation of carbides and in fact has a minor graphitizing effect. Nickel is normally added as elemental material, and no problems with dissolution have been reported.

Molybdenum. Small molybdenum additions in the range of 0.25 to 0.75% have a significant impact on the strength of gray iron. This appears to be the result of both matrix strengthening and graphite flake refinement (Ref 29). Molybdenum does not promote carbides. It is normally added as a ferromolybdenum alloy.

Tin in the range of 0.025 to 0.1% is a strong pearlite stabilizer. It does not appear to increase the strength of a fully pearlitic gray iron. It can, however, give a small strength increase in irons that would otherwise contain free ferrite. Additions above the levels required for pearlite stabilization should be avoided to prevent embrittlement. Tin is normally added as commercially pure tin. Care should be taken to avoid material contaminated with such elements as antimony, bismuth, and lead.

Vanadium has recently been suggested as a minor alloying element for gray iron (Ref 28). As shown in Fig. 17, vanadium has a significant effect on the hardness and strength of gray iron. It was reported that the strength increases were sustained even after annealing; this is a significant advantage. Vanadium at higher levels and in light sections can promote the formation of carbides, so good inoculation practices are suggested. Alloying can be accomplished by using ferrovanadium.

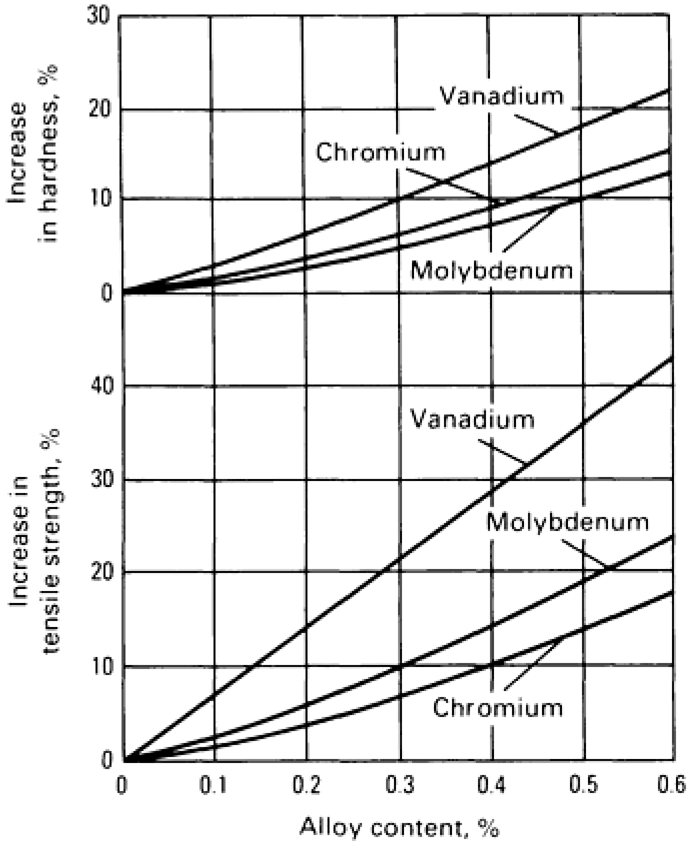

Fig. 17 Effects of alloying elements on the properties of gray cast iron. Source: Ref 28

Pouring

Metal temperature, cleanliness, and delivery technique are the essential variables to be controlled when pouring gray iron. Removal of slag and dross from the liquid iron surface reduces the possibility of inclusion-type defects. A variety of metal-pouring techniques are employed in the gray iron foundry. Each technique should enable the operator to maintain a constant flow of metal sufficient to keep the gating system full of metal until the pour is completed.

The molten iron should possess sufficient superheat to enable the cavity to be completely filled with iron without the formation of temperature-related defects. Superheat is the differential between the molten iron temperature and the liquidus temperature. The fluidity of the iron is directly proportional to the amount of superheat contained in the iron. Therefore, thinner sections that require greater fluidity for successful casting also require more superheat than thicker sections. The liquidus of gray iron is determined by the composition of the iron. For hypoeutectic irons, the liquidus is inversely proportional to the carbon equivalent of the iron. Therefore, the higher-strength irons with lower carbon equivalents require higher pouring temperatures to maintain the necessary level of superheat. Table 6 lists the typical pouring temperatures required for the various classes of gray iron.

Table 6 Typical pouring temperatures for some classes of gray iron

Class	**Approximate liquidus temperature**		Pouring temperature							
			Small castings				Large castings			
			Thin sections		**Thick sections**		**Thin sections**		Thick sections	
	°C	**°F**	**°C**	**°F**	**°C**	**°F**	**°C**	**°F**	**°C**	°F
30	1150	2100	1400	2550	1370	2500	1345	2450	1315	**2400**
35	1175	2150	1425	2600	1400	2550	1370	2500	1345	**2450**
40	1200	2190	1450	2640	1420	2590	1395	2540	1365	**2490**

Iron containing insufficient superheat can lead to partially filled cavities, misruns, blowholes, and chill. An excess of superheat can lead to shrinkage, metal penetration, veining, and scabbing. The amount of superheat required will vary for individual castings, and some experimentation will be required to determine the optimum pouring temperature for each casting.

Molding

Molds. The primary function of the molding material is to produce a dimensionally stable cavity that will withstand the thermal and mechanical stresses exerted by the liquid iron. Gray iron can be produced by using most of the molding processes, which are covered in detail in the Section "Molding and Casting Processes" in this Volume.

Green sand molding is the most widely used technique for the production of gray iron castings (see the article "Sand Molding" in this Volume). Gray iron expands slightly because of the formation of graphite during eutectic solidification. This is most pronounced in higher carbon equivalent irons, in which more graphite is precipitated. This expansion stresses the molding material, causing an enlargement of the mold cavity if the sand is insufficiently compacted. This can lead to

shrinkage defects. Therefore, it is important when producing gray iron castings that the mold hardness be sufficient to withstand the eutectic expansion of the gray iron.

If the dimensional accuracy and surface finish requirements of the casting exceed the limits of the green sand molding process, other processes, such as shell molding, chemical bond molding, and permanent molding, can be used. Each process creates a rigid mold surface that withstands the eutectic expansion of gray iron, thus improving dimensional accuracy. In addition, an excellent surface finish can be obtained with each of these processes. Shell molds are produced from a mixture of sand and a thermosetting resin. Chemically bonded molds are produced from a mixture of sand and a resin binder that requires a catalyst for room-temperature curing. Permanent molds are often produced from gray iron and generally require some form of coating to assist in the removal of the casting.

Cores. The purpose of a core is to create a dimensionally stable cavity within the casting during solidification. All commercially available coremaking processes can be used in the production of gray iron castings. These processes include oil-sand, shell, hot box, carbon dioxide, and chemical bonding. The type of core does not have to be related to the type of molding material. Selection of the core material depends on core size, complexity, dimensional accuracy, and cost.

The gating and feeding system serves the same purpose in the casting of gray iron as in the other metal casting systems. These functions include:

- Filling the mold cavity without turbulence
- Preventing slag, dross, or mold material from entering the mold
- Preventing the introduction of air or mold gases into the stream of metal
- Producing heat transfer characteristics that will aid in the progressive solidification of the casting
- Enabling production of the casting with the use of a minimum amount of metal

Gating and feeding practice for gray iron is less complicated than for other materials. The precipitation of graphite during eutectic solidification causes an expansion, which offsets some of the contraction usually experienced during the solidification of a metal. In fact, a class 20 iron precipitates enough graphite to create sufficient expansion so that feeding is not required. As the carbon equivalent of the iron decreases, less graphite is precipitated and feeding requirements increase. A class 50 iron requires approximately 4% volumetric feeding to offset the contraction of the iron.

Dimensional Control. The production of gray iron castings with good dimensional stability requires that the foundryman produce a mold rigid enough to withstand eutectic expansion and that the pattern be constructed in such a way as to compensate for the metal contraction during cooling. The contraction depends on the amount of graphite precipitated during eutectic solidification. Irons with a higher carbon equivalent will precipitate more graphite, resulting in less shrinkage. Typical shrinkage values of the various grades of iron are:

Class	**Carbon equivalent, %**	Pattern shrinkage allowance, mm/m (in./ft)
30	. . .	**8.3** ($\frac{1}{10}$)
35	3.7-4.1	**10.4** ($\frac{1}{8}$)

40	3.5-3.9	**10.4** ($\frac{1}{8}$)
45	3.45-3.8	**10.4** ($\frac{1}{8}$)
50	3.3-3.6	**13.0** ($\frac{5}{32}$)
55	. . .	**13.0** ($\frac{5}{32}$)

Defects

Matrix discontinuities in gray iron castings caused by cavities and inclusions increase the scrap rate and decrease the productivity of a foundry. In many cases, these defects are subsurface and are revealed only after machining in-house or at the customer's facility. Accurate defect identification is required before steps can be taken to eliminate or minimize these problems. The location, shape, and size of a defect provide valuable clues about its origin. These three factors will be considered in the following review of common defects found in gray iron.

Shrinkage cavities can appear as either isolated or interconnected irregularly shaped voids, as shown in Fig. 18. When examined at low magnification, they are often found to contain dendrites that possess a treelike form (Fig. 19). Heavy sections and hot spots, such as areas adjacent to ingates and feeders or regions experiencing changes in section size, are most susceptible to this type of defect. Shrinkage, because it is subsurface, is usually revealed during machining or pressure testing. Factors that promote shrinkage formation include lack of mold rigidity, unsuitable metal composition, incorrect pouring temperature, and a high degree of nucleation. These factors may operate independently or in combination.

Fig. 18 Typical shrinkage defect in gray cast iron. As-polished. 50×

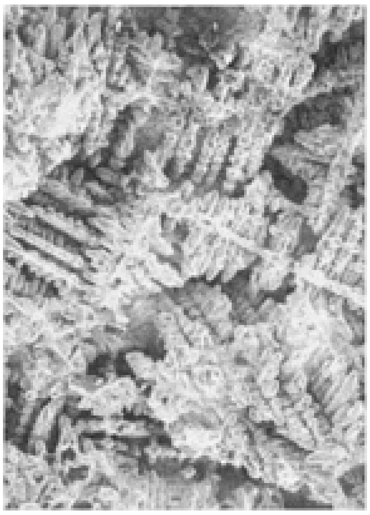

Fig. 19 SEM view of shrinkage cavities in heavy-section gray iron. 20×

Almost all liquids contract during freezing. In gray iron, however, expansion occurs during the formation of the austenite-graphite eutectic. This expansion increases if the iron is highly nucleated, a state that is produced by inoculation. Molds, particularly green sand molds, that are not rammed to sufficient hardness are incapable of containing this expansion. This leads to enlargement of the mold cavity. Shrinkage cavities are formed if the metal supply is not sufficient to accommodate this enlargement. Soft molds can be detected by measuring the dimensions and weight of the casting. Oversize or overweight castings signal a potential problem. This problem can be minimized by avoiding excessive moisture levels, by maintaining adequate levels of carbonaceous material, and by using only the amount of inoculant needed to control chill and bring about the desired properties.

Iron composition can have a pronounced effect on shrinkage. Very low carbon contents have occasionally been related to unsound castings. Phosphorus levels in the iron as low as 0.02% can cause fine porosity at eutectic cell boundaries and hot spots (Ref 3). Adjustment of the phosphorus level is usually a tradeoff between avoiding shrinkage and preventing finning and penetration defects. A maximum level of 0.3% is suggested for heavy-section castings where slow solidification times result in segregation (Ref 30). Phosphorus levels in castings that must pass pressure tests should not exceed 0.10%.

Excessively high pouring temperatures can also increase the contraction of the metal as it cools to the solidification temperature, thus encouraging shrinkage. In addition, because green sand molds are not dimensionally stable under heat, the higher temperatures increase the chances of mold wall movement. A compromise exists between too high and too low a pouring temperature. If too low a pouring temperature is used, blowhole-type defects, cold shuts, and carbides can occur. Therefore, experience is the best way of determining the optimum pouring temperature for a particular casting.

The blowholes referred to in this section are those found below the cope surface of a casting or where a core forms a ceiling in the mold. They are usually revealed by machining or by heavy shotblasting. These blowholes can be spherical or irregular in shape and have been reported to have a gray or blue-gray lining. Many of the holes contain slag, and some cavities contain exuded metal beads. Manganese sulfide inclusions are usually found clustered in the iron matrix near the defect and are sometimes present in the slag itself. An example is shown in Fig. 20.

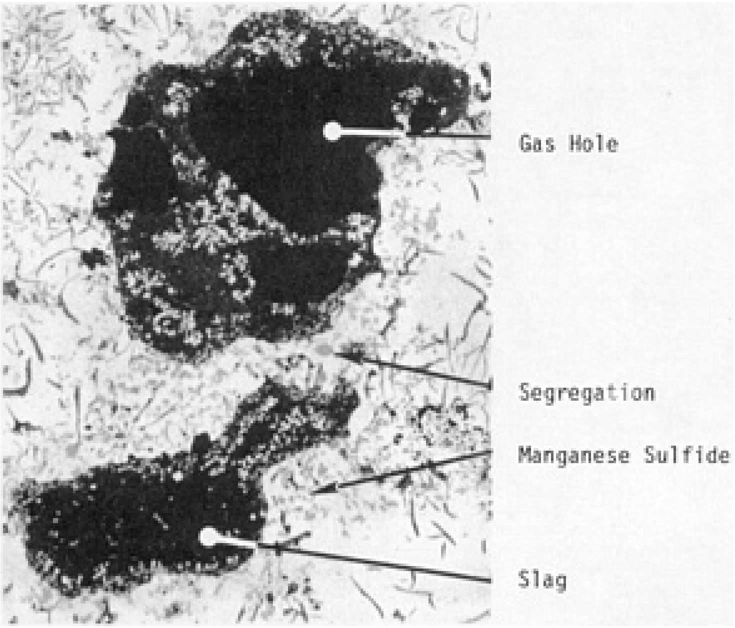

Fig. 20 Blowhole defect associated with manganese sulfide segregation. 100×

Cold metal resulting from low pouring temperatures is the primary cause of blowholes. This explains why the last castings poured from a ladle are most likely to be unsound. Excessive sulfur and manganese levels, however, compound the problem. Figure 21 shows the sulfur and manganese levels at which sound and defective castings are produced. The higher the sulfur and manganese levels, the higher the pouring temperature must be to avoid blowholes.

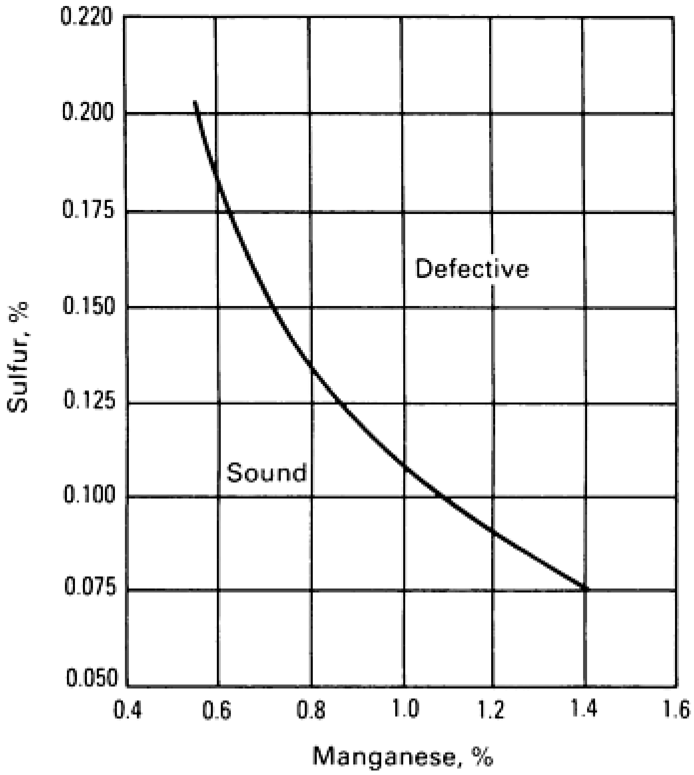

Fig. 21 Occurrence of blowhole defects in gray iron castings as a function of sulfur and manganese contents. Pouring temperature was constant at 1280 °C (2335 °F). Defective castings had blowholes associated with

manganese sulfide inclusions. Source: Ref 31

The following sequence of events leads to the formation of the blowhole. As the temperature of the molten metal falls, manganese sulfides form and separate from the melt. They float to the surface, where they mix with the ladle slag (iron and manganese silicate), creating a slag of higher fluidity. This slag enters the mold cavity, reacts with the graphite precipitating during the eutectic reaction, and results in the evolution of carbon monoxide and the formation of blowholes. Proper metal temperature, balanced manganese and sulfur levels, clean ladles, and good skimming practices help minimize blowholes.

Hydrogen pinholes (Fig. 22) are small, spherical, or pear-shaped cavities about 3 mm ($\frac{1}{8}$ in.) or less in diameter. A continuous graphite film is often found in these holes, although an iron oxide layer may be present if the castings are heat treated. Nonmetallic inclusions are not present in the voids, but some have been found to contain a small bead of metal. Pinholes are typically subsurface in nature and are therefore not visible until after heavy shotblasting or more likely after machining. Thin sections are more susceptible to this defect than thick sections, as are areas remote from the ingates.

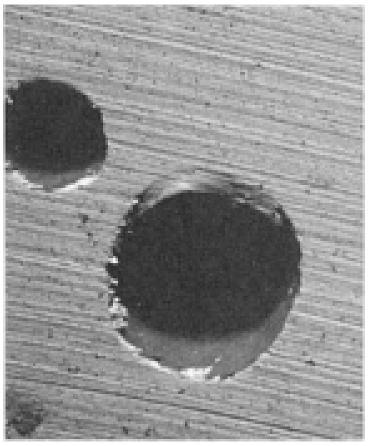

Fig. 22 SEM view of hydrogen pinholes in gray iron. 20×

A number of mold and metal factors have been associated with hydrogen pinhole formation. It is likely that these factors function in combination rather than individually. Aluminum levels in the iron as low as 0.005% have been found to encourage dissociation of the water vapor arising from the mold, thus increasing the hydrogen content of the metal. Aluminum sources include ferroalloys used in iron treatment and scrap. Excessive moisture in the mold and lack of active carbonaceous mold additions also favor pinholing. Sand grain size and mold permeability have not been found to affect this problem. Damp furnace and ladle refractories, long runners and downsprues that increase the time the metal is in contact with the mold, and turbulent pouring are other factors that can contribute to this defect.

Nitrogen Defects. Nitrogen levels of 20 to 80 ppm are normal in gray iron. At higher levels, the iron becomes less able to contain the nitrogen, resulting in its liberation during solidification. This causes the formation of interdendritic voids or blowholes (Fig. 23). These voids tend to be clear and bright and at times contain a graphite layer. An oxide film, however, may be present in castings that have been heat treated. Compacted graphite is sometimes found in the matrix along the defect perimeter. The amount of nitrogen needed to produce unsound castings varies. Light sections may not be affected until nitrogen levels reach 130 ppm, while heavy sections can experience problems at levels of only 80 ppm. Irons made from a charge with a high proportion of steel scrap (50% or greater) are quite susceptible to this problem (Ref 32). Recarburizing materials containing nitrogenous compounds, molds, and cores produced with high nitrogen content resins, as well as mold and core coatings containing carbonaceous and resin components, all act as nitrogen sources (Ref 33). The effect of nitrogen can be neutralized with the addition of 0.02 to 0.03% Ti. Acceptable levels of nitrogen may become dangerous if hydrogen is also present.

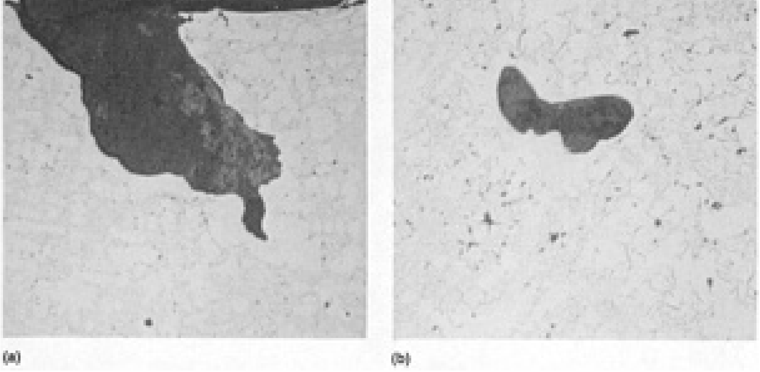

Fig. 23 Surface (a) and subsurface (b) nitrogen defects in gray iron with nitrogen content of 135 ppm. Both 100×

Abnormal graphite forms have been found to account for a high proportion of cracked castings. In extreme cases, they have resulted in premature, catastrophic failure. Lead is one of the agents that have been found to be responsible for these decreases in the physical and mechanical properties of cast iron that are associated with a change in graphite morphology. Microstructurally, lead contamination often results in fine, spiky graphite on the normal graphite flakes (Fig. 24). Degenerate graphite structures ranging from a Widmanstätten-like structure in heavy-section castings to a mesh type with long interconnected flakes in thinner sections have also been observed (Ref 35). These structures are often difficult to observe at low magnification and can be detected only when examined at high magnifications.

Fig. 24 Spiky graphite in gray iron resulting from lead contamination. Etched using 4% picral. 250×. Source: Ref 34

Heavy-section castings are particularly vulnerable to the influence of lead because their slow cooling rates favor lead segregation. A residual lead level as low as 0.004% in a heavy-section casting can result in failure. The presence of other elements, such as hydrogen and aluminum, which has been found to increase the amount of hydrogen in iron, adds to the effect. This is why castings produced in green sand molds are more susceptible to this type of defect.

There is no known neutralizing agent for lead in gray iron. Although some lead loss is experienced during melting and holding, it is best to keep lead out of the iron. This can be done by being aware of the sources of lead contamination, including leaded steel scrap, heavily painted components, vitreous enameled steels, and copper alloys.

Heat Treatment

Although most gray iron castings are used in the as-cast condition, heat treatment can be employed to meet specific casting requirements. Detailed information on the heat treatment of gray iron is available in the article "Heat Treating of Gray Irons" in *Heat Treating*, Volume 4 of the *ASM Handbook.*

The three most commonly used forms of heat treatment for gray iron are annealing, stress relieving, and normalizing. Other standard heat treatments, such as hardening and tempering, austempering, and martempering, are used on limited occasions. Gray irons can also be flame or induction hardened.

In considering the heat treatment of gray iron castings, it is important to recognize the complexity of the relationship between metallurgical and thermal phenomena. In terms of heat treatment, gray iron can essentially be considered a composite material made up of free graphite (flakes) and eutectoid steel (matrix). The situation can be further complicated by the variety of sections, and therefore thermal responses, found in most castings. For this reason, it is often necessary to develop experimentally the precise process for given castings if optimal results are desired.

Annealing. Three principal annealing processes are used for gray iron. They have a common purpose and metallurgy in that they are employed primarily to improve machinability. Therefore, all three treatments involve the production of a ferritic matrix. Figure 1 shows a section of the iron-carbon-silicon diagram at 2.5% Si. As can be seen, the eutectoid reaction consists of the transformation of austenite into ferrite plus graphite. The annealing processes are all designed to take advantage of this reaction.

The first of these processes is normally called a ferritizing or subcritical anneal. It consists of heating the casting to a temperature of 700 to 760 °C (1290 to 1400 °F), or just below the eutectoid transformation temperature. At this temperature, pearlite decomposes into a ferritic matrix. Holding times at this temperature vary to some degree with section size and iron chemistry. As a general rule, time at temperature should be approximately 1 h for each 25 mm (1 in.) of casting thickness. Longer times may be required if alloying elements are present. Cooling rates after ferritization are not critical but should not exceed 100 °C/h (180 °F/h) to avoid inducing stresses. The reduction in hardness and improved machinability associated with this process also result in a reduction in strength.

Medium or full annealing is used in situations where, because of alloying or the presence of minor amounts of chill, the subcritical anneal does not convert the iron to a ferritic matrix. In this process, the iron is heated to a temperature of 800 to 900 °C (1470 to 1650 °F), which is above the eutectoid transformation temperature. After soaking for approximately 1 h for each 25 mm (1 in.) in cross section, the iron is slow cooled through the eutectoid transformation region to promote the formation of ferrite. If the iron contains minor alloying elements such as chromium, manganese, copper, nickel, or tin, longer holding times or higher soaking temperatures may be necessary. Following transformation, the castings can be air cooled from approximately 675 °C (1245 °F).

The third form of annealing is designated as a graphitizing anneal. It is used in gray iron only when the removal of massive carbides or chilled iron is required. It consists of heating the casting to a temperature of approximately 900 to 925 °C (1650 to 1700 °F). Time at temperature should be minimized based on microstructural evaluation to avoid scaling unless a controlled-atmosphere furnace is employed. After the decomposition of carbides, the desired cooling rate depends on the microstructure desired. If a highly machinable ferritic structure is desired, furnace cooling is recommended with very slow cooling through the eutectoid transformation. If a stronger, pearlitic matrix is desired, air cooling can be used. Experimentation may be necessary to compensate for the effects of casting geometry and iron composition.

Normalizing. In principle, the normalizing of gray iron is a relatively straightforward process. The castings are heated to a temperature of 875 to 900 °C (1605 to 1650 °F) and held for about 1 h per 25 mm (1 in.) of cross section. This should result in the transformation of the matrix to austenite. The castings are then air cooled to form a pearlitic matrix.

As expected, the presence of alloying elements and variations in casting geometry complicate this practice and may alter the final results. It may be necessary to adjust holding times and/or cooling cycles to obtain the desired results. For example, forced air cooling may be desirable to avoid the formation of ferrite in heavy sections. In the case of alloyed castings, it may be possible to produce small increases in strength and hardness by normalizing.

Stress relieving is also used in gray iron castings. The purpose of this practice is to reduce stresses induced in the casting during solidification. In essence, the process consists of heating the casting to a temperature ranging from 500 to 650 °C (930 to 1200 °F), depending on composition. The casting is held in this temperature range for 2 to 8 h, then air cooled.

Properties and Applications

Graphite morphology and matrix characteristics affect the physical and mechanical properties of gray iron. Large flakes, common in high carbon equivalent irons and heavy-section castings, impart desirable properties, such as good damping capacity, dimensional stability, resistance to thermal shock, and ease of machining. Higher tensile strength and modulus of elasticity values, resistance to crazing, and smooth machined surfaces are obtainable with irons containing small flakes, which are promoted by low carbon equivalents and faster cooling rates. Pearlite refinement and stabilization of acicular structures result in an increase in hardness, tensile strength, and wear resistance. In addition to composition (particularly carbon equivalent) and section size, factors such as alloy additions, heat treatment, thermal properties of the mold, and casting geometry affect the microstructure and therefore the properties of the iron.

Mechanical Properties

The tensile properties of gray cast iron (Table 7) include tensile strength, yield strength, ductility, and modulus of elasticity. Minimum tensile strength is used to classify gray iron in ASTM A 48. Tensile strength is inversely proportional to carbon equivalence.

Table 7 As-cast mechanical properties of standard gray iron test bars

Class	**Tensile strength**		**Torsional shear strength**		**Compressive strength**		**Reversed bending fatigue limit**		**Transverse load on test bar**		Hardness, HB
	MPa	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	**ksi**	**kgf**	**lbf**	
20	152	22	179	26	572	83	69	10	839	1850	**156**
25	179	26	220	32	669	97	79	11.5	987	2175	**174**
30	214	31	276	40	752	109	97	14	1145	2525	**210**
35	252	36.5	334	48.5	855	124	110	16	1293	2850	**212**
40	293	42.5	393	57	965	140	128	18.5	1440	3175	**235**
50	362	52.5	503	73	1130	164	148	21.5	1633	3600	**262**

Yield strength can be determined from the stress-strain diagram by using either the 0.1% or 0.2% offset method. Elongation values for gray iron are very low, typically of the order of about 0.6%. The modulus of elasticity of gray iron is not a single number, because gray iron does not possess an elastic range in which stress and strain exhibit a straight line relationship. Values for modulus of tension are usually estimated by either the tangent modulus or the secant modulus method. A higher modulus of elasticity is desired for applications requiring rigidity and minimum deflection values. A low modulus of elasticity is preferred for vibration damping and severe heat shock applications.

Transverse Properties. Strength in bending and deflection are determined with the transverse bend test. Results from this method of testing are usually used in combination with the tensile test. Samples require little preparation, and the method used in loading can be more characteristic of what the part will experience in service. Modulus of rupture values

can be calculated from the transverse breaking load by using the standard beam formula. Transverse breaking loads can be found in Table 7.

Hardness tests are routinely performed because they are simple, rapid methods of determining the approximate strength characteristics and machinability of a gray iron casting. The Brinell hardness test is most often used on gray iron because the larger diameter of the indentor provides an average of the various microconstituents present in the iron. Figure 25 shows an example of the relationship between hardness and tensile strength of gray iron for a particular foundry and process.

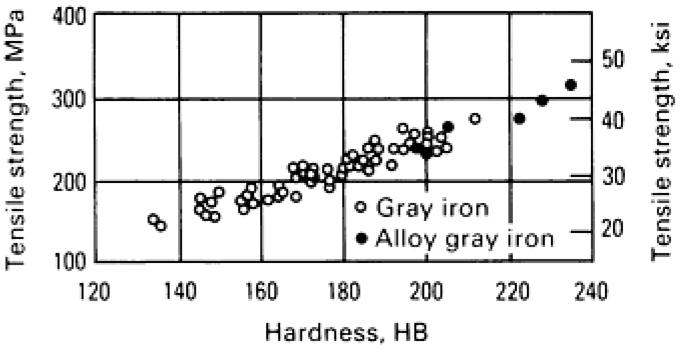

Fig. 25 Relationship between tensile strength and hardness for a series of inoculated irons from a single foundry

Compression. Gray cast iron is about three to four times stronger in compression than in tension (Ref 36). This is because the characteristics of the graphite flakes have less of an influence in compression than in tension. Matrix structure is the determining factor in compressive strength; a considerable increase in strength is associated with a change from ferrite to pearlite to martensite. Compressive strength values for a number of gray iron classes are given in Table 7.

Torsional Properties. High torsional shear strength, which is required in such applications as crankshafts, camshafts, and axles, is obtainable with gray iron (Table 7). Shear strength has been reported to range from 1.1 to 1.5 times tensile strength (Ref 36). Torsion tests can be carried out on testpieces or full-size parts.

Damping Capacity. The interconnected nature of the graphite flakes in gray iron imparts excellent damping capacity and makes gray iron ideal for applications such as machine bases and supports, cylinder blocks, and brake components. Damping capacity refers to the ability of a material to quell vibrations and to dissipate the energy as heat. Relative damping capacities for a number of ferrous materials and for aluminum are given below, where damping capacity is taken as the natural logarithm of the ratio of successive amplitude:

Material	Relative damping capacity
White iron	**2-4**
Malleable iron	**8-15**
Ductile iron	**5-20**
Gray iron, fine flake	**20-100**
Gray iron, coarse flake	**100-500**
Eutectoid steel	**4**
Armco iron	**5**

Aluminum	**0.4**

Source: Ref 36

Damping capacity increases as carbon equivalence and section size increase.

Machinability. The excellent machinability of gray iron compared to that of other ferrous materials is attributed to the presence of graphite flakes, which act as chip breakers and serve to lubricate the cutting tool. Factors such as chill, surface inclusions (sand or slag), swells, and shrinkage adversely affect the machining characteristics of gray iron. More information on this subject and on other properties of gray iron, such as fatigue strength, impact strength, residual stresses, and wear resistance, can be found in the article "Gray Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

Physical Properties

The density of gray iron is composition and temperature dependent. Increases in free graphite, which has a low density, result in a decrease in the density of the iron. This is why high-strength iron has a greater density than low-strength iron (Table 8). The density of molten cast iron falls in the range of 6.65 to 7.27 g/cm^3.

Table 8 Physical properties of gray iron as a function of tensile strength

Tensile strength		**Density**[(a)]		**Thermal conductivity at indicated temperature**[(b)], **W/m·K**			Electrical resistivity at 20 °C (68 °F)[(c)], μΩ·m

Thermal conductivity is an important consideration in applications requiring heat transfer, such as brake drums, internal combustion engines, and ingot molds. Thermal conductivity is strongly influenced by the amount and form of graphite. An increase in thermal conductivity is obtained as the amount of free graphite increases and as the flakes become coarser and longer. Matrix structure and composition also exert an influence, as does temperature. Thermal conductivity values as a function of tensile strength and temperature are listed in Table 8.

Electrical resistivity is a function of graphite structure, matrix constituents, and temperature. Increases in free graphite, coarse flakes, pearlite, and temperature result in increases in electrical resistivity. Resistivity values at 20 °C (68 °F) for various classes of gray irons are given in Table 8.

Thermal expansion is measured by the coefficient of linear expansion. It is primarily dependent on the matrix structure of the iron. Ferritic and martensitic matrices have a slightly higher coefficient of linear expansion than pearlitic ones. Values for austenitic iron can be even greater, depending on nickel content. Graphite structure has little effect on this property. The coefficient of linear expansion increases with temperature; a value of 10×10^{-6}/°C is commonly used at room temperature.

Applications

The changes in physical and mechanical properties that can be produced in gray iron by controlling the characteristics of its free graphite and matrix structures lead to versatility in its application. Gray iron can be effectively used in highly competitive, low cost applications where its founding properties are of paramount importance. Such applications include implement weights, elevator counterweights, guards and frames, enclosures for electrical equipment, and fire hydrants. A variety of iron grades can be used in these applications. Gray iron is also employed in more critical applications in which mechanical or physical property requirements determine iron selection, such as in pressure-sensitive castings, automotive castings, and process furnace parts.

Standards established by the American Society for Testing and Materials, the Society of Automotive Engineers, the federal government, and the military provide assistance in the selection of the appropriate grade or class of iron to meet specific mechanical or physical requirements. Automotive castings requiring resistance to heat checking are covered by ASTM A 159. Specifications for pressure-sensitive parts can be found in ASTM A 278, while composition information for castings requiring thermal shock resistance is available in ASTM A 319. A summary of typical applications for gray iron, based on specifications and information available in the literature, is provided in Table 9.

Table 9 Typical applications for gray iron castings

Specification	**Grade or class**	Typical applications
ASTM A 48	20, 25	**Small or thin-sectioned castings requiring good appearance, good machinability, and close dimensional tolerances**
	30, 35	**General machinery, municipal and waterworks, light compressors, automotive applications**
	40, 45	**Machine tools, medium-duty gear blanks, heavy compressors, heavy motor blocks**
	50, 55, 60	**Dies, crankshafts, high-pressure cylinders, heavy-duty machine tool parts, large gears, press frames**
ASTM A 159, SAE J431	G1800	**Miscellaneous soft iron castings in which strength is the primary consideration; exhaust manifolds**
	G2500	**Small cylinder blocks and heads, air-cooled cylinders, pistons, clutch plates, oil pump bodies, transmission cases, gear boxes, light-duty brake drums**

	G2500a	**Brake drums and clutch plates for moderate service where high carbon is desirable to minimize heat checking**
	G3000	**Cylinder blocks, heads, liners, flywheels, pistons, clutch plates**
	G3500	**Truck cylinder blocks and heads, heavy flywheels, differential carriers**
	G3500b	**Brake drums and clutch plates for heavy-duty service that require heat resistance and high strength**
	G4000	**Truck and tractor cylinder blocks and heads, heavy flywheels, tractor transmission cases, differential carriers, heavy gear boxes**
	G3500c	**Extraheavy-duty brake drums**
	G4000d	**Alloyed automotive engine camshafts**
	G4500	**Diesel engine castings, liners, cylinders, and pistons; heavy-duty parts for general industry**
ASTM A 278	40, 50, 60, 70, 80	**Valve bodies, paper mill dryer rollers, chemical process equipment, pressure vessel castings**
ASTM A 319	I, II, III	**Stoker and firebox parts, grate bars, process furnace parts, ingot molds, glass molds, caustic pots, metal melting pots**
ASTM A 823	. . .	**Automobile, truck, appliance, and machinery castings in quantity**
ASTM A 436	1	**Valve guides, insecticide pumps, flood gates, piston ring bands**
	1b	**Seawater valve and pump bodies, pump section belts**
	2	**Fertilizer applicator parts, pump impellers, pump casings, plug valves**
	2b	**Caustic pump casings, valves, pump impellers**
	3	**Turbocharger housings, pumps and liners, stove tops, steam piston valve rings, caustic pumps and valves**
	4	**Range tops**
	5	**Glass rolls and molds, machine tools, gages, optical parts requiring minimal expansion and good damping qualities, solder rails and pots**

	6	**Valves**

Introduction

DUCTILE IRON has been known only since the late 1940s, but it has grown in relative importance and currently represents about 20 to 30% of the cast iron production of most industrial countries. Ductile iron is also known as nodular iron or spheroidal graphite iron. Unlike gray iron, which contains graphite flakes, ductile iron has an as-cast structure containing graphite particles in the form of small, rounded, spheroidal nodules in a ductile metallic matrix. Therefore, ductile iron has much higher strength than gray iron and a considerable degree of ductility; both of these properties of ductile iron, as well as many of its others, can be further enhanced by heat treatment.

Ductile iron also supplements and extends the properties and applications of malleable irons. It has the advantage of not having to be cast as a white iron and then annealed for castings having section thicknesses of about 6 mm ($\frac{1}{4}$ in.) and above, and it can be manufactured in much thicker section sizes. However, it cannot be routinely produced in very thin sections with as-cast ductility, and such sections usually need to be heat treated to develop ductility. It has the advantage, in common with gray iron, of excellent fluidity, but it requires more care to ensure sound castings and to avoid hard edges and carbides in thin sections, and it usually has a lower casting yield than gray iron. Compared to steel and malleable iron, it is easier to make sound castings, and a higher casting yield is obtained; however, more care is often required in molding and casting.

Ductile iron is made by treating low-sulfur liquid cast iron with an additive containing magnesium (or occasionally cerium) and is usually finally inoculated just before or during casting with a silicon-containing alloy (inoculant). There are many variations in commercial treatment practice. In general, the composition range is similar to that of gray iron, but there are a number of important differences.

Ductile Iron

I.C.H. Hughes, BCIRA International Centre for Cast Metals Technology, Great Britain

Raw Materials for Ductile Iron Production

The spheroidal form of graphite that characterizes ductile iron is usually produced by a magnesium content of about 0.04 to 0.06%. Magnesium is a highly reactive element at molten iron temperatures, combining readily with oxygen and sulfur. For magnesium economy and metal cleanliness, the sulfur content of the iron to be treated should be low (preferably <0.02%); this is readily achieved in an electric furnace by melting charges based on steel scrap or special-quality pig iron supplied for ductile iron production, together with ductile iron returned scrap. Low sulfur content can also be achieved by melting in a basic cupola, but acid cupola melted iron has a higher sulfur content and normally needs to be desulfurized before treatment by continuous or batch desulfurization in a ladle or special vessel. Treatment of acid cupola melted iron with magnesium without prior desulfurization is not recommended, because the iron consumes more magnesium and produces excessive magnesium sulfide slag, which is difficult to remove thoroughly and may lead to dross defects in castings.

To produce ductile iron with the best combination of strength, high ductility, and toughness, raw materials must be chosen that are low in many trace elements, particularly those that promote a pearlitic matrix structure. A low manganese content is also needed to achieve as-cast ductility and to facilitate successful heat treatment to produce a ferritic structure. For this purpose, it is necessary to use deep-drawing or other special grades of steel scrap and pig iron of a quality produced specially for ductile iron production.

Draft International Standard ISO/DIS 9147 specifies two grades of pig iron for ductile iron production: Grade 3.1 (Nodular (SG) base) and Grade 3.2 (Nodular (SG) base, higher manganese). The compositions of these grades are:

Grade	Composition				
	C	**Si**	**Mn**	**P**	S
3.1	3.5-4.6	<3.0	<0.1	<0.08	**0.03 max**

The contents of elements that affect the formation of nodular graphite and promote the formation of carbide are low according to the application of the grade concerned.

Higher-strength grades of ductile iron can be made with common grades of constructional steel scrap, pig iron, and foundry returns, but certain trace elements, notably, lead, antimony, and titanium, are usually kept as low as possible to achieve good graphite structure. Their undesirable effects can, however, be offset by the addition of a small amount of cerium to give a residual cerium content of 0.003 to 0.01%. An important control of raw materials involves the exclusion of aluminum, which may promote unsoundness and dross defects. Table 1 lists the typical minor element contents of three raw materials used in ductile iron manufacture.

Table 1 Typical minor element contents of raw materials for ductile iron

Raw Material	Minor elements, %										
	Mn	**S**	**P**	**Ni**	**Cr**	**Cu**	**Mo**	**Al**	**Sn**	**As**	**B**	V
High-purity pig iron	0.04	0.015	0.013	0.06	0.01	0.02	0.01	<0.005	<0.01	<0.01	<0.0005	**<0.01**
Deep-drawing steel	0.26	0.015	0.016	0.01	0.01	0.02	0.01	<0.005	<0.01	<0.01	<0.0006	**0.01**

Ductile Iron

I.C.H. Hughes, BCIRA International Centre for Cast Metals Technology, Great Britain

Control of the Composition of Ductile iron

All elements in the composition of ductile iron need to be controlled, and this section will outline the most common and important requirements.

Carbon. In electric furnace melting practice, carbon is derived from pig iron, carburizers, and cast iron scrap. The carburization of steel scrap charges is achieved by adding low-sulfur graphite or graphitized coke, and the rate of solution and the recovery of carbon increase with the purity of the carbon source used. In cupola melting, carbon is also derived

from the coke charged. The optimum range for this element is usually 3.4 to 3.8%, depending on silicon content. Above this range, there is a danger of graphite flotation, especially in heavy sections, and of increased casting expansion during solidification, leading to unsoundness, particularly in soft green sand molds. Below this range, unsoundness may also occur because of lack of feeding, and at very low carbon contents, carbides may appear in the castings, particularly in thin sections.

Silicon enters ductile iron from raw materials, including cast iron scrap, pig iron, and ferroalloys, and to a small extent from silicon-containing alloys added during inoculation. The preferred range is about 2.0 to 2.8%. Lower silicon levels lead to high ductility in heat-treated irons but to a danger of carbides in thin sections as-cast, while high silicon accelerates annealing and helps to avoid carbides in thin sections. As the silicon content rises, the ductile-to-brittle transition temperature in ferritic iron increases. Hardness, proof stress, and tensile strength also increase.

Carbon Equivalent (CE). The carbon, silicon, and phosphorus contents can be considered together as a CE value, which can be a useful guide to foundry behavior and some properties. There are several CE formulas, and they are useful in assessing the casting properties and solidified structure of the iron. When the carbon equivalent CE = C% + $\frac{1}{3}$ (%Si + %P) is equal to 4.3, the iron will be of wholly eutectic composition and structure, and the deviation of the value of CE from this value is a measure of the relative amount of eutectic. If CE is lower than 4.3, there will be a proportion of dendrites; if CE is higher than 4.3, there will be primary graphite nodules in the structure. The degree of saturation *Sc* is sometimes used, particularly in the German literature, to express the nearness to the eutectic composition. The value of *Sc* can be determined from Eq 1:

$$Sc = \frac{Actual\ \%C}{4.23\text{-}0.3(\%\text{Si}+\%\text{P})} \qquad \textbf{(Eq 1)}$$

When *Sc* is less than 1, the iron is hypoeutectic and will contain primary dendrites. If *Sc* is greater than 1, there will be primary graphite in the structure. The carbon equivalent liquidus (CEL) is a measure of the liquidus temperature, which has a minimum value at the eutectic composition; that is, CEL = %C + %Si/4 + %P/2. Maximum fluidity occurs when this value is reached. The CEL is the only carbon equivalent that can be conveniently measured in a shop-floor thermal analysis test for metal composition, used on untreated iron prior to magnesium treatment. It is usual to aim for a CEL value of about 4.4 to 4.5, and values much higher than this are restricted in order to avoid graphite flotation. Other carbon equivalent formulas are sometimes used, and Fig. 1 is an example of a nomogram constructed to provide guidance on an optimum range of composition.

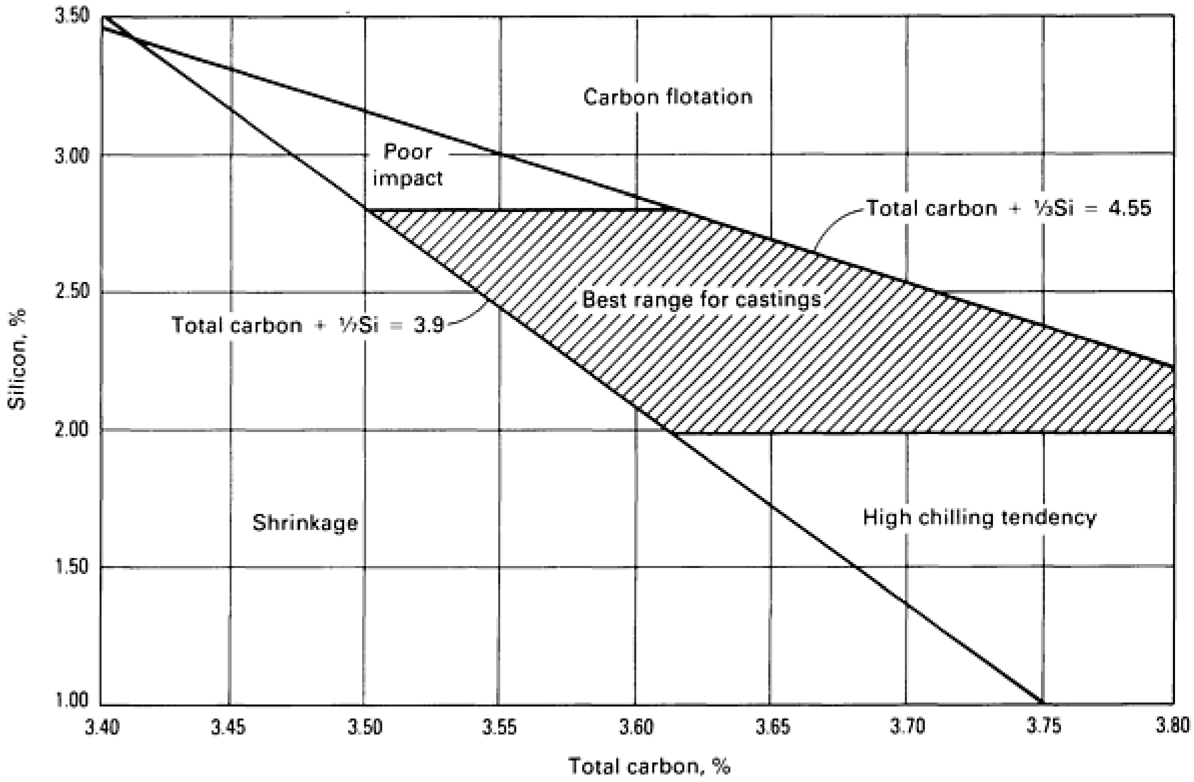

Fig. 1 Typical carbon and silicon ranges for ductile iron castings. Source: Ref 1

Manganese. The main source of manganese is steel scrap used in the charge. This element should be limited in order to obtain maximum ductility. In as-cast ferritic irons, it should be 0.2% or less. For irons to be heat treated to the ferritic condition, it should be 0.5% or less, but in irons to be used in the as-cast pearlitic condition, it may be present up to 1%. Manganese is subject to undesirable microsegregation. This is especially true in heavy sections, in which manganese encourages grain-boundary carbides, which promote low ductility, low toughness, and persistent pearlite.

Magnesium. The magnesium content required to produce spheroidal graphite usually ranges from 0.04 to 0.06%. If the initial sulfur content is below 0.015%, a lower magnesium content (in the range of 0.035 to 0.04%), may be satisfactory. Compacted graphite structures with inferior properties may be produced if the magnesium content is too low, while too high a magnesium content may promote dross defects.

Sulfur is derived from the charged metallic raw materials. In cupola melting, it is also absorbed from the coke. Before magnesium treatment, the sulfur content should be as low as possible, preferably below 0.02%. The final sulfur content of ductile iron is usually below 0.015%, but if cerium is present, it may be higher because of the presence of cerium sulfides in the iron. Excessive final sulfur contents are usually associated with magnesium sulfide slag and dross. When using cupola-melted iron, it is common to desulfurize the metal--usually with lime or calcium carbide, either continuously or in batches, before magnesium treatment--to levels of 0.02% or less. For treatments in the mold or in the metal stream, the initial sulfur may with advantage first be reduced to 0.01% or less.

Cerium can be added to neutralize undesirable trace elements that interfere with the formation of spheroidal graphite and to aid inoculation. It may then be desirably present to the extent of 0.003 to 0.01%. In irons of very low minor element content, cerium may be undesirable and may promote chunky nonspheroidal graphite, especially in thick sections; the deliberate addition of impurities may be necessary to avoid this effect. Cerium is added as a minor constituent of a number of magnesium addition alloys and inoculants to improve graphite structure. It is removed during the remelting of scrap ductile iron.

Minor Elements Promoting Nonspheroidal Graphite. Lead, antimony, bismuth, and titanium are undesirable elements that may be introduced in trace amounts with raw materials in the charge, but their effects can be neutralized by a cerium addition.

Minor Elements Promoting Pearlite. Nickel, copper, manganese, tin, arsenic, and antimony all promote pearlite and are listed here in order of increasing potency. They can enter the iron as trace constituents of raw materials. Copper up to 0.3% and tin up to 0.1% can be deliberately used as ladle additives when fully pearlitic structures are required. Almost all trace elements promote pearlite formation, and their effects are cumulative; therefore, a charge of high purity is essential for achieving fully ferritic structures as-cast or with minimal annealing.

Aluminum. The presence of even trace amounts of aluminum in ductile iron may promote subsurface pinhole porosity and dross formation and should therefore be avoided. The most common sources of aluminum are contaminants in steel and cast iron scrap, notably, in the form of aluminum pistons from scrap automobile engines. Another source is aluminum-containing inoculants, and the use of inoculants of low aluminum content is advisable whenever possible. Late metal stream inoculation, in which only very small quantities of inoculant are added, is beneficial. Aluminum as low as 0.01% may be sufficient to cause pinholes in magnesium-containing ductile iron.

Phosphorus is normally kept below 0.05% because it promotes unsoundness and lowers ductility.

Minor Elements Promoting Carbides. Chromium, vanadium, and boron are all carbide promoters. Manganese may also accentuate the carbide-stabilizing effects of these elements, especially in heavy sections in which segregation promotes grain-boundary carbides. They are controlled by careful selection of metallic raw materials for melting.

Alloying Elements Promoting Hardenability. Nickel up to about 2% and molybdenum up to about 0.75% are the usual elements added deliberately to promote hardenability when heat treatment is to be used. Small amounts of manganese and copper also promote hardenability, but are normally used only in combination with other elements. Copper has limited solubility and must be kept below 1.5%.

Alloying Elements to Achieve Special Properties. Austenitic matrix structures are achieved by the addition of 20% Ni or more when resistance to heat, corrosion, or oxidation is required, and up to 5% Cr can be added to such irons. Nickel contents to 36% produce irons of controlled low-expansion properties. Up to 10% Mn in austenitic irons leads to low magnetic permeability and allows a lower nickel content to be used to achieve a stable austenite.

Silicon contents to 6% produce ferritic matrix structures with reduced growth, scaling and thermal distortion, and cracking at elevated temperatures. The addition of up to 2% Mo to pearlitic, ferritic, and austenitic irons confers improved creep and elevated-temperature strength. Irons containing deliberately high alloying element contents are discussed in the article "High-Alloy Graphitic Irons" in this Volume.

Molten Metal Treatment

Treatment to produce ductile iron involves the addition of magnesium to change the form of the graphite, followed by or combined with inoculation of a silicon-containing material to ensure a graphitic structure with freedom from carbides. This section will discuss methods of magnesium treatment, control of magnesium content, and inoculation following magnesium treatment.

Magnesium Treatment

For magnesium treatment, the iron will normally be at a temperature of 1450 to 1510 °C (2640 to 2750 °F). Many methods of treatment are practiced; these are discussed more fully in Ref 2 and 3. Three of the most important methods will be outlined in this section.

Metallic Magnesium Treatment. The reaction between metallic magnesium and molten iron is violent. The magnesium is vaporized and burns vigorously in air. Special enclosed reaction vessels are needed, and one of the best established processes uses a converter (Fig. 2) in which ingots of magnesium are introduced into the bottom of the liquid metal in a tiltable vessel under atmospheric pressure. Other methods have involved introducing magnesium powder, rods, or wire into the molten metal with atmospheric or pressurized vessels designed to exclude air and to prevent the ejection of molten metal and fumes during the solution of the magnesium.

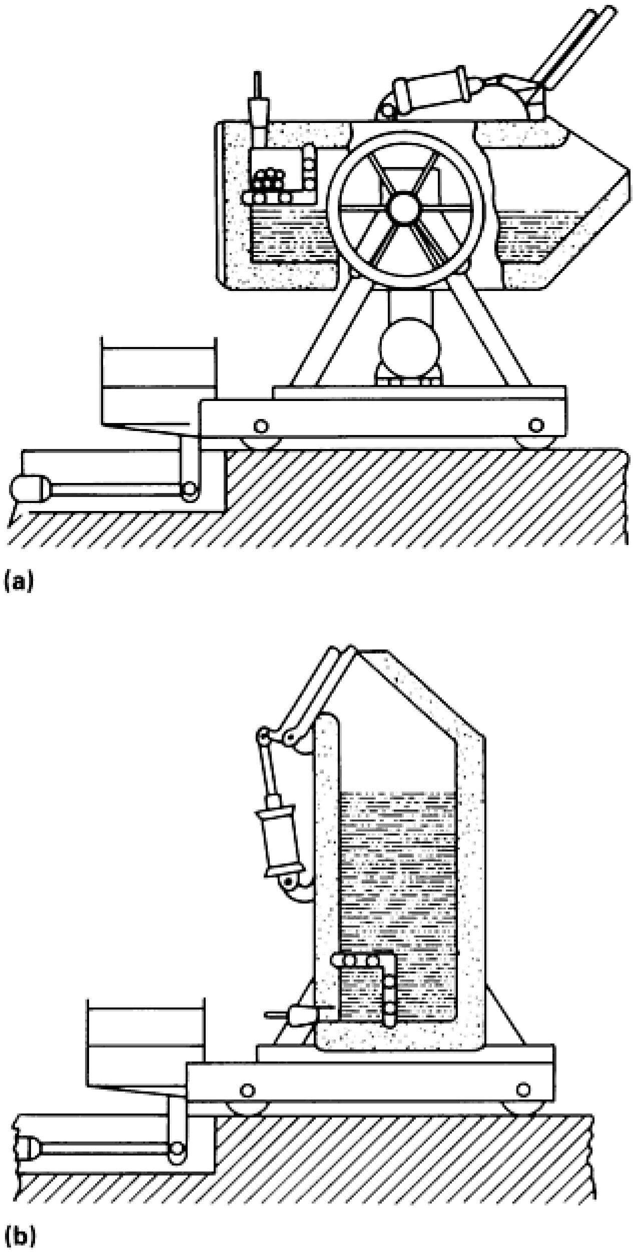

Fig. 2 Schematic of the Fischer converter. (a) Vessel in filling position. (b) Vessel in treating position

Magnesium particles have been made into compacts with iron powder or swarf, which reduces somewhat the violence of the reaction. Such materials can be added in special vessels or by plunging into the ladle in a refractory bell. In another technique, coke impregnated with magnesium is plunged into the liquid iron.

Magnesium Alloy Addition. A nickel alloy with 14 to 16% Mg can be added to the ladle during filling or by plunging. The reaction is spectacular but not violent, and a very consistent recovery is obtained. A disadvantage lies in the accompanying increase in nickel and the cost of the alloy. Other nickel alloys containing much lower magnesium contents (down to 4%) have also been used and involve a much quieter reaction. Most alloys used to introduce magnesium into molten iron are based on ferrosilicon containing 3 to 10% Mg. The reaction varies from fairly violent (with 10% Mg) to quiet (with 3% Mg). The alloy can be plunged in a refractory bell or added in the ladle using a number of different techniques, including pouring the molten iron onto the alloy in the bottom of the ladle. When this method is used, the alloy is often placed in a specially designed pocket and covered with a layer of steel turnings (this is known as the sandwich process). Treatment usually takes place in ladles having a height-to-diameter ratio of about 2:1 to contain any splashes of metal, while the use of a cover with a tundish through which the iron can be poured reduces any ejection of metal, fume, and flame and improves the yield of magnesium (Fig. 3).

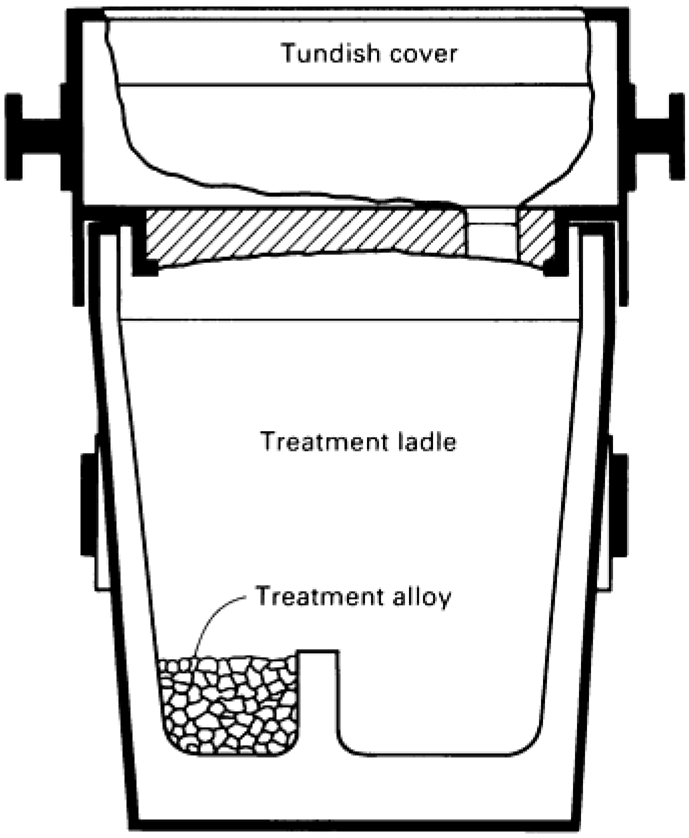

Fig. 3 Treatment ladle with tundish cover used in the magnesium treatment of ductile iron

A method of treating the molten metal as it fills the ladle is the Flotret process, in which the magnesium alloy is placed in a cavity in a closed vessel through which the molten metal is poured between the furnaces and the ladle. This method can be used when pouring the metal from one ladle to another. Another design of flow-through vessel is used in the Imconod process.

In-The-Mold Treatment (Inmold Process). Magnesium-containing alloys can be added in the mold. The alloy, usually of the ferrosilicon magnesium type, is placed in a specially designed chamber or enlargement of the running system before closing the mold, and the alloy dissolves as the metal is cast. This method contains the reaction in the mold and avoids ejection of fume and flare. Low-sulfur iron ($\leq$0.01% S) is used to avoid problems resulting from sulfide inclusions in the castings.

Control of Magnesium Content

In all methods of magnesium treatment, accurate measurement of the weight of metal treated and the amount of additive is essential. The initial sulfur content of the iron and the treatment temperature must also be known because they influence the final magnesium content. The recovery of magnesium can be expressed as:

$$\text{Recovery }\% = \left[\frac{(\%\text{final magnesium content}}{(\%\text{added magnesium}) - \frac{3}{4}(\%\text{initial sulfur content})}\right] x100 \qquad \textbf{(Eq 2)}$$

The magnesium sulfide produced by the reaction flows into the slag on the top of the ladle and is removed by skimming or by use of a teapot ladle. Typical values of recovery at a treatment temperature of 1450 °C (2640 °F) are:

- 50% for a 16% Ni-Mg alloy added in the ladle
- 40% for a 9% Mg ferrosilicon added using the sandwich process
- 60% for a 5% Mg ferrosilicon added using the sandwich process
- 50% for pure magnesium added in the converter
- 45% for the inmold or Flotret process

During magnesium treatment, there is usually a decrease in metal temperature of 35 to 50 °C (65 to 90 °F).

Inoculation (Ref 4)

Following magnesium treatment, the iron is usually subjected to final inoculation, sometimes referred to as postinoculation. Inoculation is commonly carried out in the ladle using a granular inoculant, which may be commercial ferrosilicon containing 75% Si or one of a wide range of proprietary alloys usually containing 60 to 80% Si. The amount of inoculant added will usually range from about 0.25 to 1.0%. A higher percentage of silicon in the magnesium-addition alloy may permit less inoculation. The inoculant can be added during reladling, stirred into the metal, placed on the bottom of the ladle before filling, or plunged in a refractory bell, as late as possible before casting. Effective stirring is necessary, and one way of achieving this is by bubbling air or nitrogen through the melt using a porous plug in the bottom of the ladle.

Inoculation reduces undercooling during solidification and helps to avoid the presence of carbides in the structure, especially in thin sections. It increases the number of graphite nodules, thus improving homogeneity, assisting in the formation of ferrite, and promoting ductility. It assists in reducing annealing time and reduces hardness.

The effect of an inoculant is greatest as soon as it has dissolved, after which it fades over a period of 20 to 30 min. Both the initial potency and the rate of fading are influenced by trace elements, which include calcium, aluminum, cerium, strontium, barium, and bismuth. Figure 4 shows how the number of nodules in test bars decreased with time after ladle inoculation for ten different inoculants.

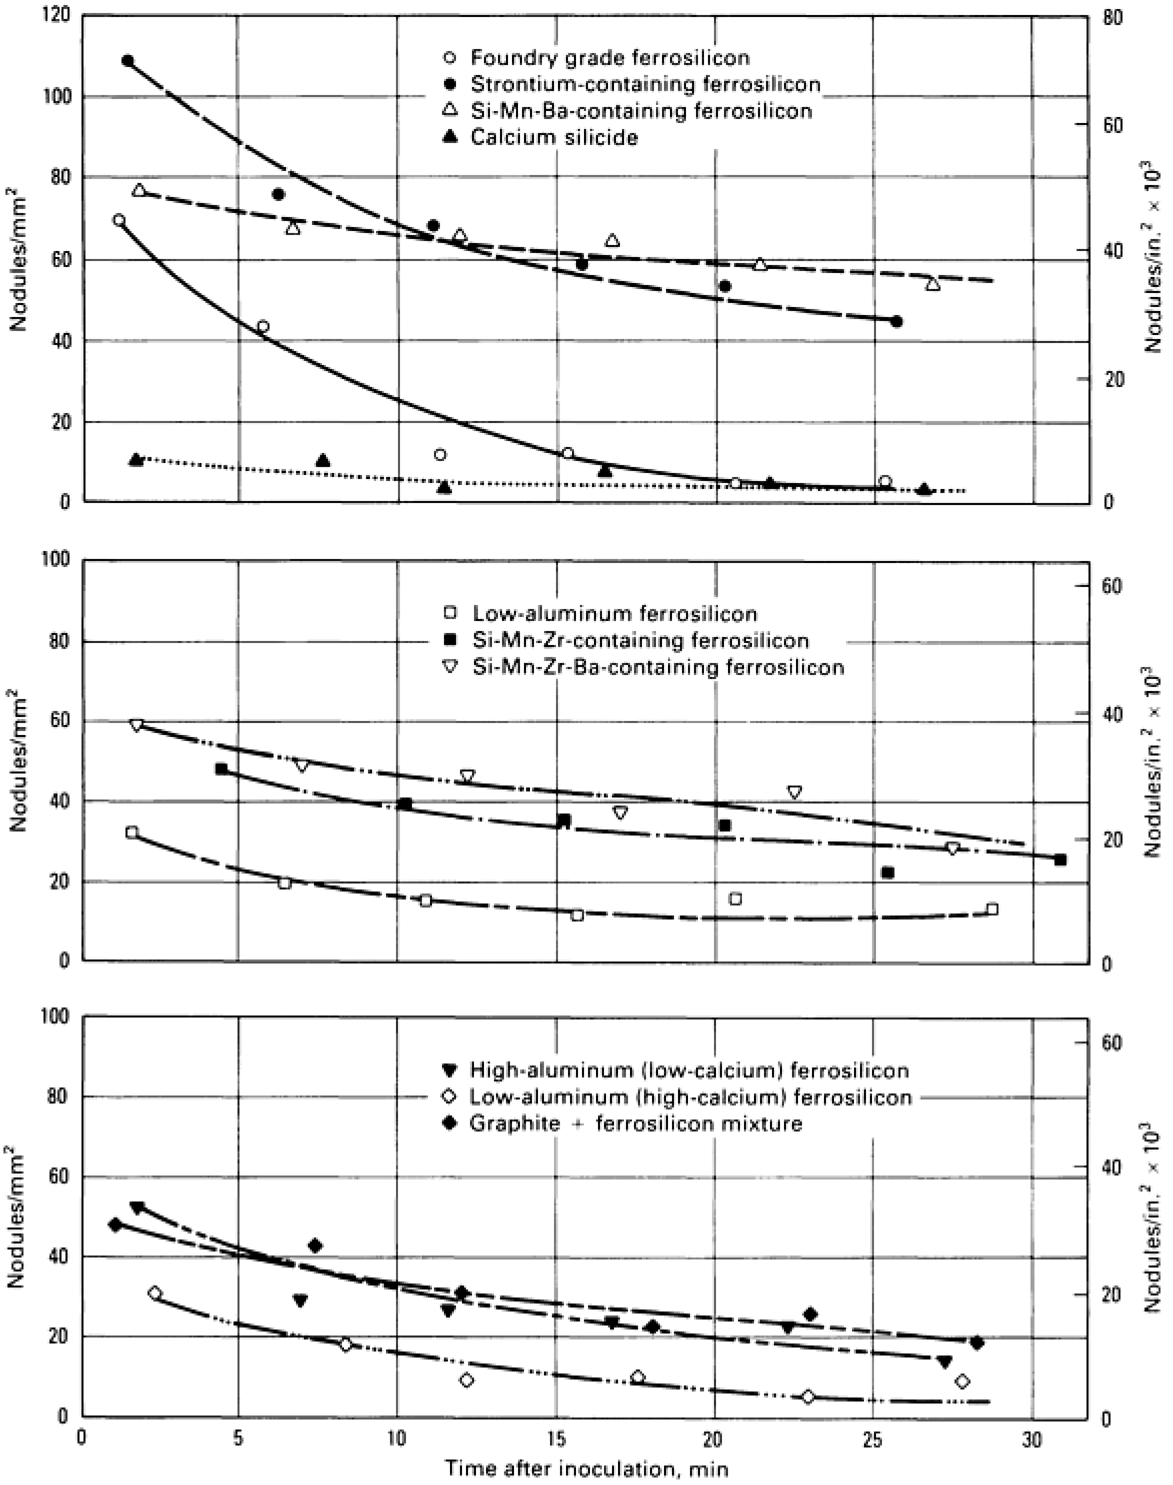

Fig. 4 Variations in nodule number with time for 22 mm (0.875 in.) bars of cerium-free ductile irons after addition of various inoculants. Source: Ref 4

Late addition of an inoculant as the metal is being cast is much more effective and can be achieved by placing granular inoculant or shaped inoculant particles in the mold in an enlargement of the runner or a special chamber in the running system. Alternatively, fine granular inoculant can be added to the metal pouring stream either by dispensing it to the sprue or by encasing it in hollow wire and passing this into the sprue. These late methods of inoculation require only $\frac{1}{5}$ to $\frac{1}{10}$ as much inoculant as ladle inoculation and are sometimes also used to supplement ladle inoculation, particularly when

fading has occurred through long holding times in the ladle. The superior effect of late inoculation in increasing nodule number is illustrated in Fig. 5, which also shows that the advantage is greatest in thinner section castings.

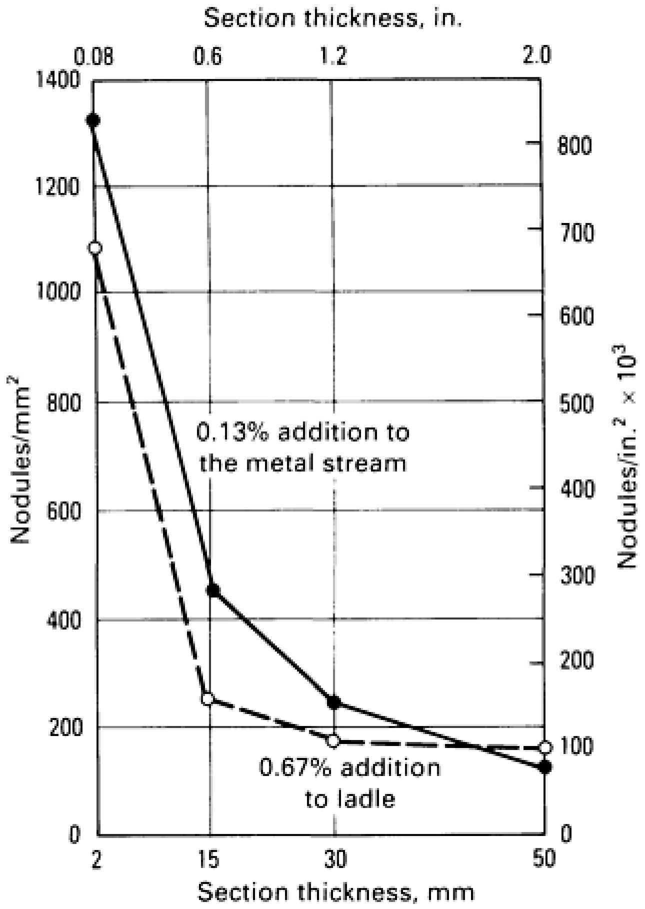

Fig. 5 Nodule numbers in ductile irons inoculated with foundry grade ferrosilicon (75% Si) added either to the ladle or to the metal stream. Source: Ref 4

Late inoculation is sometimes practiced in addition to other methods of inoculation as a means of intensifying the inoculation effect or as a safeguard against fading of inoculation in the ladle, especially when making very thin castings. When magnesium treatment is done in the mold, the magnesium alloy usually contains enough silicon to produce the required inoculation effect, but may also be supplemented by mixing additional inoculant with the magnesium alloy.

Casting and Solidification

Ductile iron shares with gray irons the properties of very good fluidity and castability, but its casting and solidification characteristics have some important differences that require special attention.

Gating Systems

Because ductile iron normally contains magnesium, oxidation of this element, together with silicon, may give rise to small inclusions and dross both in the ladle and in the gating system. This dross must not enter the casting, where it can cause laps, rough surfaces, or pinholes. Other recommendations include the following:

- Metal held in the ladle must be skimmed clean; the use of teapot ladles is advisable
- Magnesium content should be kept to a minimum, preferably less than 0.06%
- A gating system of adequate size should be used, designed to achieve rapid mold filling with minimum turbulence of metal
- A slightly pressurized gating ratio is desirable; for example, suitable ratios of cross sections of sprue-runner-ingate may be 4:8:3 to ensure a short filling time and a full sprue during casting
- Placing ingates in the drag is recommended, with ingates as near to the bottom of the casting as possible
- The use of a ceramic filter in the gating system removes small slag inclusions and assists smooth metal flow, and it has been shown to reduce dross defects and to improve the mechanical properties of the iron

Pouring Temperature and Speed. Excessive temperature gradients in the casting and pouring of cold metal are undesirable and may promote carbide formation in thin sections and casting extremities. These can be avoided by pouring at not less than 1315 °C (2400 °F) for castings of 25 mm (1 in.) section and above up to 1425 °C (2600 °F) for castings of 6 mm ($\frac{1}{4}$ in.) section and by modifying the gating system to include such features as flow-offs and runner bar extensions. There are no absolute rules for the speed of pouring, but Fig. 6 illustrates typical values found to be successful.

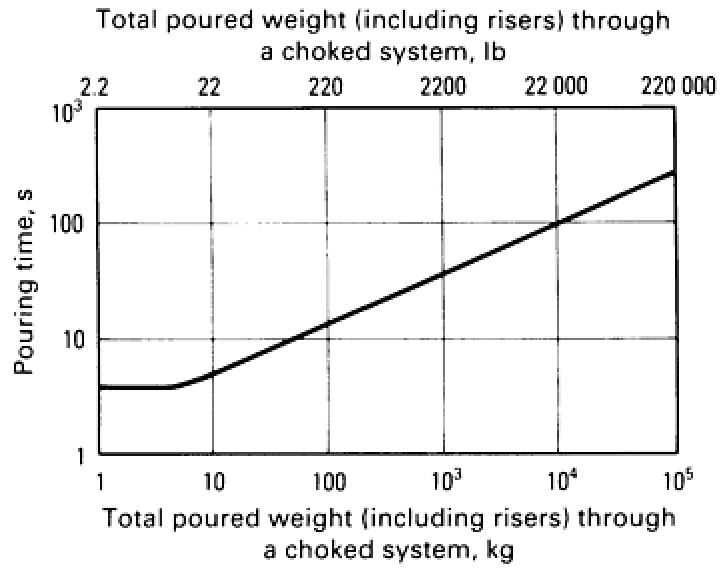

Fig. 6 Example of pouring rates found to be successful for ductile iron castings. Source: Ref 5

Solidification and Feeding (Risering)

The change from flake to nodular graphite is accompanied by important differences in solidification behavior. In hypereutectic irons, graphite segregation and flotation occur more easily than in gray iron. Such segregation can aggravate dross problems and give rise to local high-carbon regions, which adversely affect mechanical properties and the appearance of machined surfaces. During solidification, the precipitation of graphite in a nodular form causes ductile iron castings to expand to a greater degree and with more force than gray iron. Consequently, they require more rigid molds and more attention to feeding if the castings are to be sound.

In green sand molds in particular, ductile iron castings are likely to be oversize compared with the pattern and compared with gray iron castings. It is necessary to make dense molds, and flasks may need internal bars and will require good weighting and clamping, especially for larger castings. The use of chemically hardened or dry sand molds is a great advantage, provided they are adequately cured (Ref 6).

It is sometimes possible to make sound ductile iron castings of simple shapes without the use of risers by taking advantage of graphite expansion, which occurs during eutectic solidification. The requirements are:

- A strong, well-compacted, chemically bonded sand mold contained in a rigid molding flask
- A carbon equivalent of about 4.3 and a carbon content of about 3.6%
- A low casting temperature, probably below 1350 °C (2460 °F)
- A gating system and running speed to minimize temperature gradients developed in the mold

Nevertheless, for most purposes, ductile iron castings, even in rigid molds, will require the use of risers to ensure fully sound castings. The principles of directional solidification should be employed in casting design with regard to the placement of gates and the locations of risers.

There are three stages of solidification volume change, and rational risering practice takes account of them. They are:

- A volume decrease of the liquid metal as soon as it has been poured, while it cools to the temperature of eutectic solidification
- A volume increase during eutectic solidification, when graphite nodules grow and exert considerable expansion pressure on the mold; depending on casting design and mold strength, this can lead to oversize castings
- A volume decrease during the last stage of solidification (secondary shrinkage)

For the most efficient use of risers to achieve sound castings, advantage is taken of the second-stage volume increase to reduce the amount of feed metal required. This is done with pressure control, in which riser (feeder) necks are designed to freeze during solidification, causing the solidification volume increase to compensate for any casting expansion and late-stage volume decrease or secondary shrinkage.

There are a number of approaches to the feeding of ductile iron castings. A pressure control approach relates the cooling modulus of the casting to those of the riser and the riser neck. A typical nomogram is shown in Fig. 7, in which the modulus of the riser neck, M_n, is related to the significant modulus of the casting, M_s.

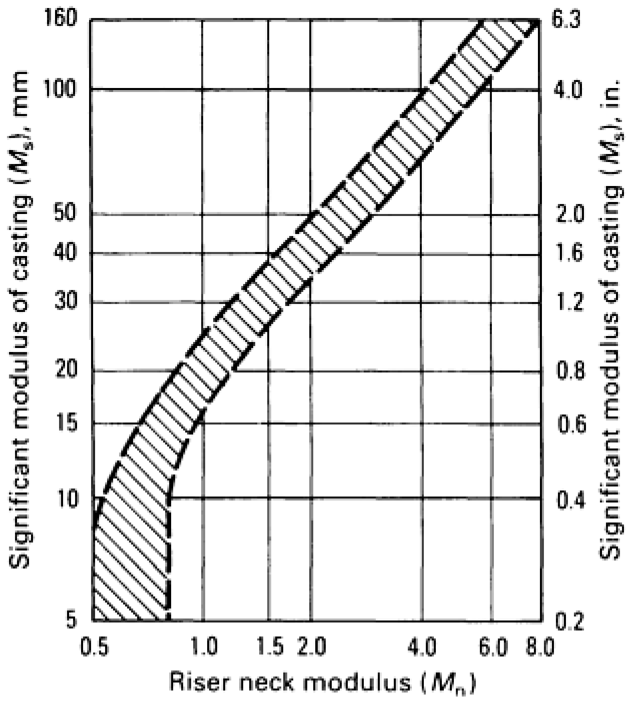

Fig. 7 A system for calculating riser dimensions. M_s = volume/effective cooling surface of largest section of casting; M_n = circumference of riser neck/cross section area of riser neck. Modulus of riser = 1.2 M_n. Source: Ref 7

More advanced calculations of feeding requirements for ductile iron take into account variables affecting mold rigidity, metal composition (including carbon equivalent and content), and pouring temperature. These can be combined to provide a factor that can be included in a nomogram such as that shown in Fig. 8.

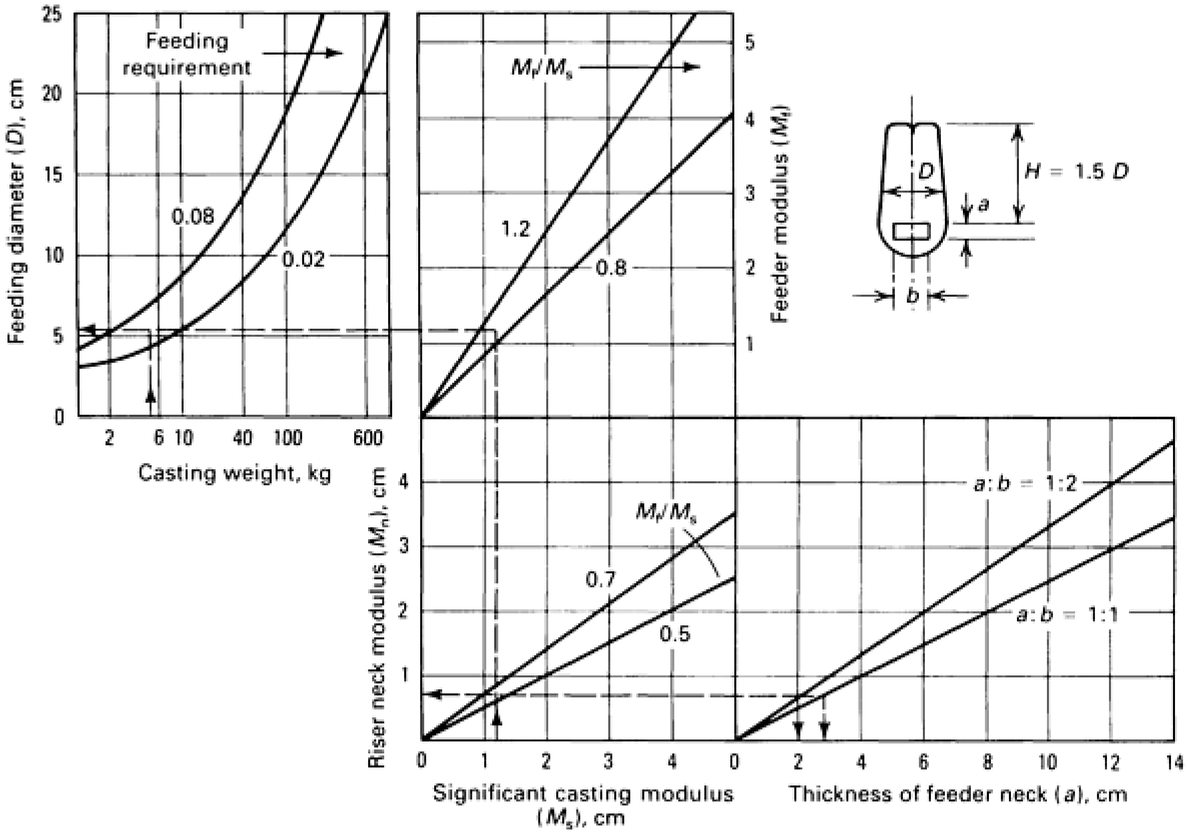

Fig. 8 System of calculating feeder dimensions. First, calculate significant modulus M_s. Second, read off from M_s the values of M_f, M_n, *D,* and *a*:*b*. Third, select feeding requirements depending on mold type and pouring temperature. Finally, select M_f/M_s based on foundry experience. Source: Ref 8

Because the risers themselves can promote or accentuate hot spots and excessive mold wall movement, the use of smaller risers by the application of exothermic feeder sleeves can be an advantage and can improve yield, often to more than 80%. Nomograms and computer programs for the use of such sleeves are generally supplied by the manufacturers. Excessive ferrostatic head should also be avoided because this increases the pressure on the mold, leading to casting swelling and further feed metal requirement. Several computer-aided methods are available for determining the best risering system, but for their use to be successful, all of the production variables affecting the shrinkage behavior of ductile iron must be controlled.

Ductile iron risers are more difficult to remove than those of gray iron. Notched riser necks and the use of breaker cores can facilitate breaking off, and mechanical devices are available to assist the breaking or levering off of risers. However, abrasive cutting wheels sometimes must be used to avoid damage to the castings.

The change in shape of graphite from flake to nodular makes ductile iron more prone to carbide formation in thin sections, and it may be difficult to obtain graphite throughout sections less than 6 mm ($\frac{1}{4}$ in.) thick. There is also a tendency for inverse chill to occur in the heat centers of round and symmetrical sections. This is related to the cooling conditions of such sections and is most likely to be cured by adjusting the gating system and by using late inoculation in the metal stream or in the mold.

Ductile Iron

I.C.H. Hughes, BCIRA International Centre for Cast Metals Technology, Great Britain

Metallurgical Controls of Ductile Iron Production

Metal Composition. Before treatment with magnesium, it is necessary to know the sulfur content of the liquid iron. This is best determined rapidly by taking a chilled coin sample for spectroscopic analysis. If required, the sulfur and the carbon content can be determined rapidly by the combustion of crushed solid samples taken from the pins attached to the test coin. Spectroscopic analysis for other elements can be carried out either before or after magnesium treatment, but it is unlikely that a completely white sample suitable for analysis will be obtained after inoculation or if a heavy addition of a silicon-containing magnesium alloy has been made. Final silicon content after inoculation may need to be determined chemically with drillings taken from a sample cast after treatment. A reliable determination of carbon in treated ductile iron cannot be obtained chemically except on a solid sample obtained, for example, from pins attached to a coin sample, because of loss of carbon during drilling and the likely presence of graphite in the coin. Rapid shopfloor control of carbon equivalent, carbon, and silicon can be carried out by thermal analysis of the metal in the same manner for gray iron, but this must be done before magnesium treatment.

Other properties of the iron can be deduced from thermal analysis data, including the undercooling of the eutectic, which is a guide to nodule number and chilling tendency, but in general such developments are still taking place. For this reason, nodularity and nodule number are generally determined by other methods.

Nodularity and Nodule Number. The success of the magnesium treatment, freedom from undesirable trace elements, and adequate postinoculation in producing an iron with a good nodular graphite structure and of adequate nodule number to ensure freedom from carbides and to yield correct properties are generally determined rapidly by casting and examining a test coupon of a design such as that recommended by American Foundrymen's Society (AFS) Committee 12K and shown in Fig. 9. The mold is made in hardened sand and consists of a central block with two ears, which are broken off as soon as the casting has solidified and the ears have cooled to a dull red or black heat. After cooling to room temperature, an ear is broken or cut in two, and the cross section is ground, polished, and examined under the microscope. Alternatively, small samples for metallographic examination can be cut from selected castings or from other types of agreed test bar. The number of nodules in a specified area is counted using a magnification usually of 100× the specified area is typically a square millimeter or a square inch of the field of view or along a specified length of line. The shape of the nodules is evaluated in accordance with the classification of the standards ISO 945 or ASTM A 247. Nodule number and perfection of shape can also be evaluated using quantitative metallographic instruments.

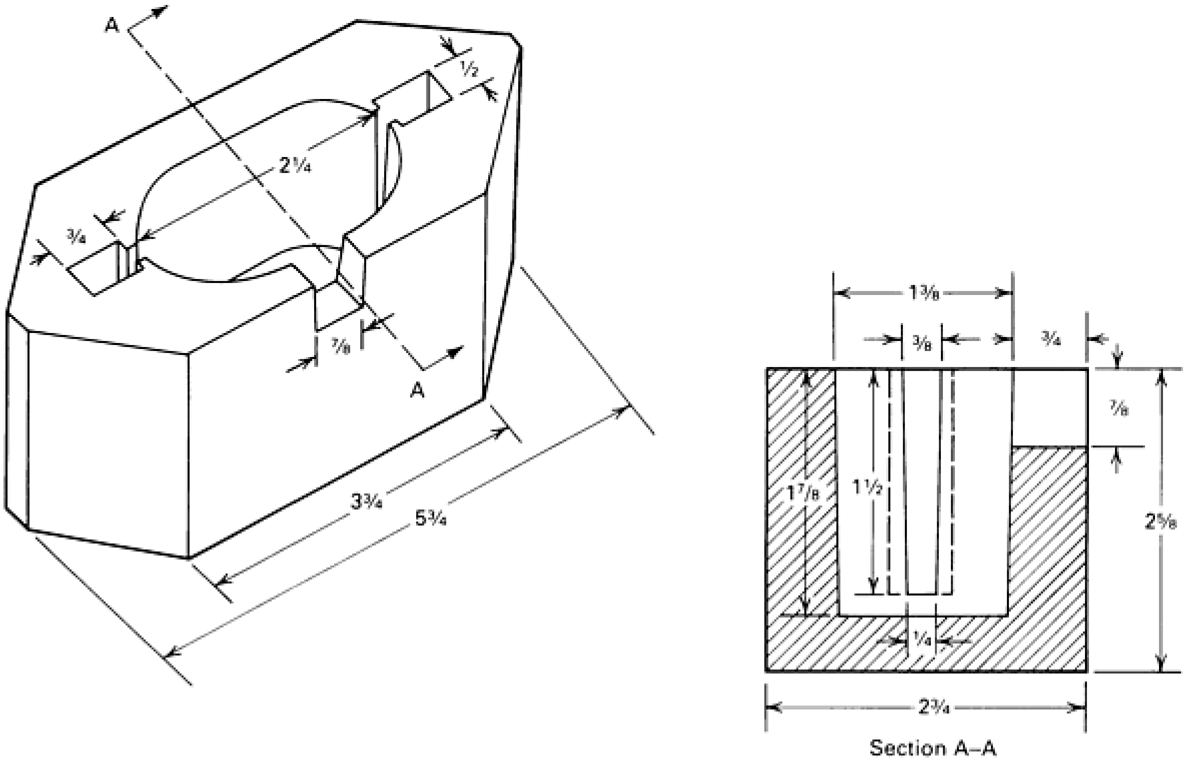

Fig. 9 Test coupon recommended by AFS Committee 12K for rapid examination of ductile iron microstructures. Dimensions given in inches

Good practice requires a nodularity sample to be taken from each batch of iron treated and poured or, when using automated holding and pouring of metal, at regular intervals of time. For most purposes, 85 to 100% of the graphite should be in a fully nodular form. Samples from castings or test bars will be periodically examined to verify the graphite and matrix structure of the iron produced, to evaluate ferrite and pearlite contents, and to verify freedom from undesirable carbides, inclusions, and dross as a general control of the production process.

Mechanical Test Coupons. To ensure that the castings meet the specified requirements, mechanical properties are checked periodically on test pieces machined from cast test coupons. Recommended test bars cast separately or attached to castings are in the form of keel blocks, Y blocks, or horizontal bars with knock-off heads and are indicated in most specifications. If the castings are to be used in the heat-treated condition, the test bars will be heat treated with the castings they represent before mechanical test specimens are obtained. The actual properties of castings are sometimes checked by machining test bars from the castings with agreement between the foundry and its customer.

Other Rapid Tests of Metal Quality. If a sand cast test bar is made from the treated iron, its nodularity can be evaluated by measuring either its resonant frequency or the velocity of ultrasonic radiation through it. Suitable tests of this kind have been described and are sometimes used as rapid shopfloor control tests. Similar tests for casting quality control are described in the section "Nondestructive Evaluation of Ductile Iron Castings" in this article.

Specifications for Ductile Iron

Standard specifications for engineering grades of ductile iron castings classify the grades according to the tensile strength of a test bar cut from a prescribed test casting. The International Standards Organization (ISO) specification ISO

1083:1976 and most national specifications also specify the ductility in terms of percentage of elongation and the 0.2% proof strength or offset yield strength. The impact values of those grades with the highest ductility are frequently specified in the ISO, UK, and West German specifications, and a guide to microstructure is included in most specifications. Hardness is usually specified, but is only mandatory in SAE J434C. Table 2 summary the ISO 1083:1976, ASTM A 536, and SAE J434C specifications.

(a) Mean value from three tests.

(b) These irons are specified primarily based on hardness and structure. Mechanical properties are given for information only.

(c) Quenched-and-tempered grade; hardness subject to agreement between supplier and purchaser

Most national specifications follow approximately the grades of the ISO specification. There are some exceptions, for example, SAE J434C and Japan JIS G 5502-1982. The standard specifications of a number of other countries are listed in BCIRA Broadsheet 156-1. An engineer's guide to many of the properties to be expected from the various grades of the British specification has been published (Ref 9) and provides information that enables an estimate to be made of a variety of other mechanical and physical properties of irons covered by this and most other specifications.

Figure 10(a) shows the relationship between minimum specified values for tensile strength and elongation representing the range of values covered by the ISO, ASTM, and SAE specifications. Figure 10(b) shows the relationship between minimum values for tensile strength and hardness ranges represented by the three specifications.

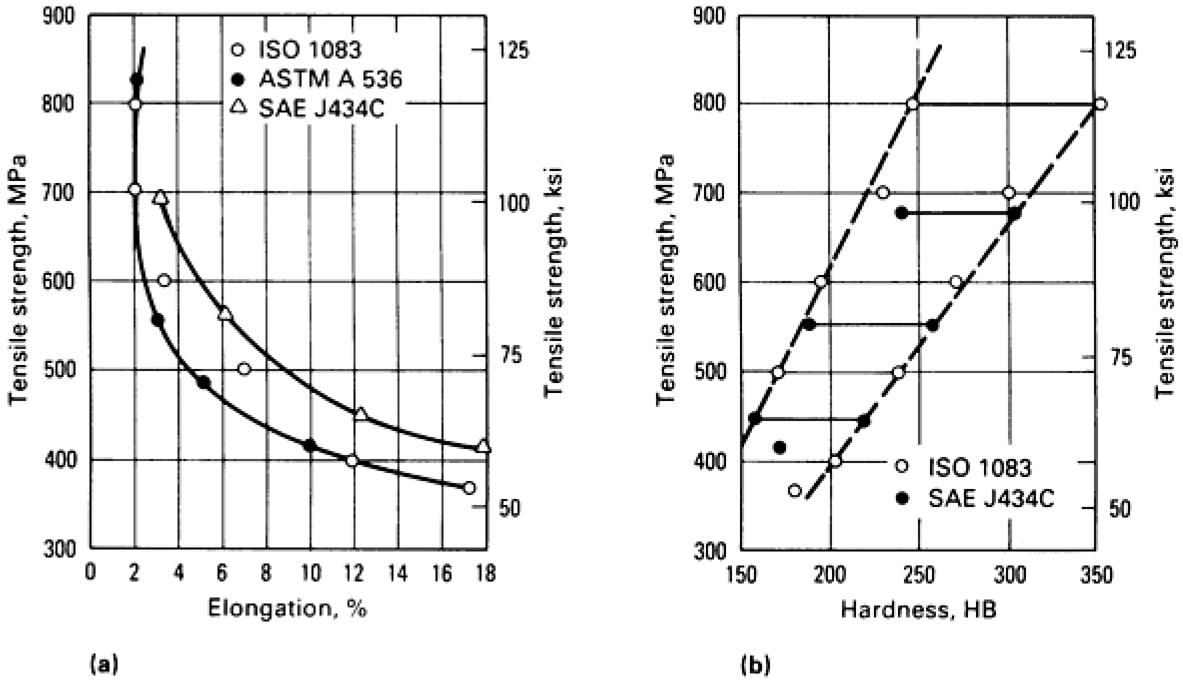

Fig. 10 (a) Tensile strength versus elongation. (b) Tensile strength versus hardness

The actual values of properties to be expected from good-quality ductile irons produced to meet any given specified grade will normally cover a range that more than satisfies the requirements of the specification. Data on strength, hardness, and elongation from actual production are recorded in Fig. 11 and illustrate the typical ranges achievable.

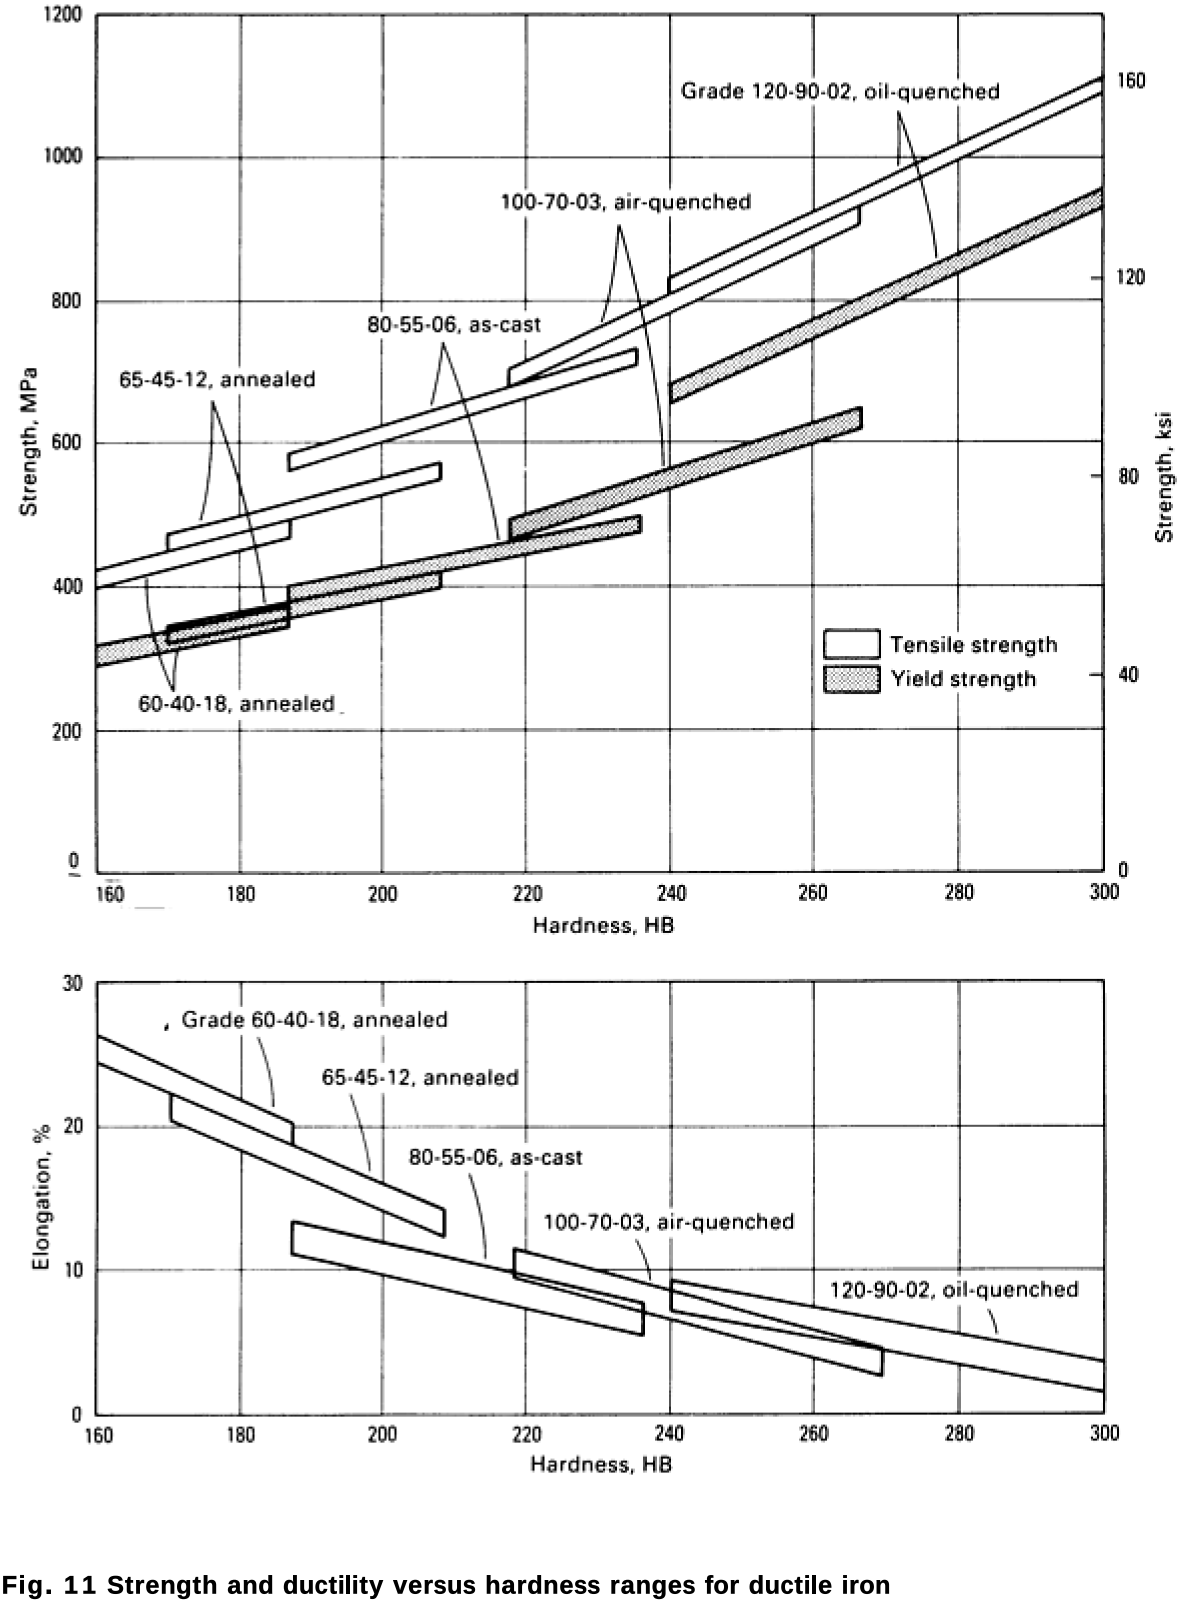

Fig. 11 Strength and ductility versus hardness ranges for ductile iron

Specifications for the highest-strength grades usually mention the possibility of hardened-and-tempered structures, but for the most recently reported austempered ductile irons, which have the highest combinations of tensile strength and ductility, there are as yet only tentative unofficial specifications. Table 3 summarizes tentative values of grades suggested in the United States, the United Kingdom, and Switzerland. Figure 12 compares the properties of austempered ductile irons with those of other ductile irons.

Table 3 Some tentative specifications for austempered ductile iron

Ductile Iron

I.C.H. Hughes, BCIRA International Centre for Cast Metals Technology, Great Britain

Factors That Affect Properties

Graphite Structures. The amount and form of the graphite in ductile iron are determined during solidification and cannot be altered by subsequent heat treatment. All of the mechanical and physical properties characteristic of this class of materials are a result of the graphite being substantially or wholly in the spheroidal nodular shape, and any departure from this shape in a proportion of the graphite will cause some deviation from these properties. It is common to attempt to produce greater than 90% of the graphite in this form (>90% nodularity), although structures between 80 and 100% nodularity are sometimes acceptable. Figure 13 illustrates microstructures containing estimated graphite nodularities of 99, 80, and 50%.

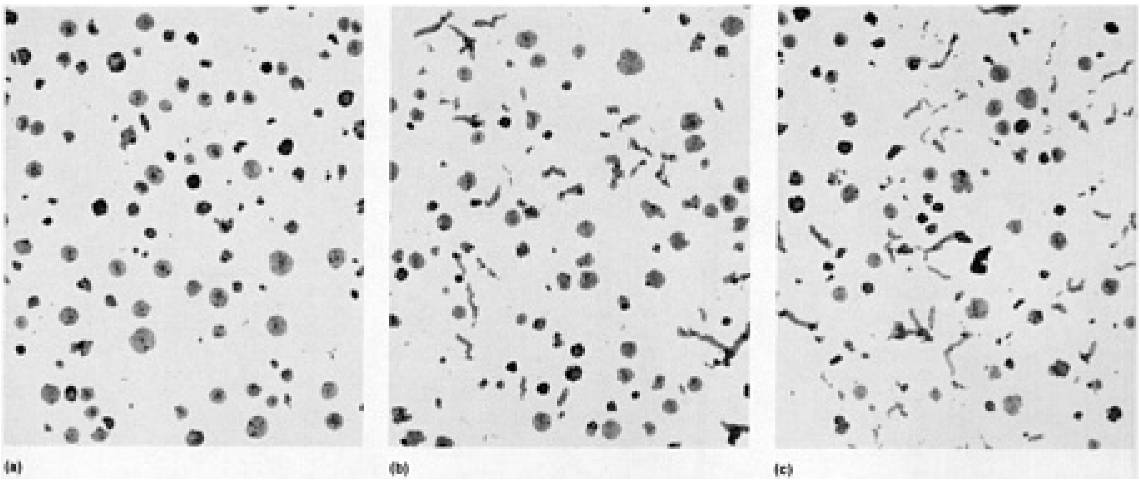

Fig. 13 Microstructures of ductile irons of varying degrees of nodularity. (a) 99% nodularity. (b) 80% nodularity. (c) 50% nodularity. All unetched. 36×

All properties relating to strength and ductility decrease as the proportion of non-nodular graphite increases, and those relating to failure, such as tensile strength and fatigue strength, are more affected by small amounts of such graphite than properties not involving failure, such as proof strength. This is illustrated in Fig. 14, which shows the typical effects of graphite form on tensile and offset yield (proof) strength.

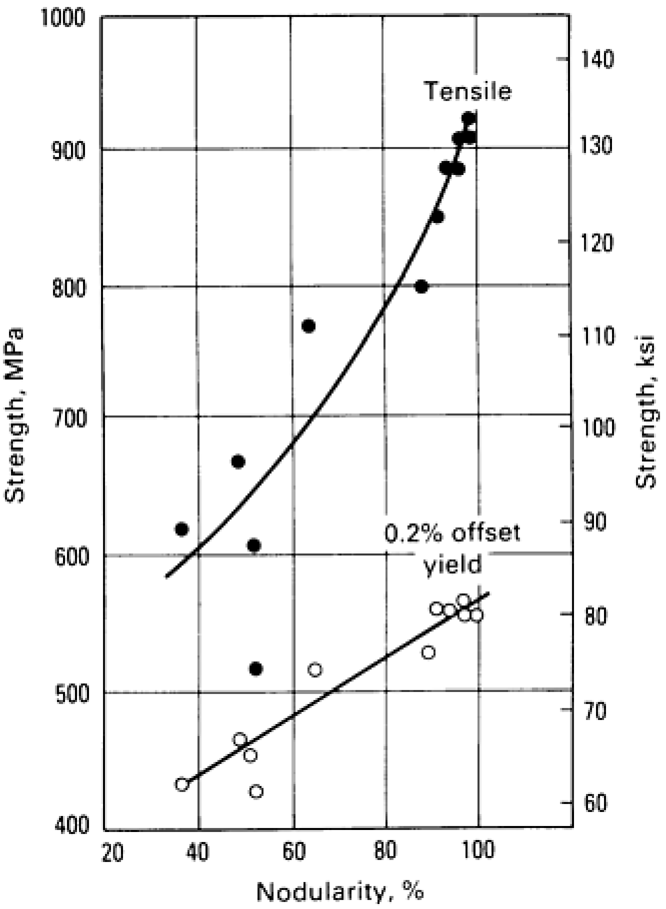

Fig. 14 Tensile and yield strength of ductile iron versus visually assessed nodularity. Source: Ref 10.

The form of non-nodular graphite is important because thin flakes of graphite with sharp edges have a more adverse effect on strength properties than compacted forms of graphite with rounded ends. For this reason, visual estimates of percentage of nodularity are only a rough guide to properties. Graphite form also affects modulus of elasticity, which can be measured by resonant frequency and ultrasonic velocity measurements, and such measurements are therefore often a better guide to nodularity and its effects on other properties (see the section "Nondestructive Evaluation of Ductile Iron Castings" in this article). A low percentage of nodularity also lowers impact energy in the ductile condition, reduces fatigue strength, increases damping capacity, increases thermal conductivity, and reduces electrical resistivity.

Inoculation has the effect of increasing nodule number, which prevents the formation of carbides and increases ferrite, thus avoiding hard, brittle castings. Figure 15 shows how nodule number increased in thin plate castings as the amount of inoculant added was increased.

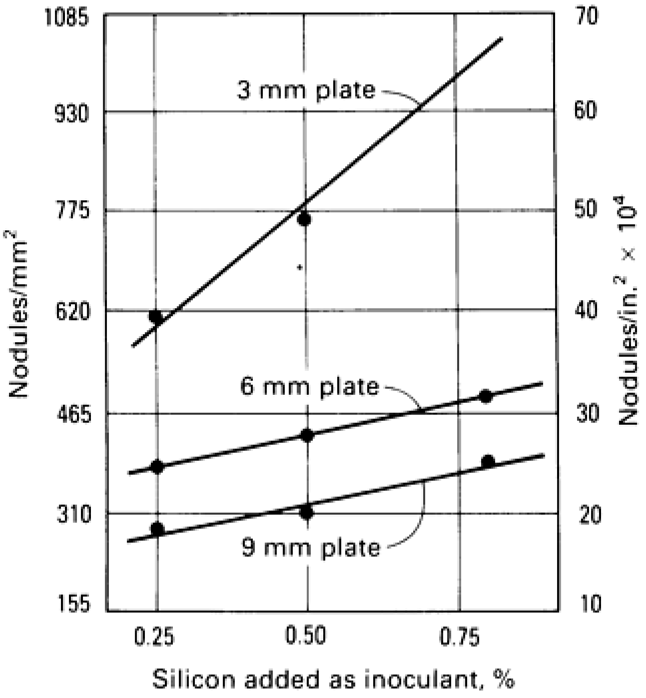

Fig. 15 Nodule number versus amount of silicon inoculant added in the ladle

Graphite Amount. As the amount of graphite increases, there is a relatively small decrease in strength and elongation, a decrease in modulus of elasticity, and a decrease in density. In general, these effects are small compared with the effects of other variables because the carbon equivalent content of spheroidal graphite iron is not a major variable and is generally maintained close to the eutectic value.

Matrix Structure. The principal factor in determining the different grades of ductile iron in the specifications is the matrix structure. In the as-cast condition, the matrix will consist of varying proportions of pearlite and ferrite, and as the amount of pearlite increases, the strength and hardness of the iron also increase.

Ductility and impact properties are principally determined by the proportions of ferrite and pearlite in the matrix, as illustrated in the article "Ductile Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.* As the amount of pearlite decreases, the maximum impact energy in the ductile condition increases, and the ductile-to-brittle transition temperature range falls.

The matrix structure can be changed by heat treatments, and those most often carried out are annealing to produce a fully ferritic matrix and normalizing to produce a substantially pearlitic matrix (see the section "Heat Treatment of Ductile Iron " in this article). Other heat treatments will be described later. In general, annealing produces a more ductile matrix with a lower impact transition temperature than is obtained in as-cast ferritic irons. Normalizing produces a higher tensile strength with a higher amount of elongation than is obtained in fully pearlitic as-cast irons. In the former case, properties

are due to a refined ferrite grain structure; in the latter case, increased strength and ductility result from homogenization and a finer pearlite structure than occurs in the as-cast condition. Figure 16 shows how pearlite content influences tensile strength and yield strength, how heat treatment increases strength, and how reduced nodularity lowers strength at given pearlite content.

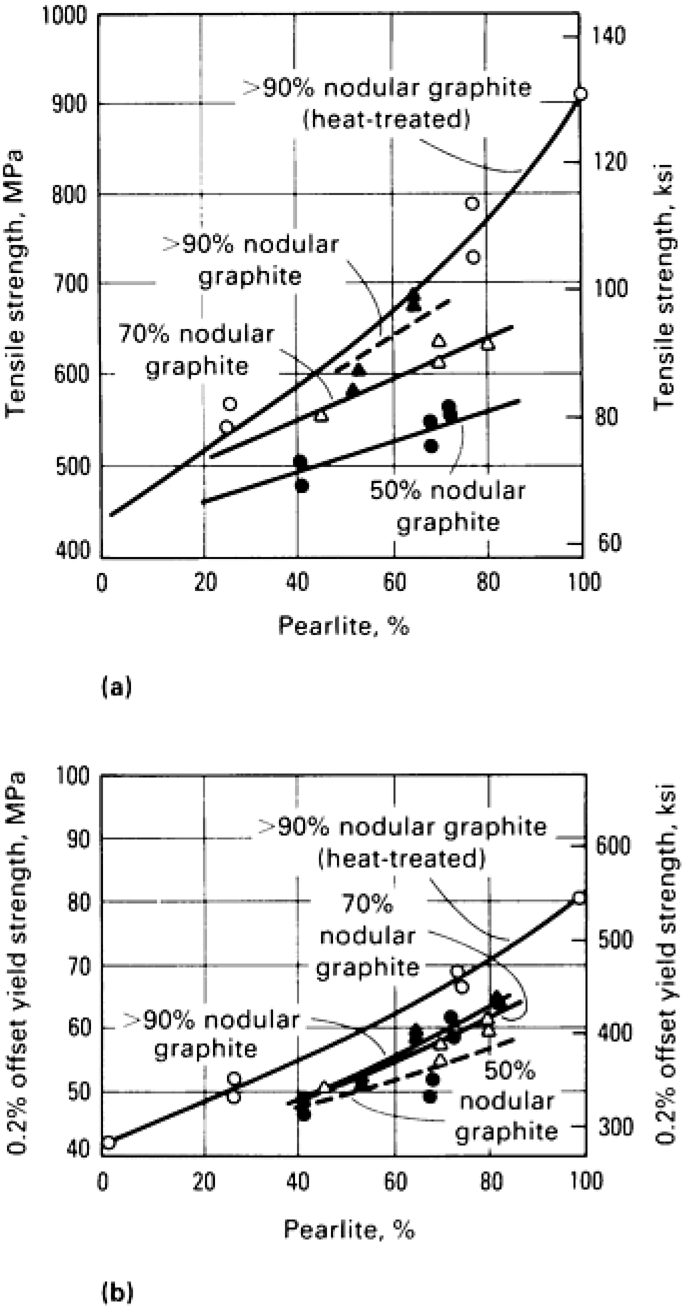

Fig. 16 Relationships between strength and amount of pearlite. (a) Tensile strength versus amount of pearlite in irons having varying properties of graphite in a nodular form. (b) 0.2% offset yield strength versus amount of pearlite in irons having varying proportions of graphite in a nodular form. Source: Ref 11

The graphite structure can affect the matrix structure. An increased nodule number, achieved by better inoculation, will tend to increase the amount of ferrite in the as-cast condition and will lead to more rapid annealing with less chance of retained pearlite after a given annealing time.

The presence of carbides reduces ductility, increases hardness, and promotes premature failure in tension and in fatigue and impact loading. Special care is necessary to avoid carbides because they are difficult to detect by nondestructive

means. It is desirable to ensure adequate silicon content and inoculation for the section size being cast and freedom from carbide-forming trace elements, particularly chromium.

Section Size. As section size decreases, the solidification and cooling rates in the mold increase. This results in a fine-grain structure that can be annealed more rapidly. In thinner sections, however, carbides may be present, which will increase hardness, decrease machinability, and lead to brittleness. To achieve soft ductile structures in thin sections, heavy inoculation, probably at a late stage, is desirable to promote graphite formation through a high nodule number.

As the section size increases, the nodule number decreases, and microsegregation becomes more pronounced. This results in a large nodule size, a reduction in the proportion of as-cast ferrite, and increasing resistance to the formation of a fully ferritic structure upon annealing. In heavier sections, minor elements, especially carbide formers such as chromium, titanium, and vanadium, segregate to produce a segregation pattern that reduces ductility, toughness, and strength (Fig. 17). The effect on proof strength is much less pronounced. It is important for heavy sections to be well inoculated and to be made from a composition low in trace elements.

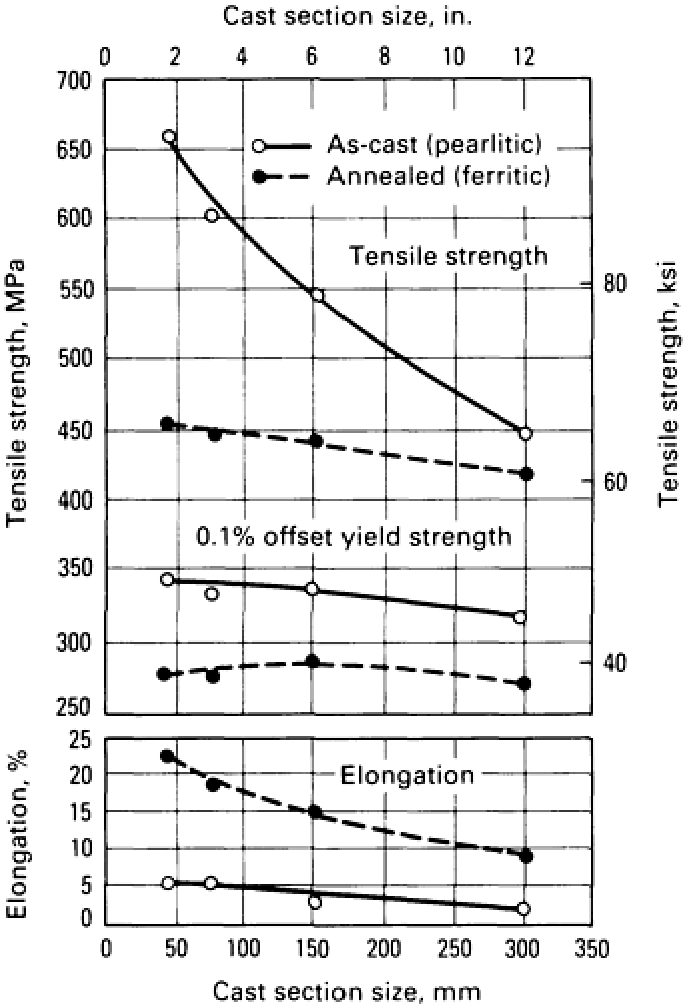

Fig. 17 Effect of cast section size on the properties of ductile iron

Composition. In addition to the effects of elements in stabilizing pearlite or retarding transformation (which facilitates heat treatment to change matrix structure and properties), certain aspects of composition have an important influence on some properties. Silicon hardens and strengthens ferrite and raises its impact transition temperature; therefore, silicon content should be kept as low as practical, even below 2%, to achieve maximum ductility and toughness. Figure 18 summarizes information reported more fully earlier, showing how increasing ferrite lowers impact transition temperature and raises the ductile impact value. Figure 18 also shows how, in the ferritic condition, a range of values is obtained with improving properties as the silicon content is lowered. Further improvement in impact properties is obtained with

phosphorus contents below about 0.05%; phosphorus also has a powerful embrittling effect in ferritic ductile iron and is therefore normally kept low.

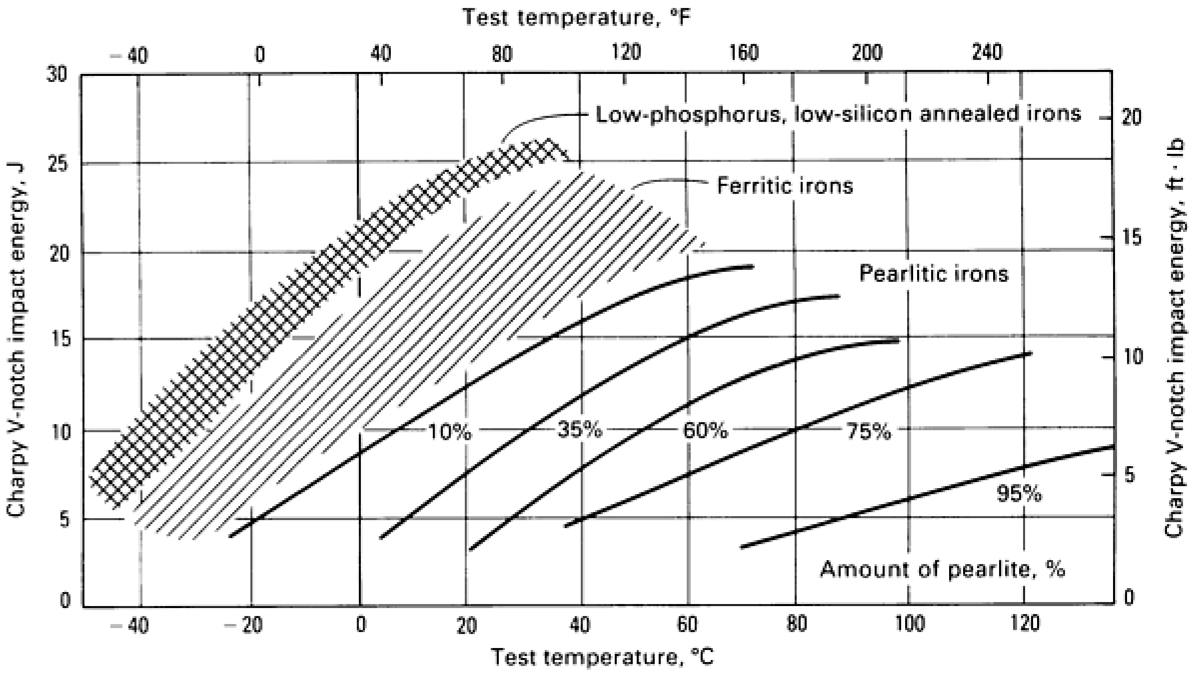

Fig. 18 Charpy V-notch impact energies of ductile irons. Source: Ref 12.

Nickel also strengthens ferrite, but has much less effect than silicon in reducing ductility. When producing as-cast grades of iron requiring fairly high ductility and strength such as ISO Grade 500-7, it is necessary to keep silicon low to obtain high ductility, but it may also be necessary to add some nickel to strengthen the iron sufficiently to obtain the required tensile strength.

Almost all elements present in trace amounts combine to reduce ferrite formation, and high-purity charges must be used for irons to be produced in the ferritic as-cast condition. Similarly, all carbide-forming elements and manganese must be kept low to achieve maximum ductility and low hardness. Silicon is added to avoid carbides and to promote ferrite as-cast in thin sections.

The electrical, magnetic, and thermal properties of ductile irons are influenced by the composition of the matrix. In general, as the amount of alloying elements increases, resistivity increases, thermal conductivity decreases, and the magnetic hardness of the material increases.

Heat Treatment of Ductile Iron (Ref 13, 14)

The first stage of most heat treatments designed to change the structure and properties of ductile iron consists of heating to, and holding at, a temperature between 850 and 950 °C (1560 and 1740 °F) for about 1 h plus 1 h for each 25 mm (1 in.) of section thickness to homogenize the iron. When carbides are present in the structure, the temperature should be approximately 900 to 950 °C (1650 to 1740 °F), which decomposes the carbides prior to subsequent stages of heat treatment. The time may have to be extended to 6 or 8 h if carbide-stabilizing elements are present. In castings of complex shape in which stresses could be produced by nonuniform heating, the initial heating to 600 °C (1110 °F) should be slow, preferably 50 to 100 °C (90 to 180 °F) per hour.

To prevent scaling and surface decarburization during this stage of treatment, it is recommended that a nonoxidizing furnace temperature be maintained using a sealed furnace; a controlled atmosphere may be necessary. Care must also be taken to support castings susceptible to distortion and to avoid packing so that castings are not distorted by the weight of other castings placed above them.

The most important heat treatments and their purposes are:

- Stress relieving, a low-temperature treatment, to reduce or relieve internal stresses remaining after casting
- Annealing to improve ductility and toughness, to reduce hardness and to remove carbides
- Normalizing to improve strength with some ductility
- Hardening and tempering to increase hardness or to give improved strength and higher proof stress ratio
- Austempering to yield bainitic structures of high strength, with some ductility and good wear resistance
- Surface hardening by induction, flame, or laser to produce a local wear-resistant hard surface

Stress Relieving. The object of stress-relieving heat treatment is to remove residual stress without causing any change in structure or properties. High stresses can be present as-cast in ductile iron castings of complex shape and can be substantially removed by heat treatment at approximately 500 to 600 °C (930 to 1110 °F). The casting is typically heated at 50 °C (90 °F) per hour from 200 to 600 °C (390 to 1110 °F), held at 600 °C (1110 °F) for 1 h for each 25 mm (1 in.) of section thickness plus 1 h, and then furnace cooled at 50 °C (90 °F) per hour to below 200 °C (390 °F), after which the castings can be air cooled to room temperature. It is of great importance to ensure that the heating and cooling rates are slow enough to avoid thermal shock and to avoid the generation of more stress through the formation of high-temperature gradients in the casting. Stress relief is not likely to be necessary for annealed castings, but may be required for as-cast pearlitic castings and for those that have been air cooled during normalizing.

Annealing. The primary purpose of annealing is to generate a ferritic structure and to remove pearlite and carbides, thus achieving maximum ductility and toughness. Annealing would normally be used to achieve properties in grades specifying 15% or more elongation. The treatment may take one of several forms, but interrupted cooling, controlled slow cooling, and single-stage treatment are typical.

Interrupted Cooling. The first stage is to homogenize the iron as described above. This is followed by cooling to 680 to 700 °C (1255 to 1290 °F) and holding at this temperature for 4 to 12 h to develop ferrite. The higher the purity of the iron, the shorter the time required. Castings of simple shape can be furnace cooled to below 650 °C (1200 °F) and air cooled, but complex castings that could develop residual stresses should be furnace cooled according to the recommendations for stress relieving.

Controlled Slow Cooling. The first stage is homogenization, as above. This is followed by cooling at 30 to 60 °C (55 to 110 °F) per hour through the temperature range of 800 to 650 °C (1470 to 1200 °F). Lower-purity irons require slower cooling rates. Cooling to room temperature is then carried out as in the interrupted method.

Single-Stage Treatment. The casting is heated from room temperature to 680 to 700 °C (1255 to 1290 °F) without a prior first-stage austenitizing treatment, then held at this temperature for 2 to 16 h to graphitize the pearlite. The time increases with decreased metal purity and is generally longer than for other methods because of a lack of prior homogenization. Cooling to room temperature is carried out as in the interrupted cooling method. This treatment is used only to break down pearlite in irons that have no eutectic carbide. If the iron contains carbides, interrupted cooling or controlled slow cooling treatments should be used.

Selection of Annealing Treatment. Most rapid annealing occurs in irons of higher silicon content, of low manganese, copper, tin, arsenic, and antimony contents, and of generally low trace element content. If the iron contains no carbides, any of the treatments outlined above can be used, but for optimum ductility, interrupted cooling should be chosen. It should be noted that if single-stage treatment is used the ferrite grain structure of the iron will be inferior to that produced by the other structures and ductility and toughness will be lower. The ferrite-forming temperature in the range of 680 to 700 °C (1255 to 1290 °F) can be increased with increased silicon content, and the rate of annealing is then increased.

The annealing cycle can be varied to produce structures containing mixed pearlite and ferrite matrices with higher strength and intermediate ductility. For example, the time in the temperature range of 700 to 720 °C (1290 to 1330 °F) can be reduced to achieve this, but a very good combination of strength with improved ductility can be obtained by austenitizing at 900 to 925 °C (1650 to 1695 °F), air cooling to room temperature, and then reheating and holding at 680 to 700 °C (1255 to 1290 °F) for a sufficient time to form ferrite around the nodules in a bull's-eye structure. Figures 19(a) and 19(b) show annealed iron microstructures with a fully ferritic and a bull's-eye ferrite structure, respectively. A form of embrittlement may occur in ferritic irons if they are rapidly cooled from the range of 500 to 600 °C (930 to 1110 °F); the quenching of castings from this temperature range should be avoided.

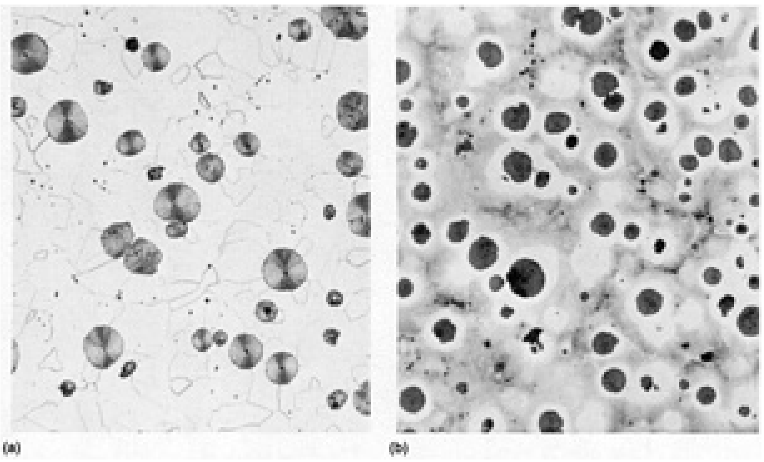

Fig. 19 Microstructures of annealed irons. (a) Fully annealed ferritic matrix. (b) Partially annealed bull's-eye structure. Both etched in picral. 100×

An overall increase in casting dimensions occurs during annealing because of the graphitization of pearlite and carbides. This increase in size can be as much as 0.005 cm/cm (0.005 in./in.) when annealing a fully pearlitic iron.

Normalizing consists of soaking the castings at a high temperature at which they are fully austenitized and any carbides decomposed, followed by cooling in air at a rate that produces a fine pearlitic matrix with traces of ferrite and free from other transformation products. Normalizing can be used to achieve grades with strengths of 700 to 900 MPa (100 to 130 ksi), and it improves the ratio of proof stress to tensile strength. A typical cycle is as follows.

The first-stage treatment is homogenization. Castings are then removed from the furnace and cooled in air to room temperature. The air cooling rate through the range of 780 to 650 °C (1435 to 1200 °F) must be fast enough to produce a fully pearlitic matrix in the casting section being treated. This may require the use of a forced air blast, especially for thicker sections. In any case, castings will probably have to be cooled suspended individually, jigged, or vibrated over a grid, but not merely placed on the floor nor in batches in a basket or in other containers. This completes the cycle.

To achieve a substantially pearlitic structure, the iron matrix must be saturated in carbon at the austenitizing temperature before air cooling; this is most quickly achieved if the iron is substantially pearlitic as-cast. If the iron contains a ferritic matrix as-cast, a longer time at the high temperature or the same time at a higher temperature will be required to ensure adequate solution of carbon from the graphite nodules. As the cooling rate increases, the pearlite will become finer, the strength and hardness will increase, and elongation may decrease. As the austenitizing temperature is increased, the strength increases and elongation decreases because of a higher carbon content of the matrix. Elements that promote pearlite in the as-cast condition, notably, manganese, nickel, copper, and tin, will shorten the time required at the soaking temperature and will enable fully pearlitic structures to be obtained in thicker section sizes. Figure 20 shows a typical normalized microstructure.

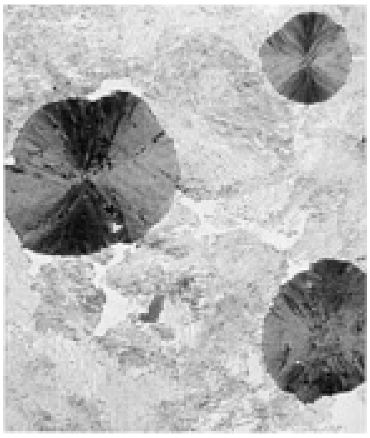

Fig. 20 Microstructure of normalized iron showing pearlite matrix. Compare with Fig. 22 and 23. Etched in picral. 500×

Hardening and Tempering. Ductile iron of high strength, generally in excess of 700 MPa (100 ksi), and with low elongation is obtained by heating to 875 to 925 °C (1605 to 1695 °F), holding at this temperature for 2 to 4 h (or longer if required to break down carbides), quenching in an oil bath to produce a matrix structure of martensite, and then tempering at 400 to 600 °C (750 to 1110 °F) to produce a matrix structure of tempered martensite. Care must be taken to avoid cracking intricate castings during quenching, and this can be prevented by quenching into warm oil at, for example, 100 °C (212 °F), followed by final cooling to room temperature. Marquenching can also be used, involving quenching in hot oil at approximately 200 °C (390 °F), but this must be followed by cooling to room temperature, preferably in a cold water bath, to obtain the desired structure and properties.

For successful hardening during quenching, a fully martensitic structure must be obtained, and except in very thin sections, this will require alloying with elements that impart hardenability. Copper, nickel, manganese, and molybdenum increase hardenability in ascending efficiency. Copper can only be used sparingly in ductile iron because of its limited solubility. Although silicon increases hardenability in steels, it has the opposite effect in ductile iron through decreasing carbon solubility, while increasing carbon content also decreases hardenability slightly through increasing the amount of graphite rather than increasing carbon in solution.

In practice, increased hardenability is achieved by combinations of alloying elements. The combinations listed in Table 4 are examples showing the effects of manganese, nickel, and molybdenum in increasing hardenability. Additional data on the hardenability of ductile irons are available in Ref 14.

Table 4 Examples of alloying combinations used to increase the hardenability of ductile iron

Tempering should normally be carried out in an air circulation furnace for at least 4 h, during which there is a progressive decrease in strength and hardness and an increase in ductility. The effect of tempering temperature on the properties of hardened-and-tempered ductile iron is illustrated by the examples shown in Fig. 21 for 25 mm (1 in.) bars of an unalloyed iron. Figure 22 illustrates the microstructure of an iron that was hardened and tempered at 550 °C (1020 °F).

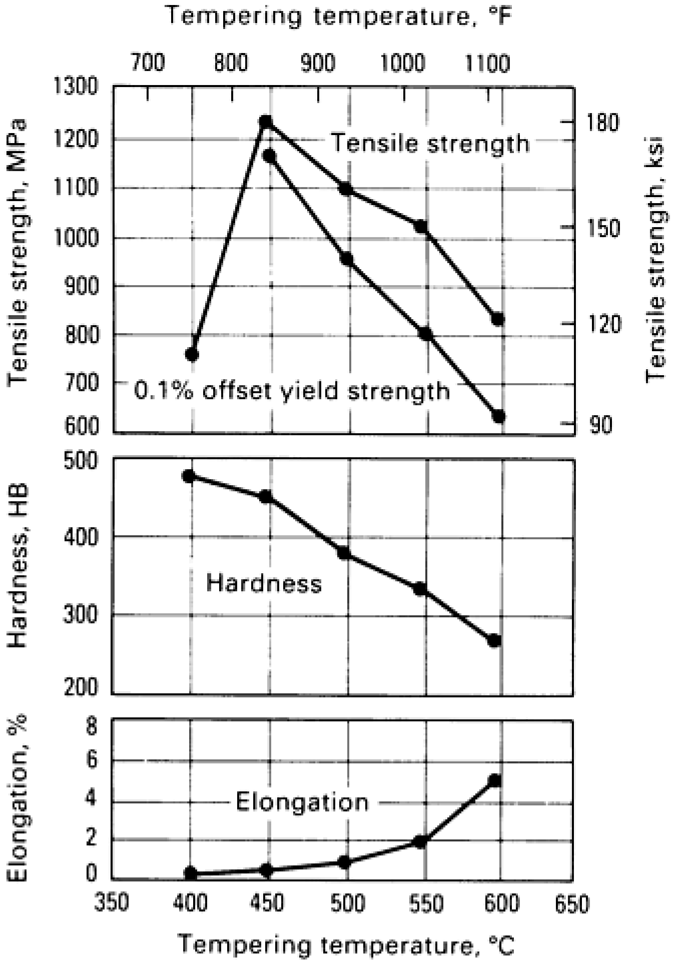

Fig. 21 Properties of hardened-and-tempered iron (Fe-3.2C-1.96Si-0.29Mn) quenched from 900 °C (1650 °F) and tempered 4 h at different temperatures

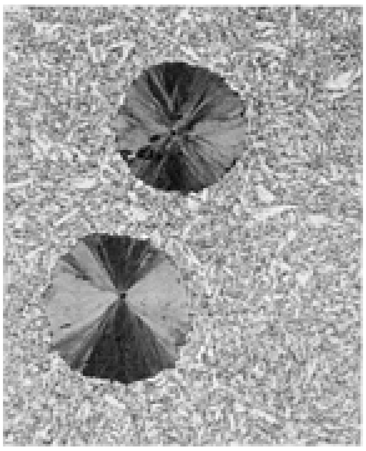

Fig. 22 Microstructure (tempered martensite) of hardened-and-tempered iron. Compare with Fig. 20 and 23. Etched in picral. 500×.

Austempering. If ductile iron is austenitized and quenched into a salt bath or a hot oil transformation bath at a temperature of 320 to 550 °C (610 to 1020 °F) and held at this temperature, transformation to a structure containing mainly bainite with a minor proportion of austenite takes place. Irons that are transformed in this manner are referred to as austempered ductile irons. Austempering generates a range of structures, depending on the time of transformation and the

temperature of the transformation bath. The properties are characterized by very high strength, some ductility and toughness, and often an ability to work harden, giving appreciably higher wear resistance than that of other ductile irons. The properties depend principally on austempering temperature and time, and typical austempering treatment fall into two categories:

- Heat to 875 to 925 °C (1605 to 1695 °F), hold for 2 to 4 h, quench into a salt bath at 400 to 450 °C (750 to 840 °F), hold for 1 to 6 h, and cool to room temperature
- The same as above but hold for 1 to 6 h at 235 to 350 °C (455 to 660 °F)

The first treatment listed above would yield high ductility and high strength with medium hardness but a very good ability to work harden. The second treatment would yield very high strength with some ductility and a fairly high hardness. Austempering is successful only if the quench avoids the formation of pearlite. This may require the presence of alloying elements in sections greater than about 15 mm (0.6 in.). Typical alloys are nickel, copper, and molybdenum. Manganese is generally not recommended, because it creates segregation, which can lead to failure to achieve the optimum combination of properties. Maximum wear resistance and work hardening occur when there is a high amount of residual austenite. Residual austenite results from the use of short austempering times and incomplete transformation to bainite and is favored by higher alloying element contents and especially by the relatively high silicon content of ductile iron. Figure 23 shows the microstructure of an iron austempered at 375 °C (705 °F) containing about 15% austenite.

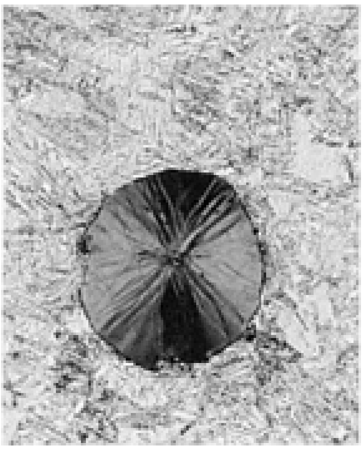

Fig. 23 Microstructure of austempered iron showing matrix of upper bainite and retained austenite. Compare with Fig. 20 and 22. Etched in picral. 500×

Useful information on austempered ductile irons is available in Ref 15 and 16. Figure 24 illustrates the influence of austempering temperature on the properties of an unalloyed ductile iron in section size of about 25 mm (1 in.).

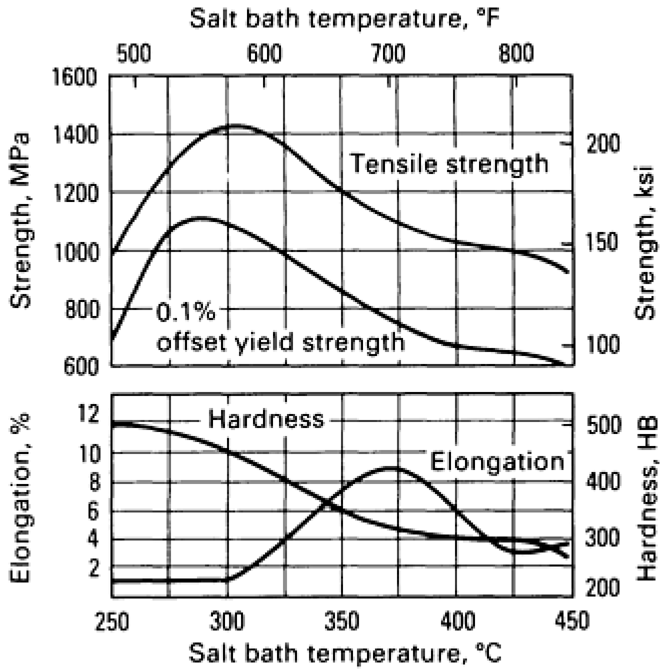

Fig. 24 Properties achieved by austempering an unalloyed iron for 7 h at different temperatures after austenitizing for 1 h at 900 °C (1650 °F)

The surface-hardening treatments that will be discussed in this section are flame and induction hardening, nitriding, and laser or plasma surface remelting.

Flame and induction hardening are usually employed to produce a hard surface layer on the surface of a casting. A flame or a specially shaped induction coil is passed over the surface of the casting at a rate that raises the temperature of the surface to 850 to 950 °C (1560 to 1740 °F) to a depth of about 2 to 4 mm (0.08 to 0.16 in.). The flame or induction source is followed by a water-quenching arrangement, and this produces a martensitic layer having a hardness of 600 to 700 HV.

The development of maximum hardness depends on the carbon content of the matrix, which transforms to austenite upon heating and to martensite during quenching. The time allowed does not normally permit adequate solution of carbon in initially ferritic matrix structures; therefore, it is important to use fully pearlitic grades of iron for flame or induction hardening. The depth of hardening achieved can be increased by alloying, as indicated below:

Composition	**Initial hardness, HRC**	**Surface hardness after treatment, HRC**	Depth of hardened layer	
			mm	in.
Fe-0.4Mn-0.07Ni-0.05Mo-0.1Cu	60	62	1.5	**0.06**

Flame and induction hardening are used to harden components requiring wear resistance, such as tappets, rolls, and gears, and may reduce the amount of wear by a factor of five or six.

Nitriding is a case-hardening process that involves the diffusion of nitrogen into the surface at a temperature of about 550 to 600 °C (1020 to 1110 °F). Most commonly, the source of nitrogen is ammonia, and the process produces a surface layer about 0.1 mm (0.004 in.) deep with a surface hardness approaching 1100 HV. The surface layer is usually white and featureless in an etched microstructure, but nitride needles can be found just below it. Alloying elements can be used to increase case hardness, and 0.5 to 1% of aluminum, nickel, and molybdenum have been reported to achieve useful results. Nitrided cases provide, in addition to very high hardness, increased wear resistance and antiscuffing properties, improved fatigue life, and improved corrosion resistance. Typical applications are for cylinder liners, bearing pins, and small shafts.

Nitriding can also be carried out in liquid salt baths based on cyanide salts. Such processes have lower temperatures of treatment, although case depth may be decreased. More recently, processes for nitriding in a plasma have been developed and applied to ductile iron with success, but the process may be more restricted because of the special equipment and cost likely to be involved.

Remelt Hardening. With the very high local heating achievable with plasma torches or lasers, it is possible to produce a very small melted area on the surface of a ductile iron component. This area then rapidly resolidifies because of the self-quenching effect of the casting mass. The remelted and resolidified region has a structure of white iron that is substantially graphite free and therefore has high hardness and wear resistance. The area that is remelted by a 2 kW laser is very small, typically 1.5 mm (0.06 in.) in diameter, 0.5 to 2 mm (0.02 to 0.08 in.) deep, and having a hardness of about 900 HV without cracking. By traversing the casting surface, the area hardened by this method can be of useful size and is likely to find application in tappets, cams, and other small components subjected to sliding wear. Figure 25 shows the microstructure of a pearlitic iron traversed by a 1.5 kW laser at 456 mm/s (18.25 in./s).

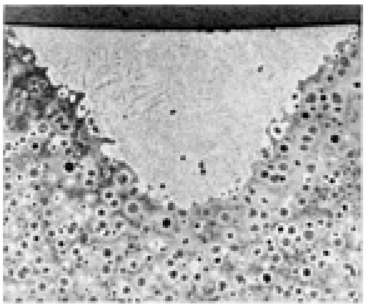

Fig. 25 Remelt-hardened and transition zones in a pearlitic iron after treatment with a 1.6 kW, 1.5 mm (0.06 in.) diam laser beam at 4.56 mm/s (0.18 in./s). Etched in picral. 50×

Mechanical Properties

Tensile, Compressive, and Torsional Properties. Tensile properties are given in Table 2 and Fig. 10 and 11 in relation to standard specifications, which refer only to the minimum values of strength and ductility and mean hardness ranges to be expected. Higher strengths and greater elongations will generally be expected in commercial castings of good graphite structure. The ranges of values to be expected from these properties in commercial irons and the applicable multiplying factors are discussed in Ref 9. These factors can be applied to any grades in any national specifications.

Tables 5 and 6 summarize several measurements of the major mechanical and physical properties of irons conforming to British specifications, most grades of which are the same as those of the ISO specifications. These are typical values for unalloyed irons. Other typical tensile, compressive, and torsional data are reported in the article "Ductile Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

Compressive strength is higher than tensile strength, and in Table 5 the 0.2% proof strengths in compression reported are generally approximately 1.05 times the 0.2% proof strength in tension, although values have been reported that range up to 1.2 times greater. Similar ratios have been reported for 0.1% and 0.5% proof strengths.

Shear strengths have been reported at around 0.9 times the values of tensile strength. Few data are available, and it is difficult to make accurate measurements on ductile materials because of bending during testing.

Modulus of elasticity in both tension and compression is generally in the range of 162 to 176 GPa, depending on the graphite content and the perfection of the graphite structure. It is, in general, equal in tension and compression.

Poisson's ratio ν does not vary significantly from 0.275 for most ductile irons. Modulus of rigidity G is related to ν and to modulus of elasticity E by the formula $E = 2G(1 + \nu)$. A typical value of G is about $0.39E$, and values of 62 to 68.6 GPa (23.5×10^3 to 25.5×10^3 ksi) have been reported.

All ductile irons deform considerably under torsional shear stresses, and it is difficult to obtain satisfactory test data to failure. It is estimated that torsional strength is about 0.9 times the tensile strength and that values measured for limit of proportionality and proof strength in torsion are generally between 0.7 and 0.775 times the corresponding values in tension.

A damping capacity of ductile iron greater than 90% nodularity exceeds that of steels by a factor of six or seven. It is, however, much less than that of flake graphite irons by a factor of about ten. Values have been reported from about 6.1 to 8.3×10^{-4} (measured by resonant frequency as a decay of vibration) for irons with more than 90% nodularity. The value is very sensitive to the graphite structure and falls markedly if a small proportion of flake graphite is present.

Impact Properties. The energy needed to cause fracture in an impact test is generally measured in a Charpy test using a V-notch specimen 10 mm (0.4 in.) square in cross section. Earlier work undertaken to compare variables was carried out on unnotched specimens that had impact energies in the ductile condition some six times those of unnotched specimens.

The article "Ductile Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook* reports the effects of a number of variables on impact energy, and much of the data are summarized in Fig. 18, which shows how changing from a fully pearlitic to a fully ferritic matrix structure lowers the ductile-to-brittle transition temperature and raises the maximum impact energy in the ductile condition. Decreasing the silicon content also lowers transition temperature and raises maximum impact energy in the fully ferritic annealed condition by an important amount, and for optimum impact properties, silicon contents below 2.5% and preferably below 2%, are desirable. Phosphorus also has a powerful embrittling effect in the impact test, and for optimum properties, a value well below 0.1%, and preferably below 0.05%, is desirable. In the ferritic annealed condition, optimum impact properties are obtained by a two-stage anneal involving austenitization and then subcritical graphitization. By combining all of these variables and maintaining all other alloying and trace elements at low levels, it is possible to obtain impact transition temperature below -25 °C (-13 °F), which is superior to that of most steels and is critical in determining if a component will fail in a ductile manner at low temperature. The maximum impact energy in the ductile range in ferritic irons is generally 12 to 20 J (8.9 to 14.8 ft · lbf).

The effects of various heat treatments have been compared with regard to the as-cast condition on a number of ductile irons (Ref 17). More recent data on austempered ductile iron confirm that a very good combination of low transition temperature and high impact energy can be obtained in irons containing retained austenite (Ref 14, 15).

Fracture Toughness. Many figures have been reported for the stress intensity factor K_{Ic} obtained under plane-strain linear-elastic conditions. However, because of the ductility of ductile irons, most investigations of ferritic and pearlitic/ferritic irons have been conducted at subzero temperatures to obtain the necessary criteria of elastic behavior. Values ranging from 25 to 54 MPa$\sqrt{m}$ (23 to 49 ksi$\sqrt{in}$) have been reported with the higher values for ferritic irons. In general, the value of K_{Ic} has been observed to increase with testing temperature. Values of crack-opening displacement obtained from cast irons have also shown wide-ranging values increasing from 0.015 to about 0.2 mm (6×10^{-4} to 0.008 in.) upon passing from pearlitic to ferritic structure. More information on the fracture toughness testing of ductile iron is available in Ref 18.

Fatigue. In the unnotched condition, the fatigue limit for a ferritic iron is about 0.5 times the tensile strength obtained in a Wöhler reversed-bending test. The fatigue limit decreases with increasing hardness to about 0.4 times the tensile strength in hardened irons up to 740 MPa (107 ksi) and may be even lower in stronger irons. Ductile irons are notch sensitive, and in a Wöhler specimen 10.6 mm (0.42 in.) in diameter with a 45° notch of root radius measuring 0.25 mm (0.01 in.), the fatigue limit decreases to about 0.63 times the unnotched value for ferritic irons and 0.6 times the unnotched value for hardened-and-tempered irons.

The fatigue strength decreases as the cast section size is increased, as shown in Fig. 26 for both ferritic and pearlitic irons notched and unnotched. As the size of the component subjected to reversed-bending fatigue increases, there is a decrease in fatigue strength up to about 50 mm (2 in.) in diameter. This effect is not thought to occur in axial fatigue in tension/compression.

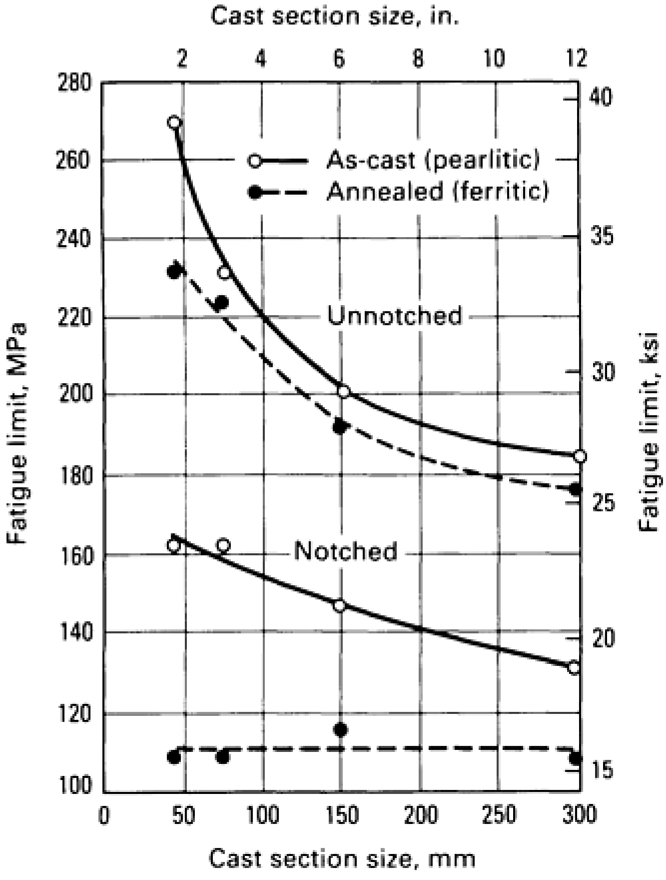

Fig. 26 Effect of cast section size on the fatigue properties of ductile irons

Fatigue test results generally refer to machined and polished surfaces. Surfaces of poorer quality and as-cast surfaces show lower values of fatigue strength, and the presence of minor surface defects has an even more detrimental influence on fatigue strength. Some improvement in the fatigue life of the cast surface is obtained by shotpeening. Because of the notch sensitivity of ductile iron, fatigue strength is reduced if modularity decreases.

Corrosion Fatigue (Ref 19). The fatigue strengths of pearlitic and ferritic ductile irons are reduced in a water environment by some 15 to 19% as a result of corrosion. In a saltwater environment, this reduction may increase to 68 to 83%. Corrosion inhibitors generally do not prevent corrosion fatigue; but alkaline sodium nitrite solutions can reduce it, and a solution of 0.05% of sodium chromate protects against corrosion fatigue in a water spray environment.

Mechanical Properties at Elevated Temperatures. The short-term tensile strength of unalloyed pearlitic ductile irons decreases more or less continuously with increasing temperature and at 400 °C (750 °F) is about two-thirds the room-temperature strength. For ferritic irons, the decrease is less pronounced and at 400 °C (750 °F) the strength is about three-fourths the room-temperature value. Proof stress, however, for both ferritic and pearlitic irons is more or less maintained up to 350 to 400 °C (660 to 750 °F), above which it falls rapidly. The hot hardness of ductile iron is also maintained up to about 400 °C (750 °F), above which it falls rapidly.

For temperatures to 300 °C (570 °F), static design stress can, as at room temperature, be based on proof stress values obtained at room temperature. Design stresses are given in Table 7. At temperatures above 350 °C (660 °F), design stresses should be based on creep data.

The growth and oxidation for scaling of ductile iron at all temperatures are much less than for gray irons, and data have been obtained at 350 and 400 °C (660 and 750 °F) for times well in excess of 100,000 h. These data are given in Table 8.

Creep and stress rupture data have been obtained to support the use of pearlitic and ferritic ductile irons to 350, 375, and 400 °C (660, 705, and 750 °F). Table 9 lists the stresses needed to produce 0.1, 0.2, or 1% strain or rupture in 1000, 10,000, 30,000, and 100,000 (extrapolation) at 350 and 400 °C (660 and 750 °F).

Table 9 Stress required to produce specific creep strain or rupture in ductile iron

Type of ductile iron	**Creep strain or rupture, %**	Stress required at indicated time and temperature, MPa (ksi)							
		350 °C (660 °F)				400 °C (750 °F)

(a) Extrapolated from stress/log time curve

A small addition of molybdenum considerably improves the short-term hot strength and creep properties of both ferritic and pearlitic irons. The improvement brought about by molybdenum enables useful creep and rupture properties to be extended to temperatures of 450 °C (840 °F).

Low-Temperature Tensile Properties (Ref 20). As for impact properties, there is also a transition temperature range below which the tensile elongation decreases. Proof stress increases continuously with decreasing temperature, but tensile strength also exhibits a transition. Above the transition temperature range, tensile strength tends to remain constant or increases with decreasing temperature, but once the transition temperature is passed, tensile strength decreases with further lowering of temperature. In ferritic irons in the ductile range, because there is some reduction in area, the true fracture stress is higher than that normally reported, and if this were to be taken into consideration, the transition in tensile strength and in elongation would be seen to occur over the same temperature range. As with impact properties, silicon and phosphorus increase the tensile transition temperature and reduce the maximum tensile strength in the ductile range.

Physical Properties

Data on the physical properties of ductile iron are less well established than mechanical properties and fewer figures are available than for mechanical properties. The following sections summarize the best available values.

Density decreases slightly with increasing graphite content and decreases slightly with increasing ferrite content. Typical values for ISO and British grades at 20 °C (68 °F) are:

Grade BS 2789:1973	370/17	420/12	500/7	600/3	**700/2**
Density, g/cm^3	**7.10**	**7.10**	**7.10-7.17**	**7.17-7.20**	**7.20**

Coefficient of Thermal Expansion. Typical values are given in Table 6. The expansion characteristics of cast irons are complex because of the transformations that take place involving the solution and precipitation of graphite, the

graphitization of pearlite, and austenite formation above 700 °C (1290 °F). Upon repeated heating and cooling above about 700 °C (1290 °F), irreversible expansion occurs because of growth, and in air, additional expansion may occur because of oxidation. Any carbides present in the as-cast structure may be graphitized, giving rise to further nonreversible expansion.

Other Physical Properties. Typical values of electrical, magnetic, and thermal properties for ISO or BS grades of ductile iron are given in Table 6.

Corrosion Resistance. In many applications, the corrosion resistance of ductile iron is similar to that of gray iron and is often superior to that of steels. Ductile iron pipes normally perform well in soils and can be further protected by the use of sacrificial anodes, zinc coating, plastic sleeving, and in some cases polyurethane coating. A useful summary of published data on corrosion rates in various environments is given in Ref 21, and information on the corrosion of cast irons is also available in the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Nondestructive Evaluation of Ductile Iron Castings

Routine nondestructive tests can be applied to ductile iron castings to confirm their soundness and integrity, to ensure freedom from physical defects, and to confirm graphite structure and properties dependent on graphite structure.

Soundness and Integrity. Cracks and fine tears that break the surface of the casting but are difficult to detect visually can be revealed by the use of dye penetrants or by magnetic-particle inspection. Modern techniques of magnetizing the casting, followed by application of fluorescent magnetic inks, are very effective and widely used.

Methods of sonic testing that involve vibrating the casting and noting electronically the rate of decay of resonant frequency or damping behavior are also used to detect cracked or flawed castings. Internal unsoundness, when not immediately subsurface, can be detected by ultrasonic inspection. This can be detected by failure to observe a back-wall echo when using reflected radiation or by a weakening of the signal in the transmission through the casting. Coupling of the probes and interpretation of the results involve operator skill, but methods are available that involve partial or total immersion of the casting in a liquid, automatic or semiautomatic handling of the probes, and computer signal processing to ensure more reliable and consistent interpretation of results. Problems arise in detecting very-near-surface defects and when examining thin castings, but the use of angled probes and shear wave techniques has yielded good results.

The soundness of the ductile iron can also be assessed by x-ray or γ-ray examination. The presence of graphite, especially in heavy sections, makes the method more difficult to evaluate than for steels, but the use of image intensification by electronic means offers considerable promise, especially for sections up to 50 mm (2 in.) thick.

Confirmation of Graphite Structure (Ref 11). Both the velocity of ultrasonic transmission and the resonant frequency of a casting can be related to the modulus of elasticity. In cast iron, the change from flake graphite to nodular graphite is related to an increase in both modulus of elasticity and strength; therefore, ultrasonic velocity or resonant frequency measurement can be employed as a guide to nodularity, strength, and other related properties. Because microscopic estimation of nodularity is a subjective measurement, these other nondestructive methods of examination may provide a better guide to some properties provided the matrix remains constant (Ref 10). Figure 27 illustrates how ultrasonic velocity may vary with graphite nodularity.

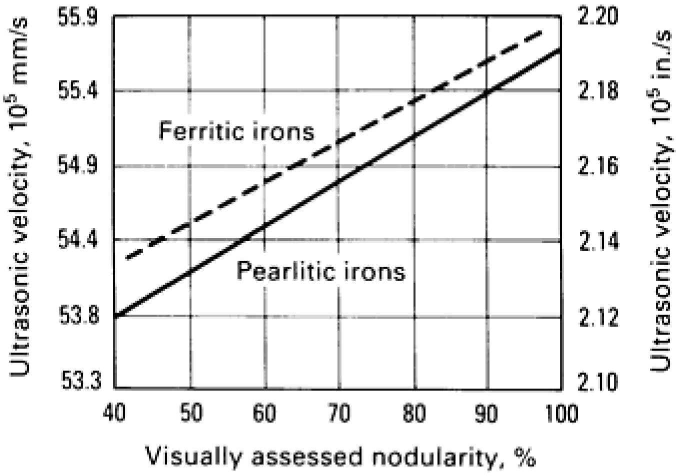

Fig. 27 Ultrasonic velocity versus visually assessed nodularity in ductile iron castings. Source: Ref 10.

Ultrasonic transmission measurement can be done with two probes on either side of the casting and provides a guide to the local properties. It must be coupled with a thickness measurement, and automatic equipment is commonly used, often involving immersion of the casting in a tank of fluid. The calculation does not require calibration of the castings. Simple caliper devices have also been used for examining castings and simultaneously measuring their thickness to provide a calculated value of ultrasonic velocity and a guarantee of nodularity (Ref 22).

Sonic testing involves measurement of the resonant frequency of the casting or rate of decay of resonance of a casting that has first been excited by a mechanical or electrical means. This method evaluates the graphite structure of the entire casting and requires calibration of the castings against standard castings of known structure. It is also necessary to maintain casting dimensions within a well-controlled narrow range. Some foundries use sonic testing as a routine method of final inspection and structure guarantee (Ref 23).

The relationship between nodularity, resonant frequency, or ultrasonic transmission velocity and properties has been documented for tensile strength, proof strength, fatigue, and impact strength. Examples are shown in Fig. 28 and 29.

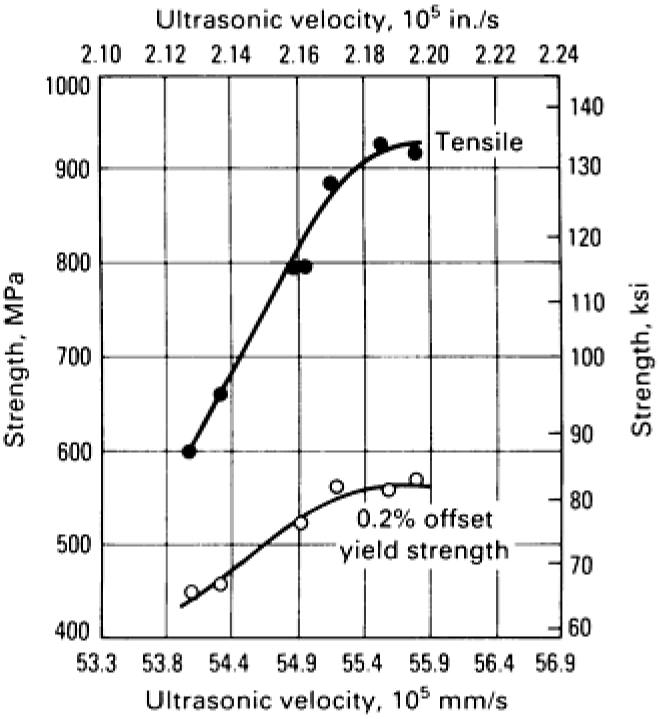

Fig. 28 Ultrasonic velocity versus strength in ductile iron castings. Source: Ref 10

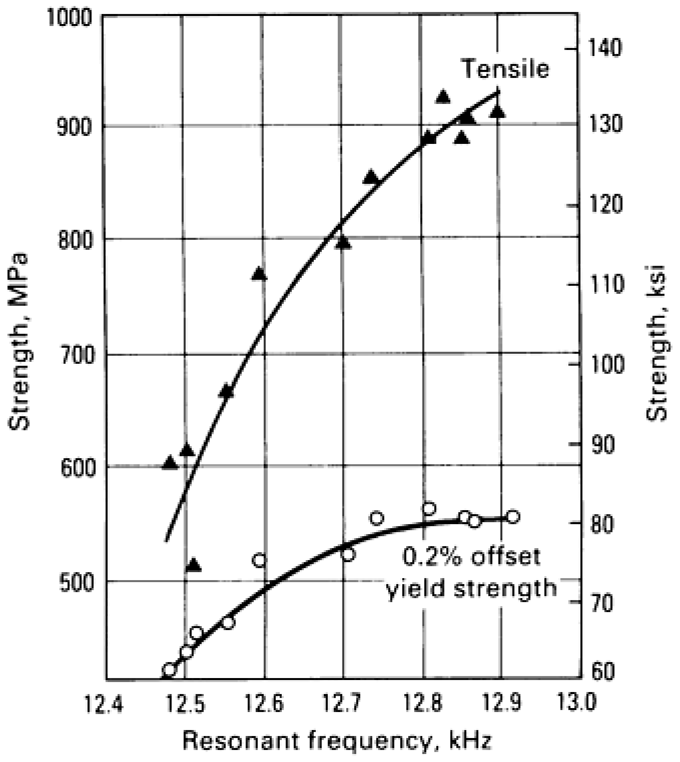

Fig. 29 Strength versus resonant frequency in nondestructive evaluation of ductile iron test bars. Source: Ref 11

The presence of carbides can also be detected with sonic or ultrasonic measurements provided enough carbides are present to reduce the graphite sufficiently to affect modulus of elasticity. Discrimination between the effects of graphite variation and carbide amount would require an additional test, such as hardness, to be carried out.

Properties Partially Dependent on Graphite Structure (Ref 23). When the matrix structure of ductile iron varies, this variation cannot be detected as easily as variations in graphite structure, and sonic and ultrasonic readings may not be able to reflect variations in mechanical properties. A second measurement, such as a hardness measurement, is then needed to detect matrix variations in the same way as would be necessary to confirm the presence of carbides.

Eddy current or coercive force measurements can be used to detect many changes in casting structure and properties; but the indications from such measurements are difficult to interpret, and the test is difficult to apply to many castings unless they are quite small and may be passed through a coil 100 to 200 mm (4 to 8 in.) in diameter. Eddy current indications are, however, useful for evaluating pearlite and carbide in the iron matrix. Multifrequency eddy current testing uses probes that do not require the casting to pass through a coil, it is less sensitive to casting size, and it allows automatic measurements and calculations to be made; but the results remain difficult to interpret with reliability in all cases. It may, however, be a very good way to detect chill and hard edges on castings of reproducible dimensions.

Trends in Nondestructive Examination (Ref 22). There is a growing trend toward combining nondestructive testing with quality assurance and statistical process control (SPC) procedures. For this reason, progress is rapid in the automatic and semiautomatic applications of tests to reduce operator fatigue and the computer interpretation of results to eliminate human error. Results are increasingly being read directly into computers provided with programs to report and record not only the results but also their statistical interpretation and the information needed to correct any departures from specification. Such developments are of particular importance when ductile iron castings are treated individually with magnesium in the mold because, even with very well-controlled reproducibility of treatment, a higher proportion of castings may require examination to provide confidence in the uniformity of the product.

Joining of Ductile Iron Castings

Welding. Ductile iron castings can be joined to each other and to steel components by welding, and many examples have been published. Successful welding depends on using a technique such as dip-transfer MIG welding with electrodes usually containing a high proportion (40 to 60%) of nickel together with iron and sometimes manganese. By restricting the heat input, the heat-affected zone, which contains carbides and martensite, is kept to a minimum, and the strength and proof stress of the joint will approach that of the parent iron (Table 10). However, it is unlikely that the ductility of the joint will match that of the ductile iron, and good practice will involve joint designs in which bending stresses and stress concentrations are minimized. Automated welding processes are likely to achieve more consistent quality of joints than hand welding. In some cases, it may be feasible to anneal the assembly after welding, and pre- and postheating are recommended for obtaining improved joint properties (Ref 25).

Brazing. Strong joints between ductile iron components can be obtained by brazing with copper-, silver-, and nickel-base brazing alloys. By using capillary joints and designs to promote shear stressing rather than tension or bending, it is

possible to obtain joint properties of strengths similar to those of the parent iron at costs comparable with those of welding, but skilled operation is desirable (Ref 24).

Adhesive Bonding. Ductile iron castings can be adhesively bonded if the joints are carefully designed to employ shear loading and freedom from bubbles in the adhesive.

Machinability. Unalloyed ductile iron is a readily machinable material, and the cost of machining components will often be less than that for cast low-carbon steels. Ductile iron is somewhat less machinable than gray iron, although at a similar hardness relatively little difference is sometimes reported. Many data have been published for machining under a wide range of conditions (see the article "Ductile Iron" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook* and Ref 26, 27, 28). In general, machinability improves upon moving from fully pearlitic irons of higher hardness to fully ferritic irons of lower hardness.

Apart from variations in machinability, tool life, machining time, and cutting speeds with cutting and tool parameters, the surface condition and depth of initial cut can have a major influence on machinability. The as-cast surface of ductile iron may be hard and abrasive because of a thin graphite-free layer and because of oxide particles. It is important that the initial cut be deep enough to remove this layer completely to avoid rapid blunting of the tool, and an initial depth of at least 2 mm (0.08 in.) is recommended when turning.

Applications of Ductile Iron Castings

Ductile iron is finding increasing application for a very wide range of components in which it can replace gray iron because of its superior properties. Examples of automotive applications are crankshafts, exhaust manifolds, piston rings, and cylinder liners. The use of ductile iron in these applications provides increased strength and permits weight savings. Gray iron spun pipes have been largely superseded by ductile iron pipes having a high degree of ductility and thinner walls, and many fittings are also made of this material. In agricultural and earth-moving applications, brackets, couplings, rollers, hydraulic valves, sprocket wheels, and track components of improved strength and toughness are made of ductile iron. General engineering applications include hydraulic cylinders, mandrels, machine frames, switch gear, rolling mill rolls, tunnel segments, low-cost rolls, bar stock, rubber molds, street furniture such as covers and frames, and railway rail-clip supports. For these applications, ductile iron has provided increased performance or weight savings.

Ductile iron can be used to replace many more expensive components previously made in wrought or cast steels or other metals because of its higher strength-to-weight ratio, lower damping capacity, better machinability, and better castability. Examples include brake calipers and cylinders, steering gear and other safety-critical components, turbochargers, connecting rods, gear boxes and gears, valve bodies, pump components, bulldozer parts, nuclear fuel containers and transporters, bridge rollers and railing supports, coal and mineral crushing components, crane wheels, oil well equipment, mining roof supports, overhead switchgear, shafts and spindles, railway axle boxes and fittings for rolling stock, and low-pressure turbine casings.

Ductile iron gears have performed well in noncritical engineering and agricultural applications, but austempered ductile iron offers a combination of strength, fatigue properties, and wear resistance that makes it of great interest for heavy engineering and automotive gears--applications in which the use of austempered ductile iron is likely to increase. A number of well-established applications of ductile iron are listed in Ref 21. However, many new engineering components are likely to be amenable to design with ductile iron. Illustrations of these are described, and their advantages illustrated, in Ref 29.

Compacted Graphite Irons

D.M. Stefanescu, University of Alabama; R. Hummer and E. Nechtelberger, Austrian Foundry Research Institute

---

Introduction

COMPACTED (VERMICULAR) GRAPHITE (CG) IRONS have inadvertently been produced in the past as a result of insufficient magnesium or cerium levels in melts intended to produce spheroidal graphite iron; however, it has only been since 1965 that CG iron has occupied its place in the cast iron family as a material with distinct properties requiring distinct manufacturing technologies. The first patent was obtained by R.D. Schelleng (Ref 1). Since that time, an impressive number of publications have been written on this subject, as summarized by the review work in Ref 2 and 3.

As discussed in the article "Solidification of Eutectic Alloys: Cast Iron" in this Volume, the shape of compacted graphite is rather complex. An acceptable CG iron is one in which there is no flake graphite (FG) in the structure and for which the amount of spheroidal graphite (SG) is less than 20%; that is, 80% of all graphite is compacted (vermicular) (ASTM A 247, type IV). Typical CG iron microstructures are shown in Fig. 1. It can be seen that although the two-dimensional appearance of compacted graphite is that of flakes with a length:thickness ratio of 2:10 (Fig. 1a), the three-dimensional

SEM structures (Fig. 1b and c) show that graphite does not appear in flakes but rather in clusters interconnected within the eutectic cell.

Production Techniques

Chemical Composition. The characteristic properties of CG irons have been demonstrated over a rather wide range of carbon equivalent (CE) values, extending from hypoeutectic (CE = 3.7) to hypereutectic (CE = 4.7), with carbon contents

of 3.1 to 4.0% and silicon in amounts of 1.7 to 3.0% (Ref 4, 5, 6). At constant silicon levels, a lower CE slightly increases the chilling tendency and results in lower nodularity. At constant CE, higher silicon increases nodularity (Ref 7). The optimum carbon and silicon contents can be selected from Fig. 2.

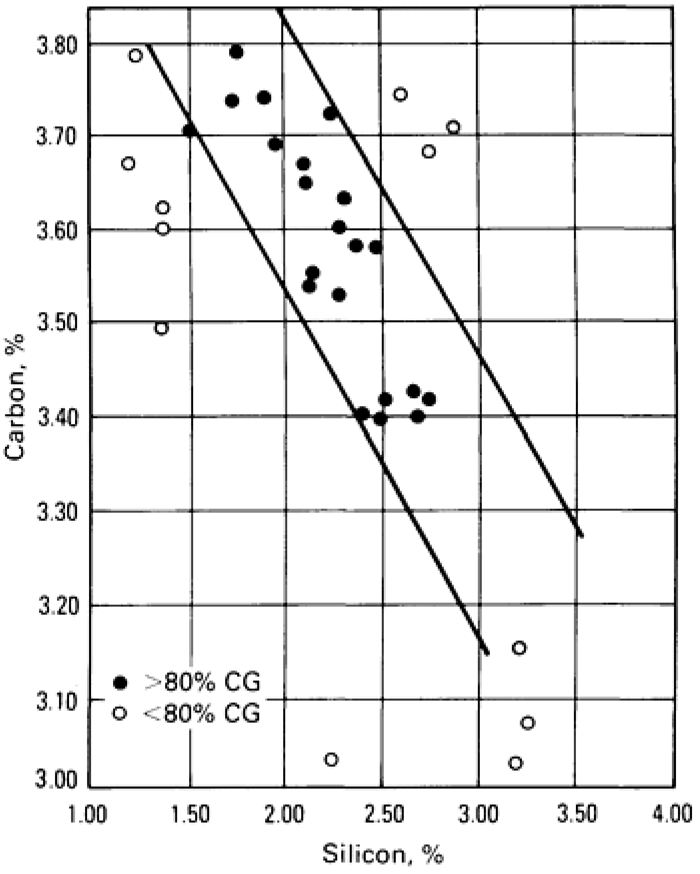

Fig. 2 Range of optimum carbon and silicon contents for CG iron. Source: Ref 7

The optimum CE must be selected as a function of section size. For a given section size, too high a CE will result in graphite flotation, as in the case of spheroidal graphite cast iron, while too low a CE may result in increased chilling tendency. For wall thickness ranging from 10 to 40 mm (0.4 to 1.6 in.), eutectic composition (CE = 4.3%) is recommended in order to obtain optimum casting properties. Manganese content can vary between 0.1 and 0.6%, while phosphorus content should be less than 0.06% in order to take advantage of the ductility of this material.

Although CG iron has been produced from base irons having sulfur contents as high as 0.07 to 0.12% (Ref 8), it is probably more economical to desulfurize the iron to a level of 0.01 to 0.025% before liquid treatment. The higher the sulfur content, the more alloy is required for melt treatment. Also, the risk of missing the composition window for CG iron is increased, because the residual treatment elements must be balanced with the residual sulfur. Typical residual sulfur levels after treatment are 0.01 to 0.02% (Ref 6).

In order to ensure the compacted (vermicular) graphite shape, it is necessary to use some treatment elements, just as in the case of SG iron. These elements include magnesium, rare earths (cerium, lanthanum, and so on), calcium, titanium, and aluminum. Their influence and use will be discussed in the section "Melt Treatment" in this article.

Alloying elements, such as copper, tin, molybdenum, and even aluminum can be used to change the as-cast matrix from ferrite to pearlite. Typical ranges are 0.48% Cu or 0.033% Sn (Ref 9), 0.5 to 1% Mo (Ref 10), and up to 4.55% Al (Ref 11, 12). Regardless of the alloying elements used, the high ferritizing tendency of CG iron should be taken into account. Figure 3 shows that even strong pearlite promoters such as copper or tin show reduced effectiveness in CG iron (Ref 12). The same is true when treating with cerium-mischmetal. A fully pearlitic structure could not be obtained even at 1.7% Cu when using high-purity charge materials. Tin, however, is effective. As shown in Fig. 4, 95% pearlite was obtained with 0.13% Sn. To produce a pearlitic matrix, therefore, it may be necessary to add higher-than-usual levels of alloying elements or to make multiple additions of two or three elements.

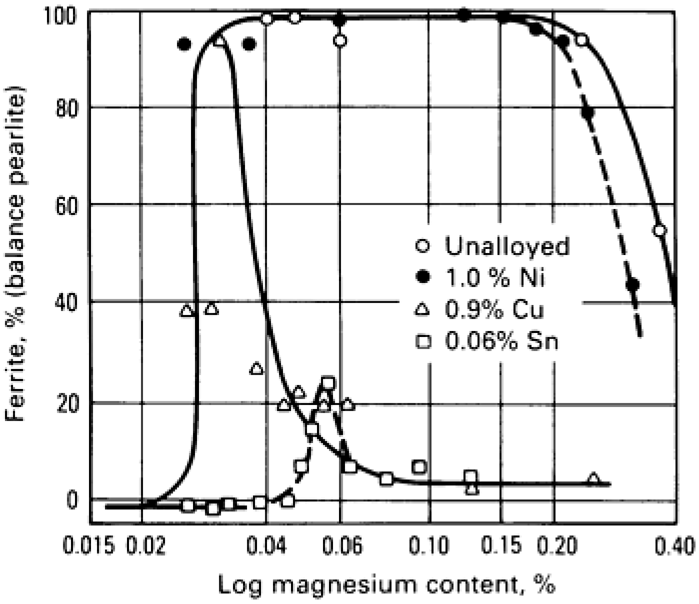

Fig. 3 The effect of copper, nickel, and tin on the type of matrix in the composition range between CG and FG iron of 25 mm (1 in.) wall thickness. Source: Ref 43

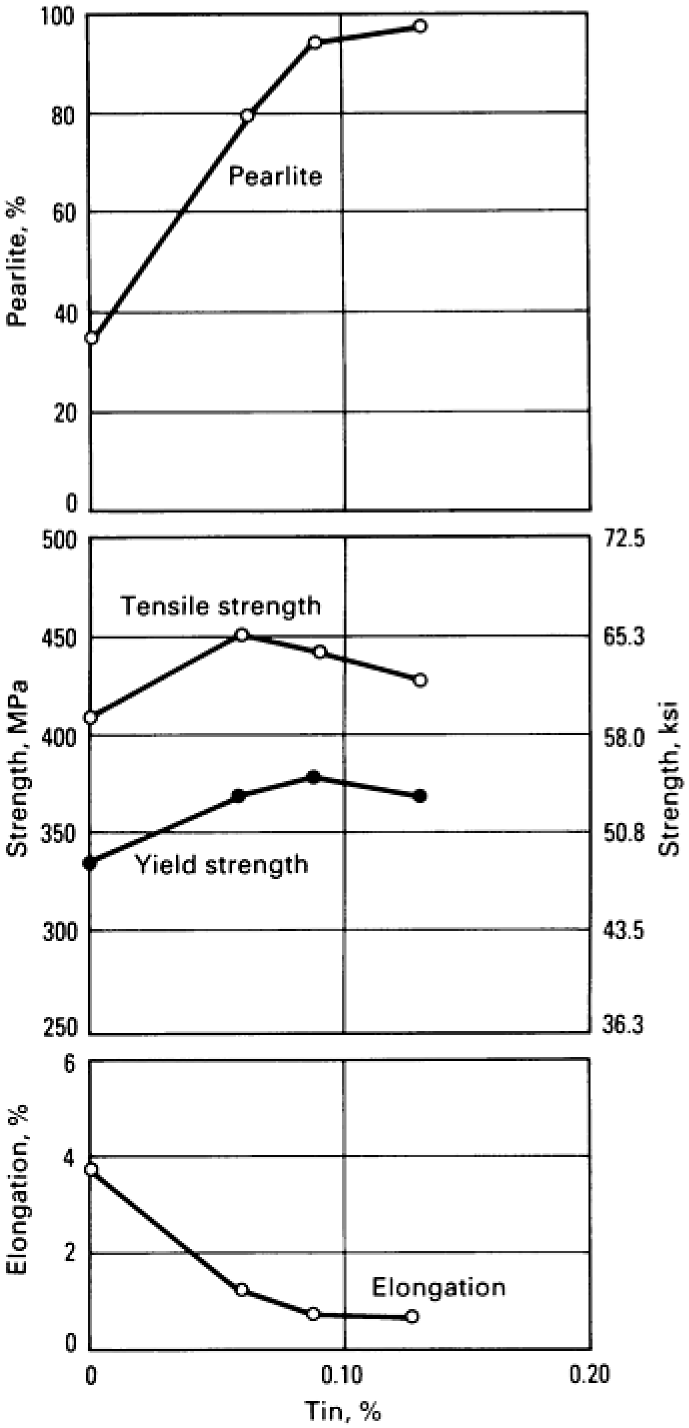

Fig. 4 The effect of tin on pearlite content and tensile properties of as-cast CG iron 25 mm (1 in.) thick. Source: Ref 43

Melting. The melting aggregates to produce CG iron are in principle the same as those used for SG iron. Induction furnaces, cupolas, and arc furnaces have been reported as being adequate for melting. Similar requirements of raw materials, superheating, and desulfurization before melt treatment apply. If a ferritic structure in the as-cast condition is desired, a pure pig iron with low manganese, phosphorus, and sulfur contents is recommended. If some pearlite is acceptable, steel scrap can be used.

Melt Treatment. The most important methods used for manufacturing CG iron can be classified as:

- Controlled undertreatment with magnesium-containing alloys
- Treatment with alloys containing both compactizing (magnesium, rare earths, and calcium) and anticompactizing (titanium and aluminum) elements
- Treatment with rare earth base alloy or magnesium-rare earth alloys
- Treatment of a base iron containing rather high amounts of anticompactizing elements (sulfur and aluminum) with alloys containing compactizing elements (magnesium and cerium)

Compositions of typical treatment alloys used in the production of iron are listed in Table 1.

Table 1 Nominal compositions of typical treatment alloys for CG iron

(a) TRE, total rare earth elements

As shown in Fig. 5, CG can be obtained when treating an SG-type base iron with magnesium-iron-silicon alloy (for example, alloy 1 in Table 1), when residual magnesium is controlled in the range of 0.013 to 0.022% (Ref 13). This type of control is difficult to achieve when ladle treatment is used; overtreatment (resulting in too much SG) or undertreatment (resulting in flake graphite) can occur. Nevertheless, instances in which this process is applied are reported in Ref 3.

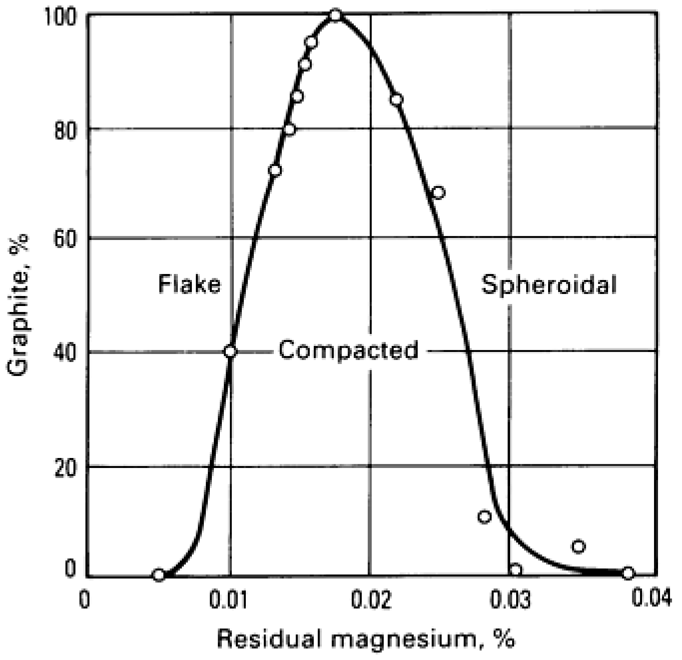

Fig. 5 The influence of residual magnesium on graphite shape. Source: Ref 3, 13

Better control of residual magnesium can be achieved if the in-mold process is used. Indeed, good quality CG iron has been produced using alloys similar to alloy 1 (Table 1) from iron with 0.008 to 0.017% base sulfur. Residual Mg was 0.015 to 0.025% in section sizes of 8 to 63 mm (0.3 to 2.5 in.) (Ref 9). As the base sulfur content increases, higher residual magnesium is required.

The treatment of iron with alloys containing compactizing elements balanced by anticompactizing elements has much wider industrial application. A treatment alloy containing about 5% Mg and 0.3% Ce balanced by about 9% Ti (for example, alloy 2 in Table 1) is used in order to obtain 0.015 to 0.035% residual Mg, 0.06 to 0.13% residual Ti, and low levels of cerium in the final cast iron (Ref 4). As shown in Fig. 6, using a magnesium-titanium combination rather than magnesium alone dramatically increases the range of residual magnesium over which CG can be obtained.

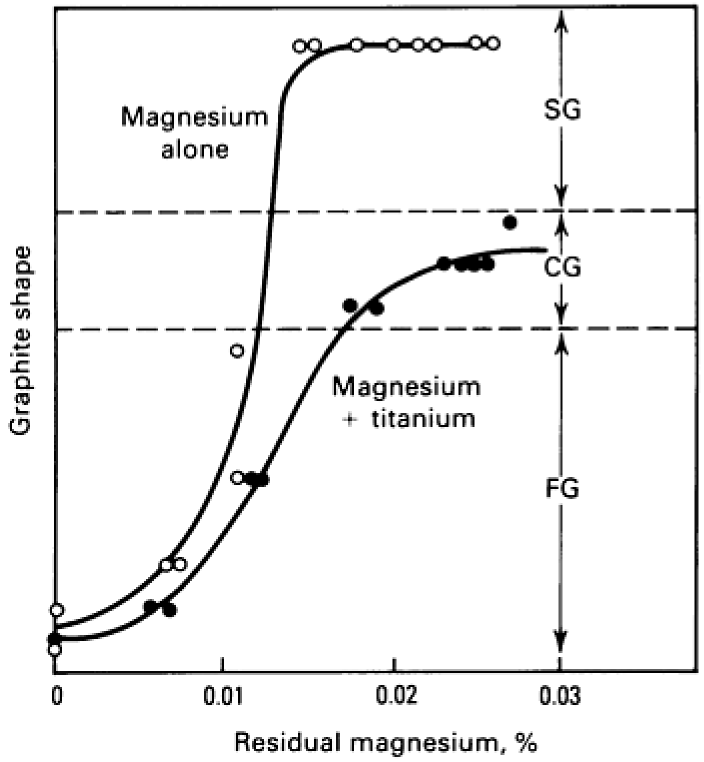

Fig. 6 Range of residual magnesium that produces compacted graphite. Source: Ref 5

This treatment alloy was later improved by the inclusion of 4 to 5.5% Ca (alloy 3 in Table 1) to extend the working range of residual magnesium and the tolerable range of base sulfur (Ref 14). A wide range of carbon and silicon contents (3.15 to 4% and 1.7 to 3%, respectively) can be used to produce CG iron in section thicknesses of 12 to 65 mm ($\frac{1}{2}$ to $2\frac{1}{2}$ in.). Base iron sulfur contents can vary from 0.02 to 0.04%, resulting in final sulfur levels of 0.01 to 0.02% (Ref 6). Excessive sulfur has been shown to promote a gray rim (flake graphite), while too low a sulfur content promotes higher nodularity. The amount of magnesium-titanium alloy used for CG treatment is not critical, but depends on the base sulfur content. As for SG iron, a ladle postinoculation is indicated. It appears important to keep a treatment of about 1400 °C (2550 °F) because lower temperatures result in higher modularity (Ref 5). The main disadvantage of this method seems to be titanium contamination (0.1 to 0.15% Ti) of returns and castings.

Alloy 4 in Table 1 can also be included in the category of alloys relying on a balance of compactizing and anticompactizing elements. Additions of 0.2% of this alloy resulted in CG structures in bar castings ranging in thickness from 25 to 127 mm (1 to 5 in.) (Ref 15). A rather high chilling tendency was observed.

The treatment of liquid iron with rare earth alloys was actually one of the first processes to gain industrial application.Cerium-mischmetal (for example, alloy 5 in Table 1) (Ref 16, 17) is used for production of medium- and heavy-section CG iron castings. Residual cerium contents of 0.013 to 0.075% are required, depending on base sulfur. The dependency of alloy addition on base sulfur level is shown in Fig. 7.

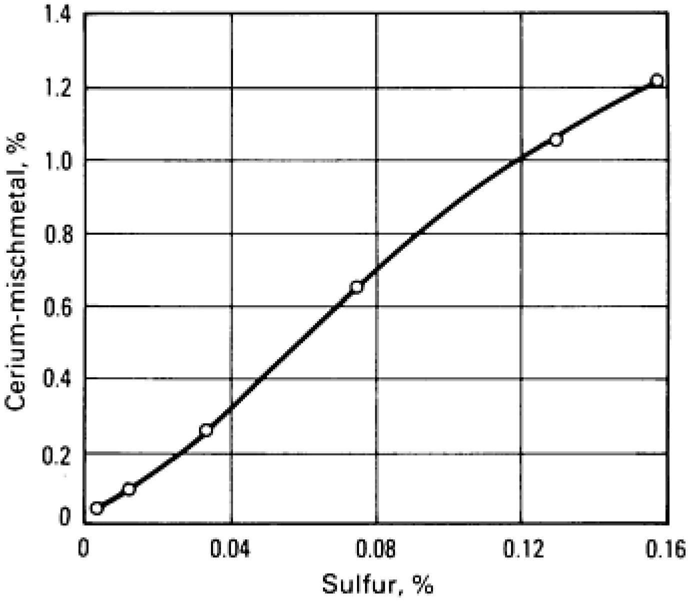

Fig. 7 The correlation between base sulfur content and amount of cerium-mischmetal treatment alloy required to produce compacted graphite. Source: Ref 17

Although rare earth treatment offers a number of advantages over magnesium treatment, including lower fading time and no smoke during the reaction time, the high chilling tendency in thin sections seems to be its biggest drawback. Enhanced postinoculation with ferrosilicon does not seem to solve the problem entirely, because it results in increased modularity.

Rare earth alloys containing a higher lanthanum/rare earth ratio than typical mischmetal have been suggested to alleviate the chilling tendency (alloys 6 and 7 in Table 1) (Ref 18). As a general observation, it should be noted that postinoculation is required when silicon-free alloys are used.

Good results in foundry practice have also been claimed when using a cerium-calcium-silicon alloy of undisclosed composition (Ref 19). With low base sulfur, good CG structure could be achieved when at least 0.016% Ce and 0.24% Ca were added to the melt. When base sulfur was raised to 0.059%, the cerium and calcium contents had to be increased to 0.091% and 0.53%, respectively. Fading times of the order of 22 min for a 500 kg (1100 lb) ladle, as well as good response to the recycling of returns were also claimed as advantages of this process.

Another way to avoid the chilling problems associated with mischmetal treatment is to use a magnesium-rare earth-ferrosilicon-type alloy such as alloy 8 or 9 in Table 1. When these alloys were used in conjunction with the in-mold process (Ref 20), a residual magnesium, cerium, and lanthanum content of 0.018 to 0.028% was required for CG structure when the base sulfur was 0.016%, which correlates with data given in Ref 9.

Finally, another group of treatment methods addresses the problem of high levels of anticompactizing elements such as sulfur or aluminum in the base iron. A special alloy with undisclosed composition, containing high levels of magnesium and cerium and conventional quantities of aluminum and calcium is claimed to allow CG iron production at virtually all sulfur levels.

Regardless of the treatment alloy used, for a specific alloy addition and base sulfur content there is an optimum range of treatment temperatures. For example, for an iron with base sulfur of 0.12 to 0.13% and a treatment addition of 1.75% alloy, the treatment temperature must be between 1468 and 1510 °C (2675 and 2750 °F). Too low a temperature results in increased nodularity; an excessive temperature causes premature alloy dissolution, and the iron remains gray with FG.

Another approach to producing CG iron is to substitute aluminum for most of the silicon in the iron. This has the advantage of allowing the use of a magnesium-ferrosilicon alloy, because aluminum has an anticompactizing effect and can counterbalance the influence of magnesium. Thus, a correct balance between aluminum and magnesium should result in CG. This idea has been applied using both ladle and in-mold treatment (Ref 12). A 5% magnesium-ferrosilicon alloy with 0.3% Ce was used. Good CG structures with no chill on wedge tests were achieved for aluminum levels of 2.68 to 4.48% by using the trigger treatment method. A 1.4% addition of magnesium-ferrosilicon alloy resulted in residual magnesium of 0.016 to 0.028%, and less than 20% nodularity was achieved over this range. No postinoculation was used. It is interesting to note that holding times in excess of 30 min have proved to be acceptable even when the treated metal was held in the induction furnace. Excellent results were obtained when the in-mold process was used with a chamber area to result in 0.013 to 0.023% residual Mg and 0.022 to 0.032% residual Ce, for irons containing 1.62 to 4.43% Al.

Regarding postinoculation, it is generally accepted that CG iron exhibits a high chilling tendency, especially in sections thinner than 6 mm ($\frac{1}{4}$ in.). To counteract this negative effect, it is necessary to use either silicon in the treatment alloy or some type of postinoculation. Most of the time, 0.2 to 0.3% ferrosilicon containing 75% Si is used for postinoculation. Nevertheless, in thin sections of CG iron castings, it is difficult to counteract chilling effects properly by postinoculation, because increasing the amount of inoculant normally results in SG rather than in CG. It has been suggested that 0.1 to

0.2% Al (Ref 21) or a ferrosilicon-titanium-aluminum alloy of undisclosed composition (Ref 2, 22) can be used as postinoculants to decrease chill without increasing nodularity.

Process Control. Production of good quality CG iron requires careful control at every stage. The chemical composition must be kept within rather rigid limits, particularly in regard to sulfur content. Sulfur content must be determined with ±0.001% accuracy before melt treatment (Ref 3), because excess sulfur can result in undertreatment, while too low a sulfur content can produce iron with excessive nodularity. Infrared determination methods are recommended for sulfur. Carbide stabilizing elements must also be checked accurately, because they increase the already high chilling tendency of CG iron. For example, chromium should be kept under 0.01%.

A variety of methods can be used for the control of melt treatment. When cerium-containing treatment alloys are used, a classic wedge test approach is recommended (Ref 3). Wedge tests are poured before treatment, after treatment with mischmetal, and after postinoculation, with required fractures being dark gray, completely white, and light gray, respectively.

Cooling curve analysis is a good way to predict microstructure before pouring and thus allow corrections if necessary. Typical cooling curves for flake, compacted, and nodular graphite irons and for white iron are shown in Fig. 8. It can be seen from Fig. 8(a) that hypoeutectic CG iron has a temperature of eutectic undercoating (T_{EU}) lower than that of FG or SG iron, although its temperature of eutectic recalescence (T_{ER}) is between the other two. Nevertheless, depending on the level of postinoculation, it is sometimes possible for CG to have a higher T_{EU} or a lower T_{ER} than SG, although this is the exception rather than the rule. It is apparent that the easiest way to identify a good CG structure is based on the value of $\Delta T = T_{ER} - T_{EU}$. The value of ΔT should be in excess of 25 to 30 °C (77 to 86 °F) for rare earth-treated iron, or in excess of 10 °C (50 °F) for magnesium-treated irons (Ref 24). For hypereutectic composition (Fig. 8b), the undercooling can be higher for either SG or CG iron, so that simple cooling curve analysis cannot be used to differentiate between these two irons.

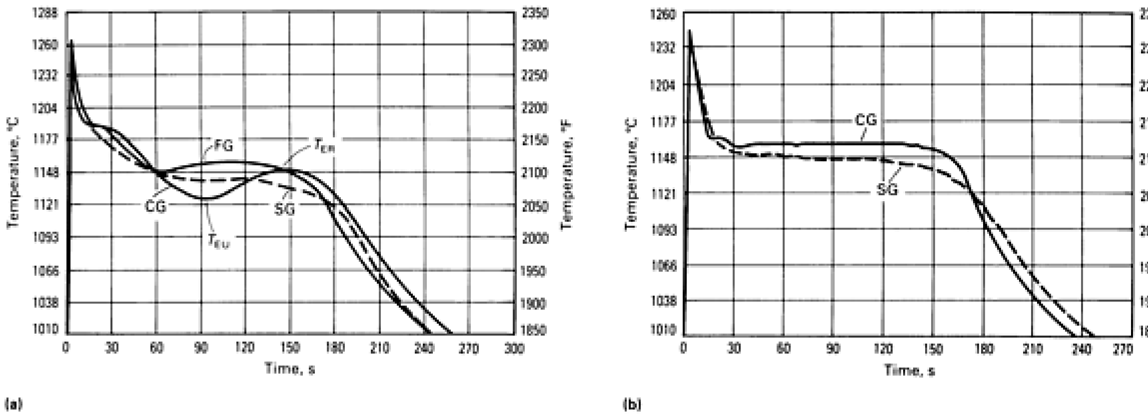

Fig. 8 Cooling curves. (a) For hypoeutectic irons. (b) For hypereutectic irons. T_{EU}, temperature of eutectic undercooling; T_{ER}, temperature of eutectic recalescence. Source: Ref 23

Improved microstructure predictions can be made by computer-aided differential thermal analysis (CADTA), which consists of numerical processing of cooling curve data. Based on first derivative curves obtained using CADTA, hypoeutectic CG differs from other irons by the fact that it has only one slope on the second part of the curve (after recalescence) while the other irons have two. For hypereutectic irons, the first derivative curve of CG iron exhibits two maxima compared with only one for SG iron.

When large quantities of compacted graphite iron are poured, it may be possible to run a metallographic sample, as is done in some SG iron foundries, immediately after melt treatment and before pouring. To date, a universally accepted method for estimating the amount of CG in cast iron is not available. Certainly the simplest method is one in which the nodularity is determined by the ratio between the number of type I and II (nodular) graphite particles (ASTM A 247) and the total number of graphite particles (Ref 25):

$$Nodularity(\%) = \frac{\text{type I + type II}}{\text{type I + type II + type III + type IV}}$$

The amount of CG is considered to be the difference between 100% and the percent of nodularity.

This quantitative method is likely to be satisfactory for graphite shape estimation in production conditions, but has the disadvantage that it neglects the fact that several CG particles can belong to the same graphite aggregate, or that graphite considered to be spheroidal is in fact part of a CG aggregate. Another method suggests the use of different standard microphotographs (Ref 4, 15).

Molding Materials. As for SG iron, all molding materials that can produce rigid molds can be used. They include bentonite-bonded sands, cement-bonded sands, and resin-bonded sands.

Compacted graphite iron melts are more sensitive to sulfur pickup from the mold than are SG iron melts: unlike SG iron, CG iron must not be overtreated (Ref 3). Particular attention should be payed when using reclaimed resin-bonded sand with paratoluosulfonic acid (PTS) as a hardening catalyst. While such a new sand contains 0.086% S, at an amount of 80% reclaimed sand, the sulfur content increases to 0.31%, which can cause sulfur pickup in the casting of up to 0.05% S in the surface area, resulting in a FG rim up to several millimeters in thickness. To avoid graphite deterioration in the surface layer, especially for fatigue-stressed components, it may be useful to substitute phosphoric acid in part for PTS as a hardener. Also, the application of protective mold coatings with lime, magnesia, or talc base, is recommended (Ref 3).

Quality Control. Typical quality control procedures may include verification of structure, mechanical properties, physical properties, casting soundness, and dimensional accuracy. Structure can be assessed by classic metallographic techniques on coupons but also, to a certain extent, by ultrasonic velocity measurements on castings. While FG is easily separated from CG using the ultrasonic technique, it is virtually impossible to differentiate between CG and low-nodularity SG (Ref 9). Nevertheless good correlations between mechanical properties and ultrasonic velocity are reported and will be discussed in the section "Mechanical Properties" in this article. When ultrasonic tests are applied to castings, the ultrasonic velocity for CG structures is independent of the shape of the casting, but should be calibrated for the section thickness. For example, for 30 mm (1.2 in.) diam bars, the ultrasonic velocity range associated with CG is 5.2 to 5.45 km/s (3.2 to 3.4 mi/s), but for very large castings such as ingot molds, the ultrasonic velocity for good CG structures lies between 4.85 and 5.1 km/s (3.0 and 3.15 mi/s). Resonant frequency (sonic testing) on the other hand, must be calibrated for a particular casting design, for which examples of satisfactory and unsatisfactory structures must be previously checked to provide a calibration range.

Separately cast samples are recommended for determination of mechanical properties. They can be 30 mm (1.2 in.) diam cylindrical bars poured in a vertical position or keel (U) blocks with 25 mm (1 in.) wide legs. For larger castings, however, sample bars cast on the appropriate location on the casting are preferred (Ref 3, 26).

Compacted Graphite Irons

D.M. Stefanescu, University of Alabama; R. Hummer and E. Nechtelberger, Austrian Foundry Research Institute

Castability

The fluidity of molten cast iron is broadly governed by carbon and silicon contents and temperature. In addition, solidification morphology plays a role (Ref 27). Figure 9 shows three fluidity spiral samples. They were poured from the same base metal at the same temperature and have comparable chemical compositions. They differ only in their melt treatment. Flake graphite iron shows the best fluidity, and SG iron shows the worst. As expected, CG iron occupies an intermediate position. However, because CG irons are stronger than gray iron with the same CE, a higher CE can be used to obtain the same strength, allowing greater fluidity and easier pouring of thin sections.

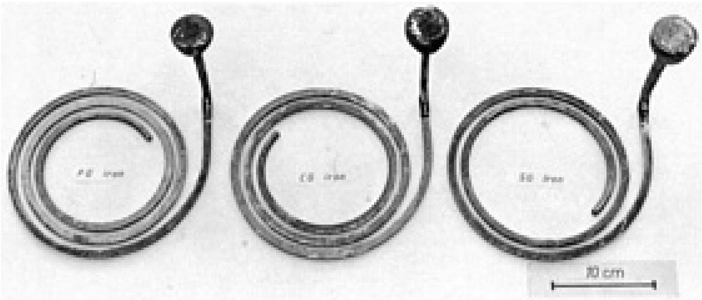

Fig. 9 Spiral fluidity samples poured from FG, CG, and SG iron. Source: Ref 27

Shrinkage Characteristics. Obtaining sound castings in CG irons, free from external and internal shrinkage porosity, is easier than with SG irons and slightly more difficult than with FG irons. This is because the tendency for mold wall movement to occur also lies between that of SG and FG irons. Figure 10 shows the results of experiments that demonstrate these effects using a 76 mm (3 in.) diam spherical test (Ref 5).

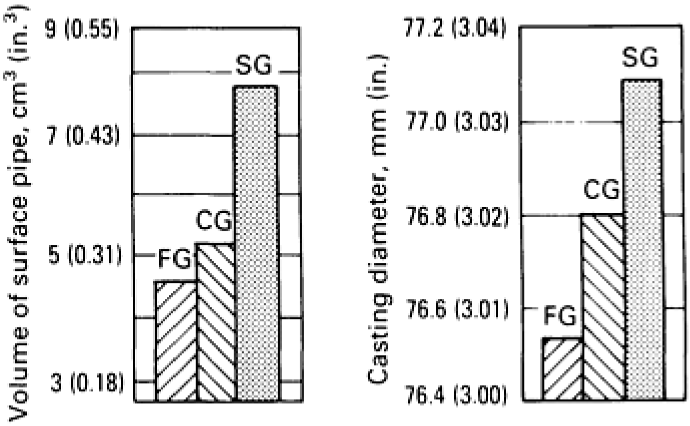

Fig. 10 Comparison of shrinkage and dimensions of spherical FG, CG, and SG iron castings poured in green sand molds. Source: Ref 5

For cast iron of eutectic composition cast in sand molds, it is reported that the shrinkage volume is 4.1% for FG, 4.8% for CG, and 7.0% for SG irons (Ref 28). A higher-grade FG iron will have a shrinkage volume very close to that of CG iron. In relative numbers, solidification expansion has been found to be 4.4 for SG iron and 1 to 1.8 for CG iron if FG iron is 1 (Ref 22).

Because of the rather low shrinkage of CG iron, it can sometimes be cast riserless. Expensive pattern changes are therefore not necessary when converting from gray iron to CG iron, because the same gating and risering techniques can be applied.

Yields for large castings vary between 65 and 75%, depending on casting complexity and weight (Ref 3).

Dross Formation. Magnesium, cerium, and calcium are dross-forming elements, and the problem of dross exists in CG irons just as it does in SG irons. Lower magnesium contents should be an advantage, but the best conditions for producing dross-free CG irons are the same as for SG irons: low CE composition, low sulfur content before treatment, treatment alloy low in calcium, high pouring temperature, adequate slag traps in the gating system, and smooth, nonturbulent pouring.

Chilling Tendency. Contrary to the belief of some, the chilling tendency of CG iron does not fall between that of FG and SG irons. This correlates with cooling curve data and is explained by the combination of low nucleation rate and low growth rate occurring during solidification of CG iron.

Compacted Graphite Irons

D.M. Stefanescu, University of Alabama; R. Hummer and E. Nechtelberger, Austrian Foundry Research Institute

Mechanical Properties

Mechanical properties of CG irons have been summarized in a number of publications (Ref 2, 3, 29, and 30). More than 80% of all failures of parts can be attributed to fatigue, which is not caused by insufficient mechanical strength, but by the initiation of cracks due to lack of plasticity, particularly at elevated temperatures. For high-duty gray iron, elongation is normally less than 1%, which in many cases is insufficient. Replacement of gray iron with a material of higher strength, ductility, and toughness, such as ductile iron, is not always possible because of poorer casting properties, lower thermal conductivity, higher modulus of elasticity, and so forth. In such cases, CG iron can close the gap between the two materials, because its mechanical properties are closer to those of SG iron, while its physical (expansion, conductivity) and elevated-temperature properties (thermal fatigue, thermal shock) are closer to those of FG iron.

Tensile Properties and Hardness. The typical range of room-temperature properties for CG irons with ferritic or pearlitic matrices is given in Table 2. Compacted graphite irons exhibit linear elasticity for both pearlitic and ferritic matrices but to a lower limit of proportionality than SG iron (Fig. 11). The yield point ratio (ratio of yield strength to tensile strength) ranges from 0.72 to 0.82 (higher than for SG iron of the same composition). This makes possible a higher loading capacity.

Table 2 Typical mechanical properties of CG iron

Tests were performed on 30 mm (1.2 in.) diam test bars.

Iron matrix	Tensile strength		0.2% offset yield strength		Elongation, %	Modulus of elasticity		Hardness, HB
	MPa	ksi	MPa	ksi		GPa	ksi × 10^3	

Ferritic	250-380	36-55	175-300	25-43	3-8	120-126	17.5-18.3	**130-179**
Pearlitic	**405-620**	**59-90**	**315-425**	**45-63**	**1-2**	**127-165**	**18.5-24**	**207-269**

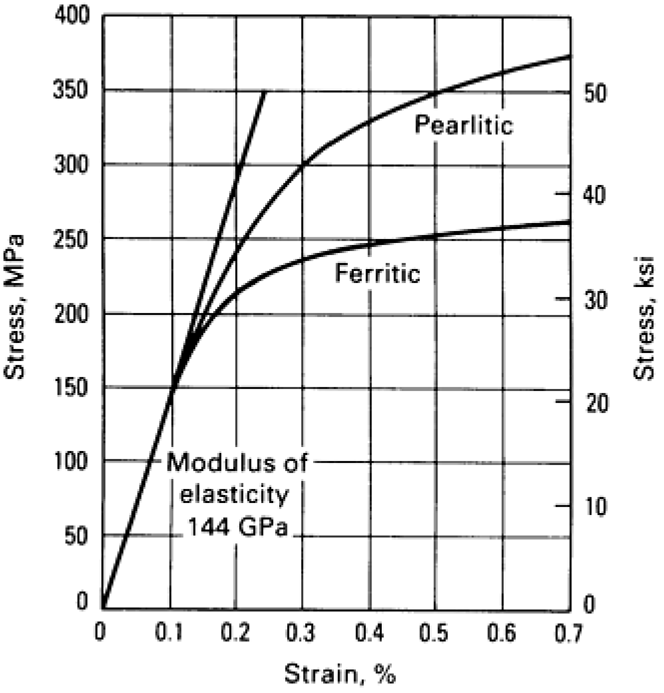

Fig. 11 Typical stress-strain curves for CG irons. The pearlitic iron had a tensile strength of 410 MPa (59.5 ksi) and elongation of 1%. The ferritic iron had a tensile strength of 320 MPa (46.5 ksi) and elongation of 3.5%. Source: Ref 3, 17

The graph in Fig. 12 compares hardness with tensile strength for SG, CG, and FG irons. The average tensile strength to hardness ratio of gray iron is 1.3, compared with 2.08 for compacted graphite, and 2.75 for ductile iron. The intermediate behavior of CG iron and the apparent effect of sulfur content are worth noting (Ref 31).

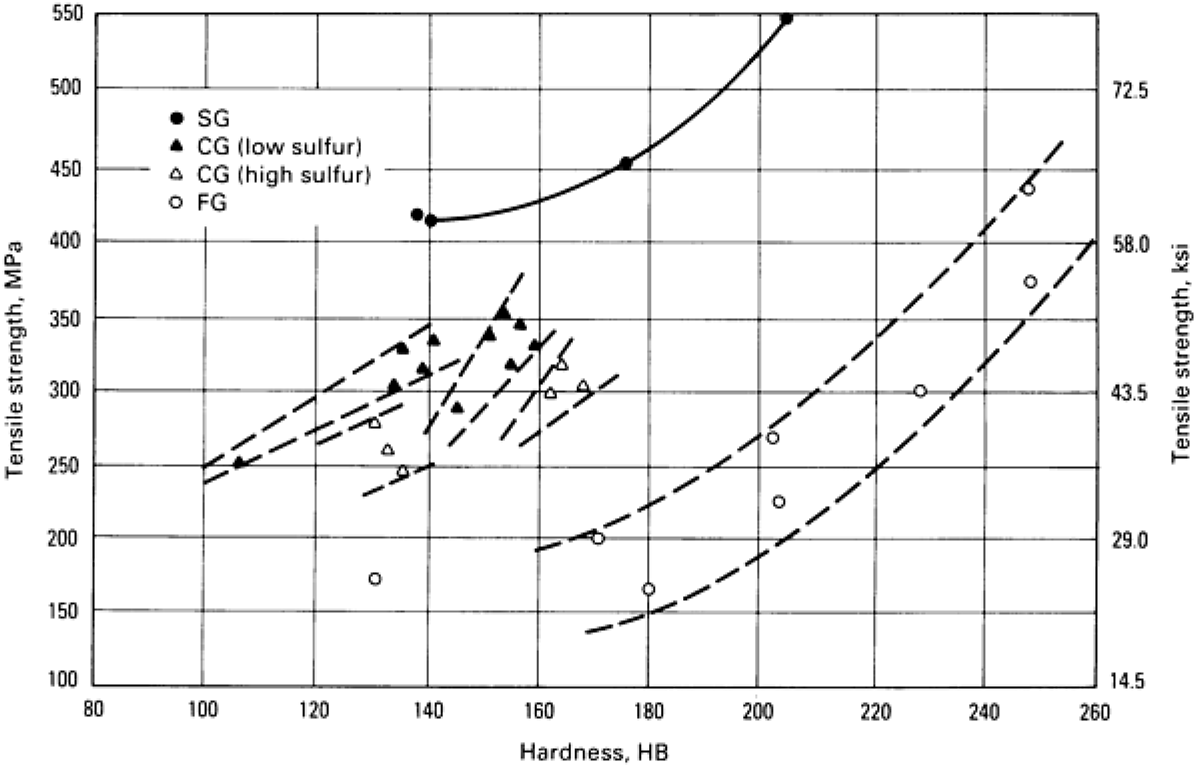

Fig. 12 Tensile strength versus hardness for SG, CG, and FG irons. Source: Ref 31

The main factors affecting mechanical properties are:

- Composition
- Structure (nodularity and matrix)
- Section size

All of these factors are interdependent.

It has been demonstrated that the tensile properties of CG irons are much less sensitive to variations in carbon equivalent than are those of FG irons. Even at CE near the eutectic value of 4.3, both pearlitic and ferritic CG irons have higher strengths than low CE, high-duty, unalloyed FG cast iron (Ref 5).

An increase in the silicon content up to 2.6% benefits strength and hardness in both the as-cast and annealed conditions (Fig. 13). This is true even though the matrix becomes more ferritic, because silicon strengthens the ferrite. The same is true in the case of as-cast elongation because there is a decrease in the amount of pearlite with an increase in Si, while elongation in the annealed condition decreases (Ref 31). Although increasing the phosphorus content slightly improves strength, a maximum of 0.04% P is desirable to avoid lower ductility and impact strength.

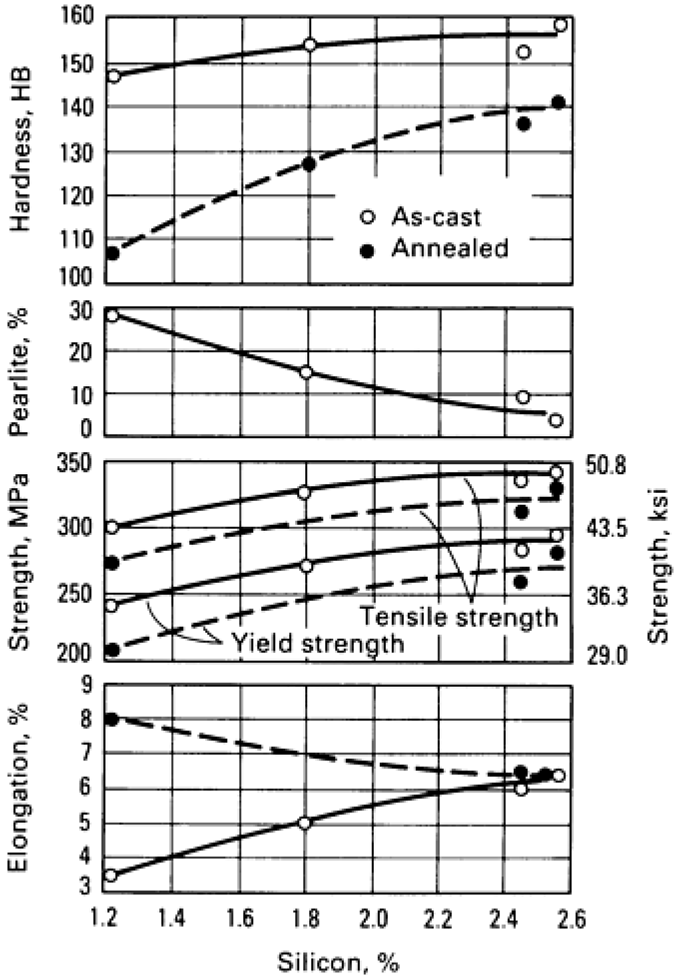

Fig. 13 The effect of silicon on mechanical properties of CG irons produced by the in-mold process. Carbon equivalents ranged from 4.33 to 4.45. Source: Ref 12

A number of alloying elements, such as copper, molybdenum, tin, manganese, and aluminum (Ref 9, 10, 12, 25, and 32), or heat treatment can be used to increase the pearlite/ferrite ratio. Some microstructure-properties correlations for iron-carbon-aluminum CG irons produced by the in-mold process are shown in Fig. 14.

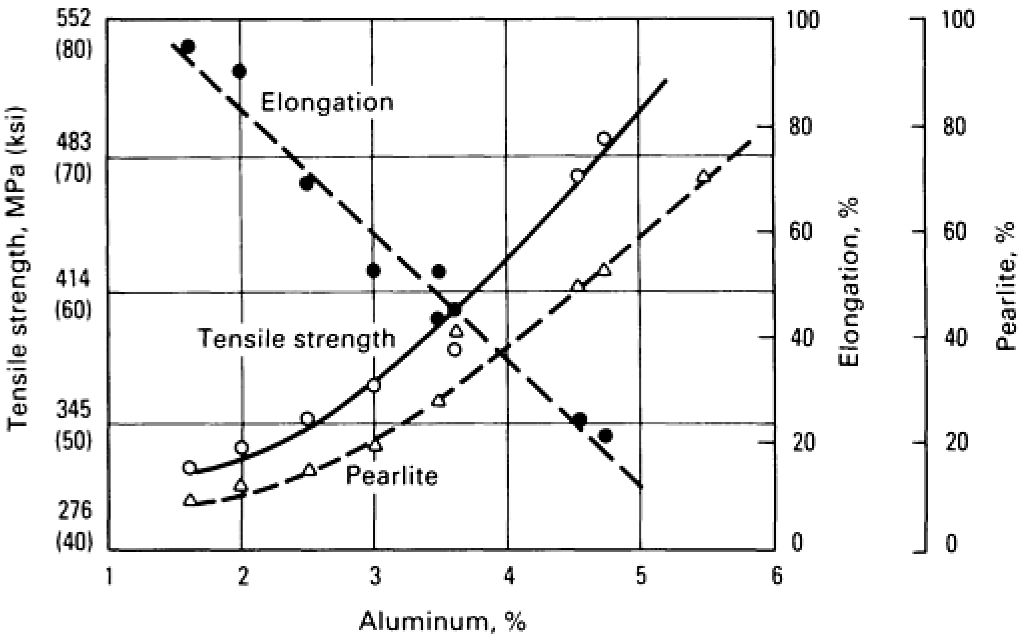

Fig. 14 The effect of aluminum on the structure and mechanical properties of CG irons produced by the in-mold process. Source: Ref 12

Both the pearlite/ferrite ratio and nodularity influence mechanical properties. Tensile strength and elongation increase as the nodularity of CG irons increases (Table 3), but nodularity must be maintained at less than 20% for the iron to qualify as CG iron. However, SG contents of up to 30% and even more must be expected in the thin sections of castings with considerable variation in wall thickness.

Table 3 Properties of CG as a function of nodularity

Nodularity, %	**Tensile strength**		**Elongation, %**	**Thermal conductivity, W/m · K**	Shrinkage, %
	MPa	**ksi**			
10-20	320-380	46-55	2-5	50-52	**1.8-2.2**
20-30	380-450	55-65	2-6	48-50	**2.0-2.6**
40-50	**450-500**	**65-73**	**3-6**	**38-42**	**3.2-4.6**

As for gray and ductile iron, tensile strength, yield strength, and hardness of CG iron increase with an increasing pearlite/ferrite ratio, whereas elongation decreases. The influence of heat treatment on mechanical properties of CG irons with 20% nodularity is illustrated in Table 4.

Table 4 Effect of heat treatment on tensile properties of CG iron

		Tensile	**Yield**		

		strength		strength			
		MPa	ksi	MPa	ksi		
As-cast	60% ferrite	425	62	330	48	3.5	**170**
Annealed	100% ferrite	393	57	317	46	5.0	**156**
Normalized	**90% pearlite**	**490**	**71**	**420**	**61**	**2.5**	**229**

Source: Ref 33

Mechanical properties of CG irons are less sensitive to wall thickness than are those of FG irons (Ref 2), but the influence of wall thickness may still be significant (Fig. 15). Other factors influencing the cooling of the casting, such as shakeout temperature, can also influence properties.

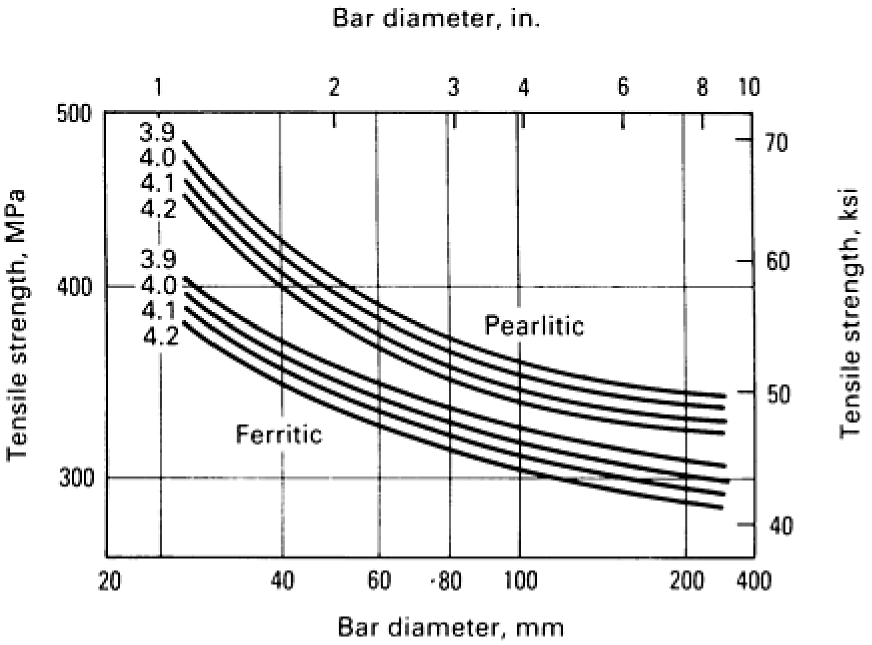

Fig. 15 The effect of section size on tensile strength of CG irons with various structures and carbon equivalents. Numbers beside curves indicate carbon equivalents. Source: Ref 5

Tensile strength correlates well with resonant frequency (sonic testing) and ultrasonic velocity measurements. Nevertheless, it must be noted that it is difficult to distinguish between high-nodularity CG and low-nodularity SG (Ref 3).

Compressive Properties. The ultimate compressive strength of predominantly pearlitic CG iron is approximately three times the tensile strength. More details are available in Ref 3, 29, and 30.

Impact Properties. While ductile iron exhibits substantially greater toughness at low pearlite contents, pearlitic CG irons have impact strengths equivalent to those of SG irons (Fig. 16). Charpy impact energy measurements at 21 °C (70 °F) and -40 °C (-40 °F) showed that CG irons produced from a ductile iron base absorbed greater energy than those made from gray iron base iron (Ref 31). This is attributed to tramp elements in the gray iron having solute hardening effects in the matrix.

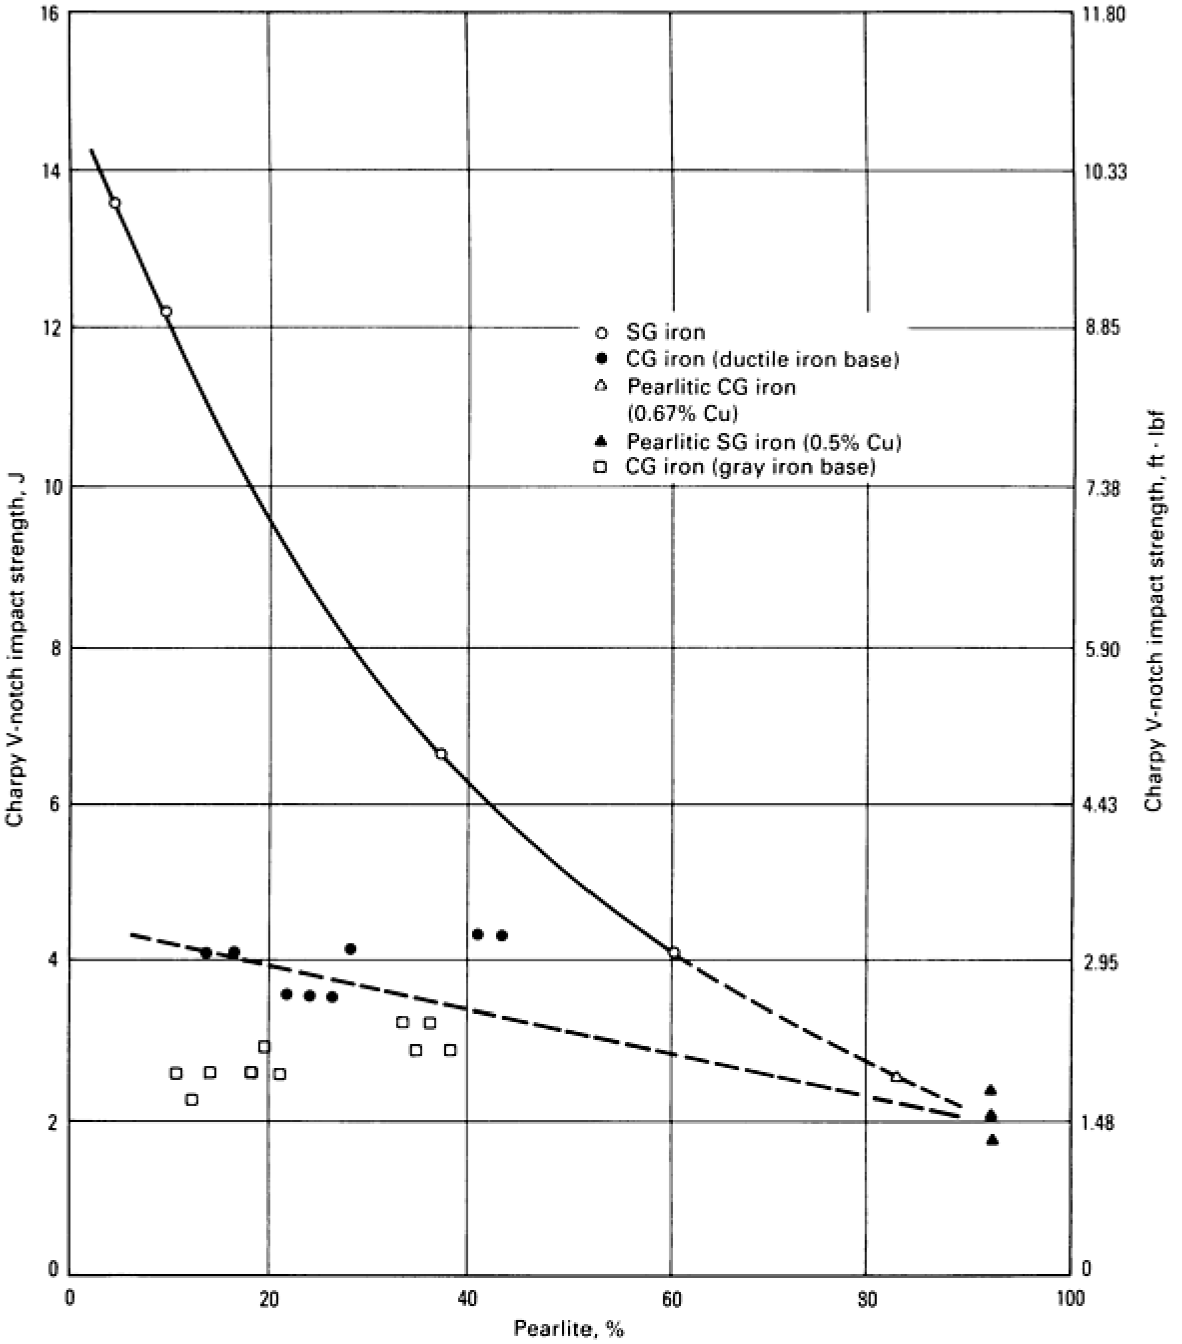

Fig. 16 The effect of pearlite content on the room-temperature Charpy V-notch impact strength of as-cast CG irons compared to that of SG iron. Source: Ref 31

Studies on crack initiation and growth under impact loading conditions showed that, in general, initiation of matrix cracking was preceded by graphite fracture, either at the graphite-matrix interface or through the graphite, or both. The most dominant form of graphite fracture appeared to be that occurring along the boundaries between graphite crystallites (Ref 34). Matrix cracks were usually initiated in the ferrite by transgranular cleavage (graphite was nearly always surrounded by ferrite), although in some instances intergranular ferrite fracture appeared to be the initiating mechanism. Matrix crack propagation generally occurred by a brittle cleavage mechanism, transgranular in ferrite and interlamellar in pearlite. In general, the impact resistance of CG irons increases with carbon equivalent, and decreases with phosphorus or increasing pearlite.

Fatigue Properties. Typical fatigue properties for CG irons are shown in Fig. 17. It is evident that pearlitic structures, higher nodularity, and unnotched samples resulted in better fatigue properties. The fatigue endurance ratio was 0.46 for ferritic matrix, 0.45 for pearlitic matrix, and 0.44 for pearlitic higher-nodularity CG iron (Ref 35).

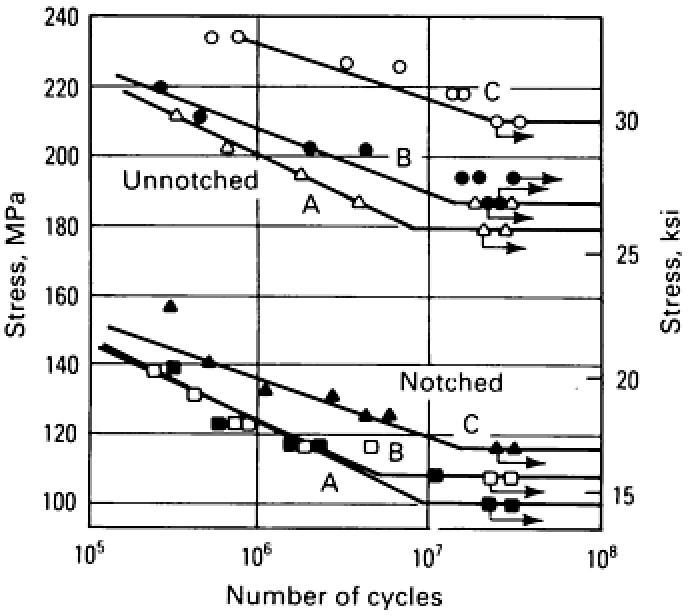

Fig. 17 Fatigue curves for CG irons. (a) With ferritic matrix. (b) With pearlitic matrix. (c) With higher modularity. Source: Ref 29, 35

Compacted Graphite Irons

D.M. Stefanescu, University of Alabama; R. Hummer and E. Nechtelberger, Austrian Foundry Research Institute

Elevated-Temperature Properties

Tensile Properties. The variation with temperature of tensile strength, yield strength, and elongation of CG iron produced with cerium-mischmetal treatment alloys is similar to that typical for SG iron (Fig. 18), but the values are somewhat lower (Ref 36). Similar results are reported for CG irons produced with magnesium-titanium-ferrosilicon alloys (Ref 2). As expected, a slight increase in nodularity led to higher tensile strength values at all temperatures.

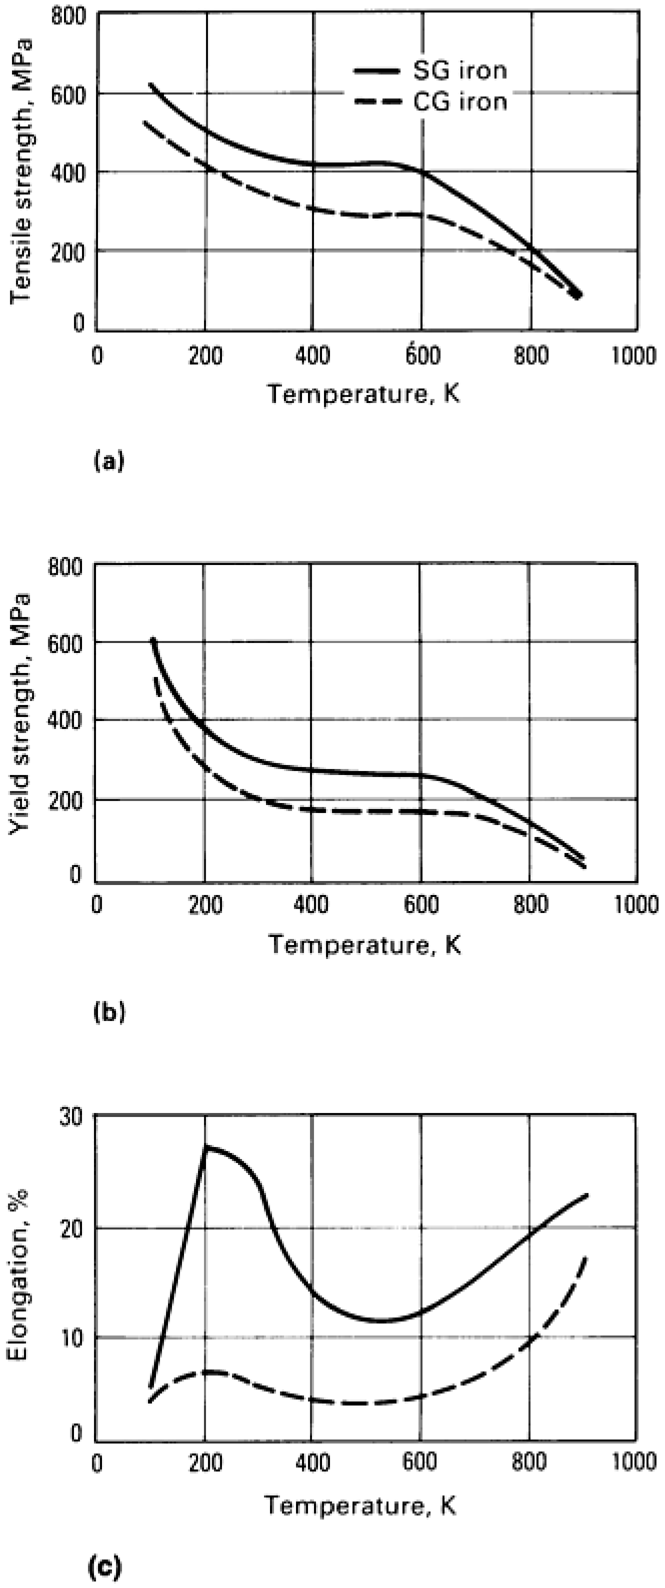

Fig. 18 Variation with temperature of tensile properties of CG and SG irons. Source: Ref 35

Growth and Scaling. Tests conducted for 32 weeks in air have shown that at 500 °C (930 °F) growth and scaling of CG iron was not significantly different from that exhibited by FG irons of similar composition. However, at 600 °C (1110 °F), the growth of CG irons was less than that of FG iron, and their scaling resistance was superior (Ref 5).

Other oxidation studies of cast irons conducted at 600 °C (1110 °F) concluded that weight gains due to oxidation are 10 to 15% higher for CG irons than for SG irons, but 30 to 60% lower than for FG irons (Ref 37).

Thermal Fatigue. Interpretation of thermal fatigue tests is complicated by the many different methods employed by various investigators. The two widely accepted methods are constrained thermal fatigue (12.7 mm, or 0.5 in., diam bars) and finned disk thermal shock tests (Ref 38, 39).

During thermal cycling, in the constrained thermal fatigue test for which the specimen is mounted between two stationary plates, compressive stresses develop upon heating, and tensile stresses develop upon cooling. As thermal cycling continues, the specimen is accumulating fatigue damage similar to that in mechanical fatigue testing; ultimately, the specimen fails by fatigue. Experimental results (Fig. 19) point to higher thermal fatigue for CG iron than for FG iron, and to the beneficial effect of molybdenum. In fact, regression analysis of experimental results indicates that the main factors influencing thermal fatigue are tensile strength (TS) and molybdenum content:

$$\log N = 0.934 + 0.026\ \mathrm{TS} + 0.861\ \mathrm{Mo}$$

where N is the number of thermal cycles to failure, tensile strength is in kips per square inch (ksi), and molybdenum is in percent.

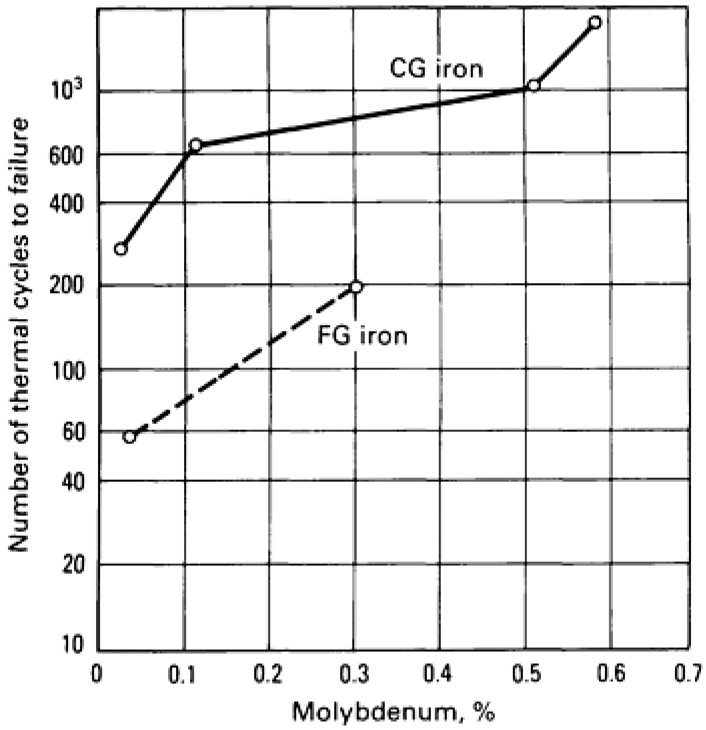

Fig. 19 Results of constrained thermal fatigue tests conducted between 100 and 540 °C (212 and 1000 °F). Source: Ref 39

In the finned disk thermal shock test, the specimen is cycled between a moderate-temperature environment and a high-temperature environment, which causes thermal expansion and contraction. For good resistance to thermal fatigue, cast irons must have high thermal conductivity, low modulus of elasticity, high strength at room and elevated temperatures and, for use above 500 to 550 °C (930 to 1020 °F), resistance to oxidation and structural change. Relative ranking of the irons varies with test conditions. When high cooling rates are encountered, experimental data and commercial experience show that thermal conductivity and low modulus of elasticity are most important. Consequently, gray irons of high carbon content (3.6 to 4%) are superior (Ref 38, 39). When intermediate cooling rates exist, ferritic SG and CG irons have the highest resistance to cracking, but are subject to distortion. When low cooling rates exist, high-strength pearlitic SG irons or SG irons alloyed with silicon and molybdenum are best with regard to cracking and distortion (Ref 38).

Physical Properties

Thermal Conductivity. As can be seen from Table 5, the thermal conductivity of CG iron is very close to that of gray cast iron, and considerably higher than that of SG iron (Ref 3, 5). This behavior is explained by the fact that much like FG, CG is interconnected. As for FG irons, increasing the carbon equivalent results in higher thermal conductivity for CG iron. As the temperature is increased, the thermal conductivity reaches a maximum at about 200 °C (390 °F), an effect also shown by SG irons but differing from FG iron. Increasing nodularity results in lower thermal conductivity (Ref 3, 40).

Table 5 Thermal conductivities of FG, CG, and SG irons at various temperatures

Graphite shape	**Carbon equivalent**	Thermal conductivity, W/m · αK (Btu/ft · h · °F)				
		100 °C (212 °F)	**200 °C (390 °F)**	**300 °C (570 °F)**	**400 °C (750 °F)**	500 °C (930 °F)
Flake	3.8	50.24 (29.02)	48.99 (28.30)	45.22 (26.12)	41.87 (24.19)	**38.52 (22.25)**
	4.8	53.39 (30.84)	50.66 (29.27)	47.31 (27.33)	43.12 (24.91)	**38.94 (22.49)**
Compacted	3.9	38.10 (22.01)	41.0 (23.69)	39.40 (22.76)	37.30 (21.55)	**35.20 (20.34)**
	4.1	43.54 (25.15)	43.12 (24.91)	40.19 (23.22)	37.68 (21.77)	**35.17 (20.32)**
Spheroidal	**4.2**	**32.34 (18.68)**	**34.75 (20.08)**	**33.08 (19.11)**	**31.40 (18.14)**	**29.31 (16.93)**

Linear Expansion. For irons of similar chemical composition, there seems to be no difference in total expansion regardless of graphite shape (Ref 40). However, when different compositions are used in order for an iron to fall in the typical range for a given type of cast iron, the linear expansion of CG iron is between that of SG and FG irons (Ref 3).

Other Properties

Corrosion Resistance. At room temperature, the corrosion rate of CG iron in 5% sulfuric acid is nearly half that of FG iron. With increasing temperature, the difference becomes smaller. The pearlitic matrix has higher corrosion resistance than the ferritic one. As expected, corrosion accelerates when stress is applied (Ref 41). Detailed information on the corrosion resistance of cast irons is available in the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Machinability. In general, from both experimental data and practical experience in machine shops, it can be concluded that for a given matrix the machinability of CG iron is between that of gray and ductile iron (Ref 3, 5, 37, 42, and 43). The CG morphology makes the iron sufficiently brittle for the machine swarf to break into small chips, yet strong enough to prevent it from forming powdery chips. Neither large swarf nor fine powdery swarf is ideal for high machinability (Ref 31).

Damping Capacity. The relative damping capacity of various irons, obtained by measuring the relative rates at which the amplitude of an imposed vibration decreased with time (Ref 35), is:

FG iron : CG iron : SG iron = 1.0 : 0.6 : 0.34

Typical Applications

Primary in the selection of CG iron for practical application is its position between FG and SG iron. CG iron can be substituted for FG iron in all cases in which the strength of FG iron has become insufficient but in which a change to SG iron is undesirable because of the less favorable casting properties of the latter. Examples are: bed plates for large diesel engines, crank cases, gear-box and turbocharger housings, connecting forks, bearing brackets, pulleys for truck servo drives, sprocket wheels, and eccentric gears. Figure 20 shows three of these applications.

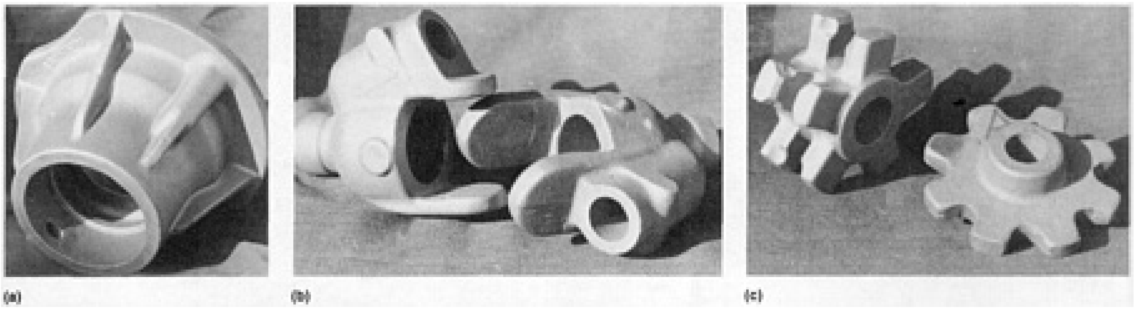

Fig. 20 Three typical applications for CG iron castings. (a) Intermediate gear box; weight, 17.9 kg (39.5 lb). (b) Connecting forks; weight, 2 and 2.6 kg (4.4 and 5.7 lb). (c) Sprocket wheels; weight, 1.1 and 1.6 kg (2.4 and 3.5 lb). Source: Ref 3

Because the thermal conductivity of CG iron is higher than that of SG iron, CG iron is preferred for castings operating at elevated temperature and/or under thermal fatigue conditions. Applications include ingot molds, crank cases, cylinder heads, exhaust manifolds, and brake disks (Fig. 21). Other engineering applications are summarized in Ref 3.

High-Alloy White Irons

Richard B. Gundlach, Climax Research Services

Introduction

HIGH-ALLOY WHITE CAST IRONS are an important group of materials whose production must be considered separately from that of ordinary types of cast irons. In these cast iron alloys, the alloy content is well above 4%, and consequently they cannot be produced by ladle additions to irons of otherwise standard compositions. They are usually produced in foundries specially equipped to produce highly alloyed irons. These iron alloys are most often melted in electric furnaces, specifically electric arc furnaces and induction furnaces, in which the precise control of composition and temperature can be achieved. The foundries usually have the equipment needed to handle the heat treatment and other thermal processing unique to the production of these alloys.

The high-alloy white irons are primarily used for abrasion-resistant applications and are readily cast into the parts needed in machinery for crushing, grinding, and handling of abrasive materials. The chromium content of high-alloy white irons also enhances their corrosion-resistant properties. The large volume fraction of primary and/or eutectic carbides in their microstructures provides the high hardness needed for crushing and grinding other materials. The metallic matrix supporting the carbide phase in these irons can be adjusted by alloy content and heat treatment to develop the proper balance between the resistance to abrasion and the toughness needed to withstand repeated impact.

All high-alloy white irons contain chromium to prevent the formation of graphite upon solidification and to ensure the stability of the carbide phase. Most also contain nickel, molybdenum, copper, or combinations of these alloying elements to prevent the formation of pearlite in the microstructure. While low-alloy white iron castings, which have an alloy content below 4%, develop hardnesses in the range of 350 to 550 HB, the high-alloy irons range in hardness from 450 to 800 HB. In addition, several grades contain alloy eutectic carbides (M_7C_3 chromium carbides), which are substantially harder than the M_3C iron carbides in low-alloy irons. For many applications, the increased abrasion resistance of the more expensive high-alloy white irons adds significantly to wear life, enabling them to provide the most cost-effective performance.

Alloy Grades. Specification ASTM A 532 covers the composition and hardness of the abrasion-resistant white iron grades (see Table 1). Many castings are ordered according to these specifications. However, a large number of castings are produced with composition modifications for specific applications. It is most desirable that the designer, metallurgist, and foundryman work together to specify the composition, heat treatment, and foundry practice to develop the most suitable alloy and casting design for a specific application.

Table 1 Composition and mechanical requirements of abrasion-resistant cast irons per ASTM A 532

Class	Type	Designation	Composition					
			C	Mn	Si	Ni	Cr	Mo
I	A	Ni-Cr-HC	3.0-3.6	1.3 max	0.8 max	3.3-5.0	1.4-4.0	**1.0 max[(a)]**

III	**A**	**25% Cr**	**450**	**. . .**	**600**	**400**	**8**	**200**

(a) Maximum: 0.30% P, 0.15% S.

(b) Maximum: 0.10% P, 0.15% S.

(c) Maximum: 0.10% P, 0.06% S, 1.2% Cu

The high-alloy white cast irons fall into two major groups:

- Nickel-chromium white irons, which are low-chromium alloys containing 3 to 5% Ni and 1 to 4% Cr, with one alloy modification that contains 7 to 11% Cr
- The chromium-molybdenum irons containing 11 to 23% Cr, up to 3% Mo and often additionally alloyed with nickel or copper.

A third group comprises the 25% or 28% Cr white irons, which may contain other alloying additions of molybdenum and/or nickel up to 1.5%. The nickel-chromium irons are also commonly identified as Ni-Hard types 1 to 4.

High-Alloy White Irons

Richard B. Gundlach, Climax Research Services

Nickel-Chromium White Irons

The oldest group of high-alloy irons of industrial importance, the nickel-chromium white irons, or Ni-Hard irons, have been produced for more than 50 years and are very cost-effective materials for crushing and grinding. In these martensitic white irons, nickel is the primary alloying element because at levels of 3 to 5% it is effective in suppressing the transformation of the austenite matrix to pearlite, thus ensuring that a hard, martensitic structure (usually containing significant amounts of retained austenite) will develop upon cooling in the mold. Chromium is included in these alloys, at levels from 1.4 to 4%, to ensure that the irons solidify carbidic, that is, to counteract the graphitizing effect of nickel. A typical microstructure is shown in Fig. 1.

Fig. 1 Typical microstructure of class I type A nickel-chromium white cast iron. 340×

The optimum composition of a nickel-chromium white iron alloy depends on the properties required for the service conditions and the dimensions and weight of the casting. Abrasion resistance is generally a function of the bulk hardness and the volume of carbide in the microstructure. When abrasion resistance is the principal requirement and resistance to impact loading is secondary, alloys having high carbon contents, ASTM A 532 class I type A (Ni-Hard 1), are recommended. When conditions of repeated impact are anticipated, the lower-carbon alloys, class I type B (Ni-Hard 2), are recommended because they have less carbide and, therefore, greater toughness. A special grade, class I type C, has been developed for producing grinding balls and slugs. Here, the nickel-chromium alloy composition has been adapted for chill casting and specialized sand casting processes.

The class I type D (Ni-Hard 4) alloy is a modified nickel-chromium iron that contains higher levels of chromium, ranging from 7 to 11%, and increased levels of nickel, ranging from 5 to 7%. Whereas the eutectic carbide phase in the lower-alloyed nickel-chromium irons is M_3C (iron carbide), which forms as a continuous network in these irons, the higher chromium in the type D alloy promotes M_7C_3 chromium carbides, which form a relatively discontinuous eutectic carbide distribution (Fig. 2). This modification in the eutectic carbide pattern provides an appreciable improvement in resistance to fracture by impact. The higher alloy content of this iron grade also results in improved corrosion resistance, which has proved to be useful in the handling of corrosive slurries.

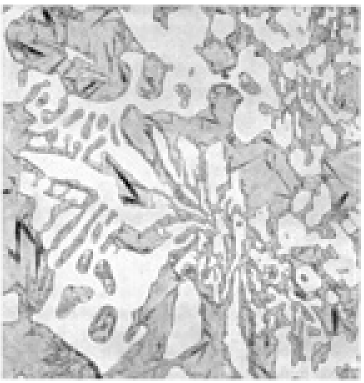

Fig. 2 Typical microstructure of class I type D nickel-chromium white cast iron. 340×

Melting Practice

A principal advantage of the nickel-chromium irons is that they can be melted in a cupola; however, better control of composition and temperature are achieved with electric furnace melting. Consequently, electric arc furnace melting and induction furnace melting are most common. The nickel-chromium irons are readily made in either acid-, neutral-, or basic-lined electric furnaces. They are normally dead melted, and there is usually no reason to use oxygen lancing except as a means of slightly reducing carbon content. Acid linings are generally more economical than basic linings. The type of lining affects silicon and chromium losses. Very little adjustment to slag composition is necessary in acid melting, which is used for the majority of current production.

Normal charge materials are various kinds of steel scrap, foundry returns, or returns of similar alloy from service. For foundries that lack the facilities for rapid melt analysis, it may be necessary to select steel scrap rather carefully to ensure that the residual levels of alloying elements, such as manganese and copper, which have a potent effect on austenite retention, are consistent and under control.

Chromium is obtained in the form of high-carbon ferrochrome and is generally added near the end of the heat to avoid excessive oxidation losses. Carbon is obtained from electrode graphite, petroleum coke, and other sources. Pig iron is also used to carburize the melt and can be an additional source of silicon. Silicon and manganese are added as ferroalloys. Molybdenum is usually added as ferromolybdenum; however, with arc furnaces, molybdenum oxide briquettes may be used. Sulfur is limited to 0.06%, and phosphorus is kept to 0.10%, as specified by ASTM A 532.

High superheating temperatures have not been necessary when melting in induction furnaces, which have good stirring action, and a final temperature of 1480 °C (2700 °F) is usually adequate for thick-section castings. Final temperatures of up to 1565 °C (2850 °F) are commonly used in arc furnace practice to ensure homogeneity of the bath composition and to accelerate the solution of carbon, added after meltdown, and late alloy additions. No particular problems have been associated with high super-heat temperatures, but it is more difficult to predict melting losses.

As in steel melting, deoxidation of the bath with aluminum was common, but it is no longer practiced by most producers, with no adverse effects on the soundness or mechanical properties of the casting. A late addition/inoculation of foundry-grade ferrosilicon is often made to improve toughness.

Composition Control

Carbon is varied according to the properties needed for the intended service. Carbon contents in the range of 3.2 to 3.6% are prescribed when maximum abrasion resistance is desired. When impact loading is expected, carbon content should be held in the range of 2.7 to 3.2%.

Nickel content increases with section size or cooling time of the casting to inhibit pearlitic transformation. For castings of 38 to 50 mm (1.5 to 2 in.) thick, 3.4 to 4.2% Ni is sufficient to suppress pearlite formation upon mold cooling. Heavier sections may require nickel levels up to 5.5% to avoid the formation of pearlite. It is important to limit nickel content to the level needed for control of pearlite; excess nickel increases the amount of retained austenite and lowers hardness.

Silicon is needed for two reasons. A minimum amount of silicon is necessary to improve fluidity of the melt and to produce a fluid slag, but of equal importance is its effect on as-cast hardness. Increased levels of silicon, in the range of 1 to 1.5%, have been found to increase the amount of martensite and the resulting hardness. Late additions of ferrosilicon (0.2% as 75% Si grade ferrosilicon) have been reported to increase toughness. It is important to note that higher silicon contents can promote pearlite and may increase the nickel requirement.

Chromium, primarily added to offset the graphitizing effects of nickel and silicon in types A, B, and C alloys, ranges from 1.4 to 3.5%. Chromium content must increase with increasing section size. In type D alloy, chromium levels range from 7 to 11% (typically 9%) for the purpose of producing eutectic carbides of the M_7C_3 chromium carbide type, which are harder and less deleterious to toughness.

Manganese is typically held to a maximum of 0.8% even though 1.3% maximum is allowed according to ASTM A 532 specification. While it provides increased hardenability to avoid pearlite formation, it is a more potent austenite stabilizer than nickel, and promotes increased amounts of retained austenite and lower as-cast hardness. For this reason, higher manganese levels are undesirable. When considering the nickel content required to avoid pearlite in a given casting, the level of manganese present should be a factor.

Copper increases both hardenability and the retention of austenite and therefore must be controlled for the same reason that manganese must be limited. Copper should be treated as a nickel substitute and, when properly included in the calculation of the amount of nickel required to inhibit pearlite, it reduces the nickel requirement.

Molybdenum is a potent hardenability agent in these alloys and is used in heavy-section castings to augment hardenability and inhibit pearlite.

Pouring Practices

High pouring temperatures aggravate shrinkage under feeder heads and other hot spots and can lead to microshrinkage and coarse dendritic structures. Careful control of pouring temperature is particularly important in the consistent production of thick-section castings. Low pouring temperatures are necessary not only to avoid shrinkage defects but also to avoid problems such as metal penetration and burned-on sand. Low pouring temperatures are also effective in controlling dendrite size and the coarseness of the eutectic carbide structure.

The eutectic temperature for the various nickel-chromium iron grades is approximately 1200 °C (2190 °F), and solidification generally begins at temperatures of 1200 to 1280 °C (2190 to 2340 °F), depending on composition. When selecting a pouring temperature, common rules apply. Pouring temperatures are seldom lower than 100 °C (180 °F) above the liquidus temperature. Higher pouring temperatures may be necessary when pouring smaller castings. Of course, casting configurations must be considered when selecting optimum pouring temperatures.

Molds, Patterns, and Casting Design

These alloys may be sand cast or chill cast in permanent molds. The chill cast microstructures develop higher hardness, strength, and impact toughness over the sand cast structures, because of the finer carbides. It is recommended that, whenever practical, the wearing faces of the casting be cast against a chill to improve abrasion resistance and toughness.

Sand molds may be made either of green sand or of dry sand, oil sand, or steel casting sand. Air-setting and thermal-setting resin sands are also commonly used. Molds must be rigid to minimize shrinkage defects.

White irons are subject to hot tearing, unless suitable precautions are taken. Occasionally when castings are extracted from the mold, they are found to be cracked. Stresses large enough to cause fracture can arise when either the mold or the cores are excessively strong and there is inadequate mold or core breakdown to allow normal thermal contraction with cooling. Large cores, such as those used in pump volutes, and even small cores used to form bolt holes, can cause cracking of this type.

Shrinkage allowance is 13 to 21 mm/m ($\frac{5}{32}$ to $\frac{1}{4}$ in./ft); a commonly used figure is 16 mm/m ($\frac{3}{16}$ in./ft). The actual pattern allowance depends on the choice of alloy and the geometry of the casting. Patterns should employ generous radii and avoid sharp section changes to avoid initiating cracking upon solidification and subsequent cooling.

These alloys exhibit relatively high liquid-to-solid shrinkage (5%); therefore, large gates and risers are required for feeding. Special consideration should be given to the design of end gates and the positioning of risers so that they can be readily removed. Risers cannot be removed by burning and are often notched or necked down to facilitate removal by impact. They are most easily removed after the castings have cooled to room temperature, that is, when martensite is present. Martensitic transformation begins at temperatures below 230 °C (450 °F).

Shakeout Practices

The shakeout practice is a critical step in the successful production of nickel-chromium iron castings. High residual stresses and cracking can result from extracting castings from a mold at too high a temperature. Cooling all the way to room temperature in the mold is desirable because, as stated above, transformation to martensite occurs below 230 °C (450 °F) during the last stages of cooling. This precaution is mandatory in heavy-section castings; the volume increase that occurs with martensite formation results in the development of high transformation stresses in castings having steep temperature gradients due to rapid cooling. Thin-section castings and castings having simple shapes are less susceptible to stresses and are often removed from the mold once the castings have reached black heat. With these alloys, slow cooling favors higher as-cast hardness.

Heat Treatment

All nickel-chromium white iron castings are given a stress-relief heat treatment because, properly made, they have a martensitic matrix structure, as-cast. Tempering is performed between 205 to 260 °C (400 to 500 °F) for at least 4 h. This tempers the martensite, relieves some of the transformation stresses, and increases the strength and impact toughness by 50 to 80%. Some additional martensite may form upon cooling from the tempering temperature. This heat treatment does not reduce hardness or abrasion resistance.

High-Temperature Heat Treatment. In the past, hardening of the class I type D, Ni-Hard 4, was performed by supercritical heat treatment when as-cast hardness was insufficient. An austenitizing heat treatment usually comprised heating the casting at temperatures between 750 and 790 °C (1380 and 1450 °F) with a soak time of 8 h. Air or furnace cooling, not over 30 °C/h (50 °F/h), was conducted, followed by a tempering/stress-relief heat treatment.

Refrigeration treatment is the more commonly practiced remedy for low hardness today. To achieve a hardness of 550 HB, it is necessary for the as-cast austenite-martensite microstructure to have at least 60% martensite present. When martensite content is increased to 80 to 90%, however, hardness values exceed 650 HB. To reduce the amount of retained austenite, that is, form more martensite, deep freeze treatments are commonly applied. Refrigeration to temperatures between -70 and -185 °C (-90 and -300 °F) for $\frac{1}{2}$ to 1 h will usually raise the hardness level 100 HB units. A

tempering/stress-relief heat treatment usually follows. The typical refrigerated nickel-chromium iron microstructure is shown in Fig. 3.

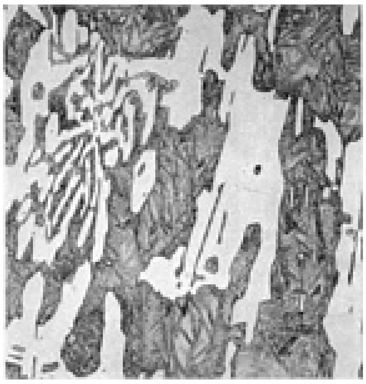

Fig. 3 Microstructure of class I type D nickel-chromium white cast iron after refrigeration. 340×

In the heat treatment of any white cast iron, care must be taken to avoid cracking by thermal shock; the castings must never be placed in a hot furnace or otherwise subjected to rapid heating or cooling. The risk of cracking increases with the complexity of the casting shape and section thickness.

Machining

Alloyed white irons are generally ground to finish size; care must be taken to avoid cracking by overheating. Single-point turning and boring can be done using heavy tooling, rigid setups, sufficient power, and carbide- or boride-tipped cutters or special ceramic inserts. Electrical discharge machining and electrochemical machining are also feasible.

Applications

Because of their low cost, the martensitic nickel-chromium white irons are consumed in large tonnages in mining operations as ball mill liners and grinding balls. Class I type A castings are used in applications requiring maximum abrasion resistance, such as ash pipes, slurry pumps, roll heads, muller tires, augers, coke-crusher segments, classifier shoes, brick molds, pipe elbows carrying abrasive slurries, and grizzly disks. Type B is recommended for applications requiring more strength and exerting moderate impact, such as crusher plates, crusher concaves, and pulverizer pegs.

Class I type D, Ni-Hard type 4, has a higher level of strength and toughness and is therefore used for the more severe applications that justify its added alloy costs. It is commonly used for pump volutes handling abrasive slurries and coal pulverizer table segments and tires.

The class I type C alloy (Ni-Hard 3) is specifically designed for the production of grinding balls. This grade is both sand cast and chill cast. Chill casting has the advantage of lower alloy cost, and, more important, provides a 15 to 30% improvement in life. All grinding balls require tempering for 8 h at 260 to 315 °C (500 to 600 °F) to develop adequate impact toughness.

Special Nickel-Chromium White Iron Alloys

Certain proprietary grades of type A alloy have been developed by the rolling mill industry. The compositions of these alloys have been modified to produce mottled structures, containing some graphite. The graphite inclusions are reported to improve resistance to thermal cracking. These indefinite chill rolls are cast in thick-wall gray iron chiller molds in roll diameters of up to 1015 mm (40 in.) or more. The silicon to chromium ratios and inoculation with ferrosilicon are carefully controlled to control the amount and distribution of the graphite particles. The rolls can be double poured with a gray iron core. With molybdenum modification, the matrix of the chill cast shell becomes martensitic. Some roll alloys are designed to be heat treated, that is, by a modified normalizing heat treatment, to obtain a bainitic microstructure.

High-Alloy White Irons

Richard B. Gundlach, Climax Research Services

High-Chromium White Irons

The high-chromium white irons have excellent abrasion resistance and are used effectively in slurry pumps, brick molds, coal-grinding mills, shot-blasting equipment, and components for quarrying, hard-rock mining, and milling. In some applications they must also be able to withstand heavy impact loading. These alloyed white irons are recognized as providing the best combination of toughness and abrasion resistance attainable among the white cast irons.

In the high-chromium irons, as with most abrasion-resistant materials, there is a trade-off between wear resistance and toughness. By varying composition and heat treatment, these properties can be adjusted to meet the needs of most abrasive applications.

As a class of alloyed irons, the high-chromium irons are distinguished by the hard, relatively discontinuous M_7C_3 eutectic carbides present in the microstructure, as opposed to the softer, more continuous M_3C eutectic carbides present in the alloyed irons containing less chromium. These alloys are usually produced as hypoeutectic compositions.

Classes of High-Chromium Irons

Specification ASTM A 532 covers the compositions and hardnesses of two general classes of the high-chromium irons (see Table 1). The chromium-molybdenum irons (class II of ASTM A 532) contain 11 to 23% Cr and up to 3.5% Mo and can be supplied either as-cast with an austenitic or austenitic-martensitic matrix, or heat treated with a martensitic matrix microstructure for maximum abrasion resistance and toughness. They are usually considered the hardest of all grades of white cast irons. Compared to the lower-alloy nickel-chromium white irons, the eutectic carbides are harder and can be heat treated to achieve castings of higher hardness. Molybdenum, as well as nickel and copper when needed, is added to prevent pearlite and to ensure maximum hardness.

The high-chromium irons (class III of ASTM A 532) represent the oldest grade of high-chromium irons, with the earliest patents dating back to 1917. These general-purpose irons, also called 25% Cr and 28% Cr irons, contain 23 to 28% Cr with up to 1.5% Mo. To prevent pearlite and attain maximum hardness, molybdenum is added in all but the lightest-cast sections. Alloying with nickel and copper up to 1% is also practiced. Although the maximum attainable hardness is not as high as in the class II chromium-molybdenum white irons, these alloys are selected when resistance to corrosion is also desired.

Microstructures

Carbide. The carbides in high-chromium irons are very hard and wear resistant but are also brittle. In general, wear resistance is improved by increasing the amount of carbide (increasing the carbon content), while toughness is improved by increasing the proportion of metallic matrix (reducing the carbon content). The influence of carbon content on the shape and distribution of the carbide phase in these alloys is illustrated in the photomicrographs of Fig. 4.

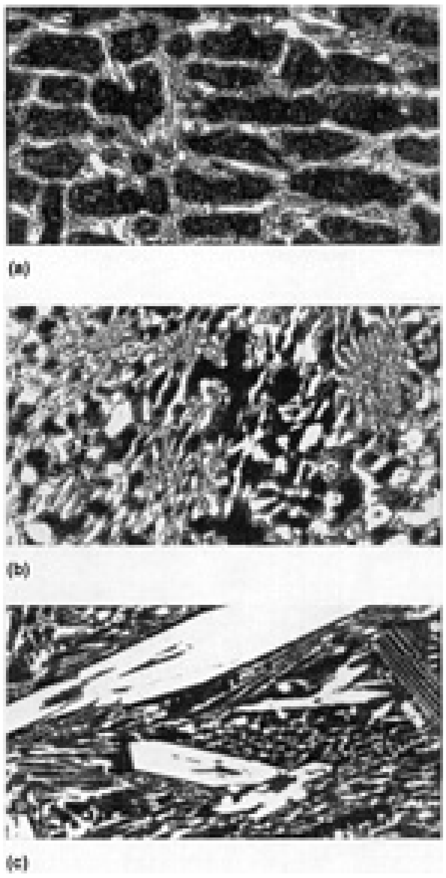

Fig. 4 Microstructures of high-chromium white iron compositions. (a) Low carbon (hypoeutectic). (b) Eutectic. (c) High-carbon (hypereutectic). All 75×. Courtesy of Climax Molybdenum Company

Large hexagonal carbide rods occur when carbon contents exceed the eutectic carbon content (Fig. 4c). These primary chromium carbides, which precipitate from the melt before eutectic solidification, are quite deleterious to impact toughness and should be avoided in castings subjected to any impact in service. The eutectic carbon content changes inversely with the chromium content in these alloys. The relationship between eutectic carbon content and chromium content is shown in Fig. 5.

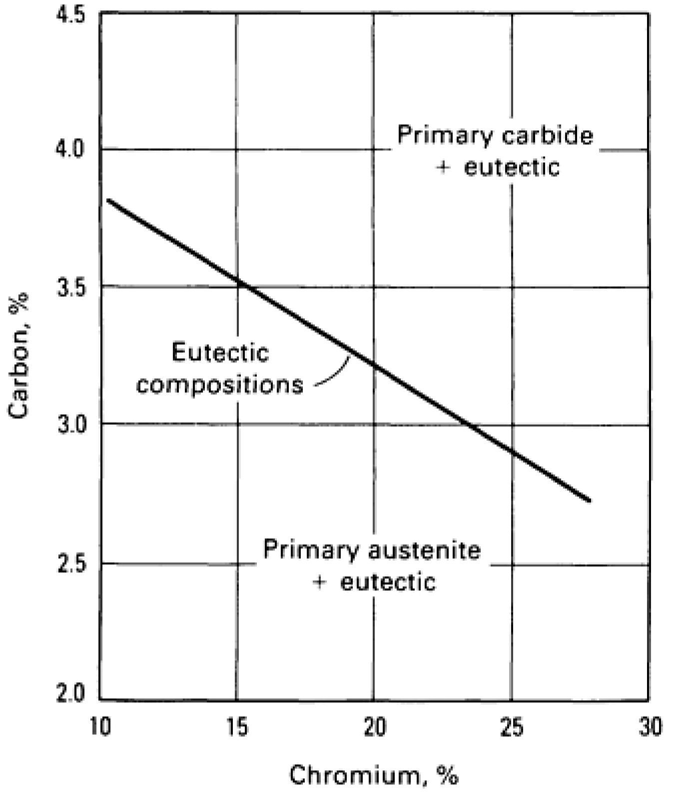

Fig. 5 Relationship between the chromium and carbon contents and the eutectic composition in high-chromium irons

As-Cast Austenitic. Solidification in the hypoeutectic alloys occurs by the formation of austenite dendrites followed by the eutectic formation of austenite and M_7C_3 chromium carbides. Under equilibrium conditions, additional chromium carbide precipitates from the austenite matrix upon cooling from the eutectic to the critical temperature, that is, about 760 °C (1400 °F), and transformation to ferrite and carbide occurs with subsequent cooling. However, when cooling under nonequilibrium conditions such as those encountered in most commercial castings, the austenite becomes supersaturated in carbon and chromium. Because of elevated carbon and chromium contents, a metastable austenitic cast iron normally develops, provided pearlitic and bainitic transformations have been inhibited (Fig. 6). With sufficient alloying with molybdenum, manganese, nickel, and copper, pearlitic transformation can be avoided in virtually any cast section.

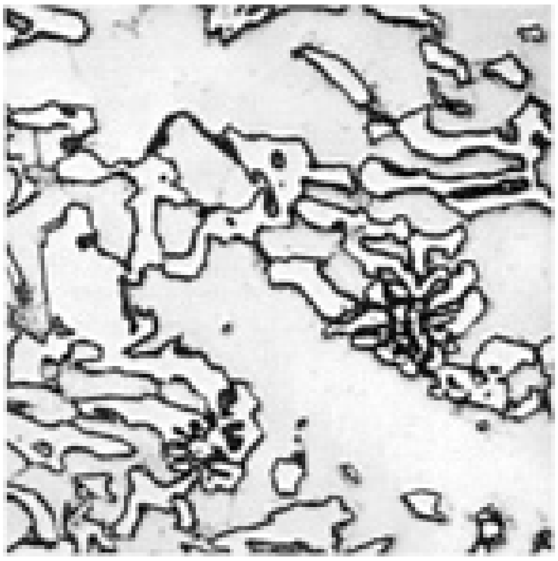

Fig. 6 High-chromium iron with an as-cast austenitic matrix microstructure. 500×. Courtesy of Climax Molybdenum Company

As-Cast Martensitic. Martensitic structures can be obtained as-cast in heavy-section castings that cool slowly in the mold. With slow cooling rates, austenite stabilization is incomplete, and partial transformation to martensite occurs. But in these castings, martensite is mixed with large amounts of retained austenite (Fig. 7), and therefore hardness levels are lower than can be achieved in heat-treated martensitic castings. These castings must contain sufficient alloy to suppress pearlite upon cooling. Some compositions (higher silicon) have been developed to assist martensite formation in refrigeration treatments. Subcritical heat treatment has been used to reduce austenite content and, at the same time increase hardness and toughness.

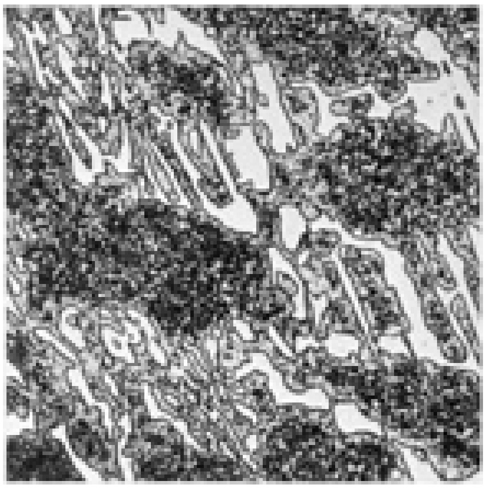

Fig. 7 High-chromium iron with an as-cast austenitic-martensitic matrix microstructure. 500×. Courtesy of Climax Molybdenum Company

Heat-Treated Martensitic. To obtain maximum hardness and abrasion resistance, martensitic matrix structures must be produced by full heat treatment. The casting must contain sufficient alloy to avoid pearlite formation upon cooling from the heat-treatment temperature.

Selecting Compositions to Obtain Desired Structures

Many complex sections, such as slurry pump components, are often used in the as-cast austenitic/martensitic condition to avoid the possibility of cracking and distortion when heat treated. To prevent pearlite in mold cooling, alloying additions are usually required. As the carbon content is increased, more chromium is consumed, forming additional carbide, and therefore, larger alloying additions are required. Table 2 presents a guide for appropriate alloying to prevent pearlite in the various classes of as-cast irons.

Table 2 Minimum alloy content to avoid pearlite in mold-cooled castings for indicated effective section size (plate thickness or radius of rounds)

ASTM A 532 class	**Cr[(a)], %**	**C[(a)], %**	Plate thickness or radius of rounds		
			25 mm (1 in.)	**50 mm (2 in.)**	100 mm (4 in.)
IIB, C	14-18	2.0	1.0 Mo	1.5 Mo	**1.5 Mo + 1.0 (Ni + Cu)**

		3.5	2.0 Mo	2.5 Mo	**2.5 Mo + 1.0 (Ni + Cu)**
IID, E	18-23	2.0	0.5 Mo	1.0 Mo	**1.0 Mo + 1.0 (Ni + Cu)**
		3.2	1.5 Mo	2.0 Mo	**2.0 Mo + 1.0 (Ni + Cu)**
IIIA	23-28	2.0	. . .	0.5 Mo	**1.0 Mo**
		3.0	**1.0 Mo**	**1.5 Mo**	**1.5 Mo + 1.0 (Ni + Cu)**

(a) In base irons containing 0.6% Si and 0.8% Mn

Optimum performance is usually achieved with heat-treated martensitic structures. Again, alloying must be sufficient to ensure a pearlitefree microstructure, with heat treatment. Of necessity, the heat treatment, discussed later in detail (see the section "Quenching" in this article), requires an air quench from the austenitizing temperature. Faster cooling rates should not be used, because the casting can develop cracks due to high thermal and/or transformation stresses. Thus, the alloy must have sufficient hardenability to allow air hardening. However, overalloying with manganese, nickel, and copper promotes retained austenite, which detracts from resistance to abrasion and spalling. Therefore, it is best to obtain adequate hardenability primarily with molybdenum. Table 3 is offered as a guide to alloying for air quenching heat-treated castings of various sections.

Table 3 Minimum alloy content to avoid pearlite in heat treatment for indicated effective section size (plate thickness or radius of rounds)

ASTM A 532 class	**Cr[(a)], %**	**C[(a)], %**	Plate thickness or radius of rounds		
			50 mm (2 in.)	**125 mm (5 in.)**	150-255 mm (6-10 in.)
IIB, C	14-18	2.0	1.5 Mo	1.5 Mo - 0.5 (Ni + Cu)	**2.0 Mo + 1.0 (Ni + Cu)**
		3.5	3.0 Mo	2.0 Mo - 1.0 (Ni + Cu)	**2.5 Mo + 1.2 (Ni + Cu)[(b)]**
IID, E	18-23	2.0	1.0 Mo	2.0 Mo	**2.0 Mo + 0.5 (Ni + Cu)**
		3.2	1.5 Mo	2.0 Mo - 0.7 (Ni + Cu)	**2.0 Mo + 1.2 (Ni + Cu)[(b)]**
IIIA	23-28	2.0	0.5 Mo	1.5 Mo	**1.5 Mo + 0.5 (Ni + Cu)**

(a) In base irons containing 0.6% Si and 0.8% Mn.

(b) Nickel and copper promote retained austenite and should be restricted to combined levels of 1.2% maximum; manganese behaves similarly and should be restricted to 1.0% maximum.

Melting Practice

The high level of carbon pickup with the high chromium contents in these alloys precludes the use of cupola melting. Consequently, electric arc and induction furnaces are normally used. The high-chromium irons are readily made in acid-, neutral-, or basic-lined electric furnaces. They are normally dead melted, and there is usually no reason to use oxygen lancing except as a means of slightly reducing carbon content. Despite rapid refractory wear due to chromium-bearing slag, acid linings are generally more economical than basic linings. Very little adjustment to slag composition is necessary in acid melting, which is used for the majority of current production. Viscous or nonfluid slags should be avoided.

Normal charge materials are various kinds of steel scrap, foundry returns, or returns of similar alloy from service. For foundries that lack the facilities for rapid melt analysis, it may be necessary to select steel scrap rather carefully to ensure that the total content of alloying elements that have a potent effect on hardenability and austenite retention is consistent and under control.

While some furnace operators prefer to add a portion of high-carbon ferrochrome to the charge, it is generally added near the end of the heat to avoid excessive oxidation losses. Carbon is obtained from electrode graphite, petroleum coke, and other sources. If pig iron is used to carburize the melt, it should have a low silicon content. The ideal silicon content is 0.6%. Less than 0.4% Si in the bath can cause difficulties with viscous slag, while higher silicon contents can promote pearlite. Selection of an incorrect grade of ferrochromium with high silicon is a common cause for an excessively high silicon content. Manganese can range from 0.5 to 1.5%, according to ASTM A 532 (see Table 1). Manganese on the high side of this range can erode acid furnace linings. Therefore, manganese content should be limited to 1% in meltdown; the remainder can be added to the ladle as crushed ferroalloy. Molybdenum is usually added as ferromolybdenum; however, with arc furnaces, molybdenum oxide briquettes may be used. Sulfur is limited to 0.06%, and phosphorus is kept to 0.10%, as specified by ASTM A 532.

High superheating temperatures have not been necessary when melting in induction furnaces, which have good stirring action, and a final temperature of 1480 °C (2700 °F) is usually adequate for thick-section castings. Final temperatures of up to 1565 °C (2850 °F) are commonly used in arc furnace practice to ensure homogeneity of the bath composition and to accelerate the solution of carbon, added after meltdown, and late alloy additions. No particular problems have been associated with high superheat temperatures, but it is more difficult to predict melting losses.

As in steel melting, deoxidation of the bath with aluminum was common in the past, but this practice has been discontinued by most producers with no adverse effects on the soundness or mechanical properties of the casting. Titanium is sometimes added to limit dendrite size. There have been reports that bath additions of aluminum and titanium aggravate feeding problems. For heats in which hardenability is marginal, there is evidence that these elements tend to promote pearlite with mold cooling or in heat-treated castings.

Pouring Practices

High pouring temperatures aggravate shrinkage under feeder heads and other hot spots and can lead to microshrinkage and coarse dendritic structures. Careful control of pouring temperature is particularly important in the consistent production of thick-section castings. Low pouring temperatures are necessary to avoid shrinkage defects and prevent problems such as metal penetration and burned-on sand. Low pouring temperatures are also effective in controlling dendrite size and the coarseness of the eutectic carbide structure.

The eutectic temperature for the various high-chromium iron grades ranges from 1230 to 1270 °C (2245 to 2315 °F), and solidification generally begins at temperatures up to 1350 °C (2460 °F), depending on composition. Pouring temperatures are seldom lower than 100 °C (180 °F) above the liquidus temperature. Castings thicker than 102 mm (4 in.) are generally poured between 1345 and 1400 °C (2450 and 2550 °F). Higher pouring temperatures may be necessary for smaller castings. Casting configurations also must be considered when selecting optimum pouring temperatures.

In the ladle or during pouring, the metal appears cold and sluggish because an oxide film readily forms on the surface; but the metal is actually quite fluid and may be poured into intricate shapes. This rather viscous surface oxide is less liable to

cause surface defects on castings that are poured quickly. Even when the metal is poured on the cold side, flasks have to be clamped, or weighted, to prevent the metal from running out at the parting line.

Molds, Patterns, and Casting Design

Molds must be rigid to minimize shrinkage defects. Molds may be made of either green sand, or of dry sand, oil sand, or steel casting sand. Air-setting and thermal-setting resin sands are also commonly used. Because white irons are subject to hot tearing, cores should break down readily.

Unless suitable precautions are taken, the high-chromium irons are somewhat more prone to crack in the foundry than are white irons of lower alloy content. Castings are occasionally found to be cracked when extracted from the mold. Stresses large enough in magnitude to cause fracture can arise when either the mold or cores are excessively strong and there is inadequate mold or core breakdown to allow normal thermal contractions upon cooling. Large cores such as those used in pump volutes, and even small cores used to form bolt holes, can cause cracking of this type.

Shrinkage allowance is 18 to 21 mm/m ($\frac{7}{32}$ to $\frac{1}{4}$ in./ft). The actual pattern allowance depends on the choice of subsequent heat treatment procedures, if any, and the geometry of the casting. Patterns should employ generous radii and avoid sharp section changes to avoid initiating cracking on solidification and subsequent cooling.

These alloys exhibit relatively high liquid-to-solid shrinkage; therefore, large gates and risers are required for feeding. Special consideration should be given to the design of end gates and to the positioning of risers so that they can be readily removed. Risers are often notched or necked down to facilitate removal by impact.

Shakeout Practices

The shakeout practice is probably the most critical step in the successful production of high-chromium iron castings. A frequent cause of high residual stresses and of cracking is the common practice of extracting castings from the mold at too high a temperature. Cooling all the way to room temperature in the mold is desirable and can be a requirement to avoid cracking, especially if martensite forms during the last stages of cooling. This precaution is mandatory in heavy-section castings to be used in the as-cast condition where the desired, mold-cooled structure is a mixture of austenite and martensite.

For irons that are heat treated, the desired mold-cooled structure is often pearlite. This softer structure facilitates removal of gates and risers, minimizes the transformational and thermal stresses that cause cracking, and shortens the response to heat treatment. Careful design of alloy composition ensures the development of a substantially pearlitic structure in the casting after mold cooling, yet provides enough hardenability to prevent pearlite formation during subsequent heat treatment. Heavy-section castings made pearlitic by such an alloy content can often be removed from the mold once the castings have reached black heat.

Heat Treatment

Toughness and abrasion resistance are improved by heat treatment to a martensitic microstructure. Figure 8, which illustrates the heat treatment process, shows the importance of slow heating to 650 °C (1200 °F) to avoid cracking. For complex shapes, a maximum rate of 30 °C/h (50 °F/h) is recommended. Simple shapes and fully pearlitic castings can be heated at faster rates. The heating rate can be accelerated above red heat.

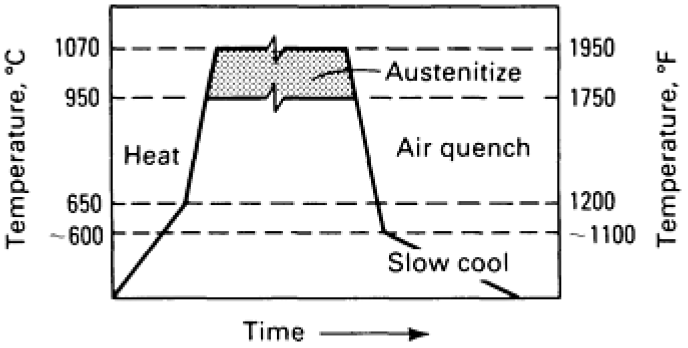

Fig. 8 Heat treatment schedule for hardening high-chromium irons

Austenitization. There is an optimum austenitizing temperature for achieving maximum hardness (Fig. 9), which varies for each composition. The austenitizing temperature determines the amount of carbon that remains in solution in the austenite matrix. Too high a temperature increases the stability of the austenite, while the higher retained austenite content reduces hardness. Low temperatures result in low-carbon martensite, reducing both hardness and abrasion resistance. Because of this sensitivity to temperature, furnaces that can produce accurate and uniform temperatures are most desirable. The successful heat treatment produces austenite destabilization by precipitation of fine, secondary M_7C_3 carbides within the austenite matrix (Fig. 10).

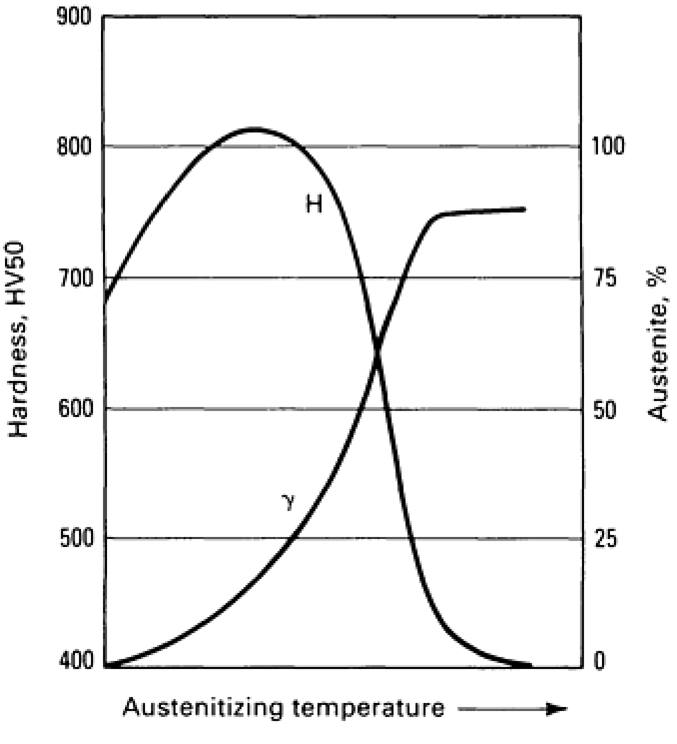

Fig. 9 Influence of austenitizing temperature on hardness (H) and retained austenite (γ) in high-chromium irons

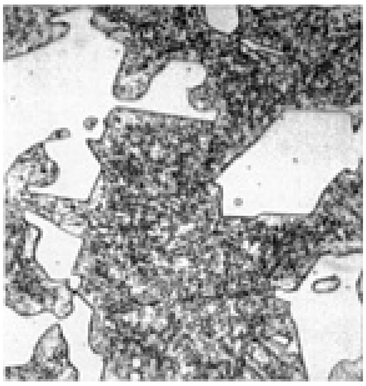

Fig. 10 Microstructure of heat-treated martensitic high-chromium iron illustrating fine secondary M_7C_3 carbides. 680×

Class II irons containing 12 to 20% Cr are austenitized in the temperature range of 955 to 1010 °C (1750 to 1850 °F). Class III irons containing 23 to 28% Cr are austenitized in the temperature range of 1010 to 1095 °C (1850 to 2000 °F). Heavy sections usually require temperatures on the upper end of the range.

Castings should be held at temperature long enough to accomplish equilibrium dissolution of chromium carbides to ensure a proper hardening response. A minimum of 4 h at temperature is necessary. For heavy sections, the rule of 1 h/in. of section thickness is usually adequate. For castings that are fully pearlitic before heat treatment, the holding time at temperature can be reduced.

Quenching. Air quenching (vigorous fan cooling) the castings from the austenitizing temperature to below the pearlite temperature range, that is, to between 550 and 600 °C (1020 and 1110 °F), is highly recommended. The subsequent cooling rate should be substantially reduced to minimize stresses; still-air or even furnace cooling to ambient temperature is common. Complex and heavy-section castings are often re-placed in the furnace, which is at 550 to 600 °C (1020 to 1110 °F), and allowed sufficient time to reach a uniform temperature within the casting. After the temperature is equalized, the castings are either furnace or still-air cooled to ambient temperature.

Tempering. Castings can be put into service in the hardened (as-cooled) condition without further tempering or subcritical heat treatments; however, tempering in the range of 205 to 230 °C (400 to 450 °F) for 2 to 4 h is recommended to restore some toughness in the martensitic matrix and to further relieve residual stresses. The microstructure after hardening always contains retained austenite in the range of 10 to 30%. Some retained austenite is transformed following tempering at low temperatures, but if spalling is a problem, higher-temperature tempering can be used to further reduce austenite content.

Subcritical Heat Treatment. Subcritical heat treatment (tempering) is sometimes performed, particularly in large heat-treated martensitic castings, to reduce retained austenite content and increase resistance to spalling. The tempering parameters necessary to eliminate retained austenite are very sensitive to time and temperature and depend on the casting composition and prior thermal history. Typical tempering temperatures range from 480 to 540 °C (900 to 1000 °F), and times range from 8 to 12 h. Excess time or temperature results in softening and a drastic reduction in abrasion resistance. Insufficient tempering results in incomplete elimination of austenite. The amount of retained austenite cannot be determined metallographically; those experienced with this heat treatment practice have developed techniques using specialized magnetic instruments to determine the level of retained austenite after tempering.

Annealing. Castings can be annealed to make them more machinable, either by subcritical annealing or by a full anneal. Subcritical annealing is accomplished by pearlitizing by means of soaking in the narrow range between 695 and 705 °C (1280 and 1300 °F) for 4 to 12 h, which produces hardnesses ranging from 400 to 450 HB. Lower hardnesses often can be achieved with full annealing, in which castings are heated in the range of 955 to 1010 °C (1750 to 1850 °F), followed by slow cooling to 760 °C (1400 °F), and holding at this temperature for 10 to 50 h, depending on composition. Annealing affects neither the primary carbides nor the potential for subsequent hardening; guidelines for hardening as-cast castings also apply to annealed castings.

Machining

These alloyed white irons are generally ground to finish size; care must be exercised to avoid cracking by overheating. Single-point turning and boring can be done using heavy tooling, rigid setups, sufficient power, and carbide- or boride-tipped cutters or special ceramic inserts. Electrical discharge machining and electrochemical machining are also feasible.

Applications

The high-chromium white irons are superior in abrasion resistance and are used effectively in impellers and volutes in slurry pumps, classifier wear shoes, brick molds, impeller blades and liners for shot blasting equipment, and refiner disks in pulp refiners. In many applications they withstand heavy impact loading, such as from impact hammers, roller segments and ring segments in coal-grinding mills, feed-end lifter bars and mill liners in ball mills for hard-rock mining, pulverizer rolls, and rolling mill rolls.

Special High-Chromium Iron Alloys

Irons for Corrosion Resistance. Alloys with improved resistance to corrosion, for applications such as pumps for handling fly ash, are produced with high-chromium content (26 to 28% Cr) and low-carbon content (1.6 to 2.0% C). These high-chromium, low-carbon irons provide the maximum chromium content in the matrix. The addition of 2% Mo is recommended for improving resistance to chloride-containing environments. For this application, fully austenitic matrix structures provide the best resistance to corrosion, but some reduction in abrasion resistance must be expected. Castings are normally supplied in the as-cast condition.

Irons for High-Temperature Service. Because of castability and cost, high-chromium white iron castings can often be used for complex and intricate parts in high-temperature applications at considerable savings compared to stainless steel. These cast iron grades are alloyed with 12 to 39% Cr at temperatures up to 1040 °C (1900 °F) for scaling resistance. Chromium causes the formation of an adherent, complex, chromium-rich oxide film at high temperatures. The high-chromium irons designated for use at elevated temperatures fall into one of three categories, depending on the matrix structure:

- Martensitic irons alloyed with 12 to 28% Cr
- Ferritic irons alloyed with 30 to 34% Cr
- Austenitic irons which, in addition to containing 15 to 30% Cr, also contain 10 to 15% Ni to stabilize the austenite phase

The carbon contents of these alloys range from 1 to 2%. The choice of an exact composition is critical to the prevention of σ phase formation at intermediate temperatures and at the same time avoids the ferrite-to-austenite transformation during thermal cycling, which leads to distortion and cracking. Typical applications include recuperator tubes, breaker bars and trays in sinter furnaces, grates, burner nozzles and other furnace parts, glass bottle molds, and valve seats for combustion engines.

High-Alloy White Irons

Malleable Iron

Introduction

MALLEABLE IRON is a cast ferrous metal that is initially produced as white cast iron and is then heat treated to convert the carbon-containing phase from iron carbide to a nodular form of graphite called temper carbon. There are two types of ferritic malleable iron: blackheart and whiteheart. Only the blackheart type is produced in the United States. This material has a matrix of ferrite with interspersed nodules of temper carbon. Cupola malleable iron is a blackheart malleable iron that is produced by cupola melting and is used for pipe fittings and similar thin-section castings. Because of its low strength and ductility, cupola malleable iron is usually not specified for structural applications. Pearlitic malleable iron is designed to have combined carbon in the matrix, resulting in higher strength and hardness than ferritic malleable iron. Martensitic malleable iron is produced by quenching and tempering pearlitic malleable iron.

Malleable iron, like ductile iron, possesses considerable ductility and toughness because of its combination of nodular graphite and low-carbon metallic matrix. Because of the way in which graphite is formed in malleable iron, however, the nodules are not truly spherical as they are in ductile iron but are irregularly shaped aggregates.

Malleable iron and ductile iron are used for some of the same applications in which ductility and toughness are important. In many cases, the choice between malleable and ductile iron is based on economy or availability rather than on properties. In certain applications, however, malleable iron has a distinct advantage. It is preferred for thin-section castings; for parts that are to be pierced, coined, or cold formed; for parts requiring maximum machinability; for parts that must retain good impact resistance at low temperatures; and for some parts requiring wear resistance (martensitic malleable iron only).

Ductile iron has a clear advantage where low solidification shrinkage is needed to avoid hot tears or where the section is too thick to permit solidification as white iron. (Solidification as white iron throughout a section is essential to the production of malleable iron.) Malleable iron castings are produced in section thicknesses ranging from about 1.5 to 100 mm ($\frac{1}{16}$ to 4 in.) and in weights from less than 0.03 to 180 kg ($\frac{1}{16}$ to 400 lb) or more.

Composition. The chemical composition of malleable iron generally conforms to the ranges given in Table 1. Small amounts of chromium (0.01 to 0.03%), boron (0.0020%), copper (~1.0%), nickel (0.5 to 0.8%), and molybdenum (0.35 to 0.5%) are also sometimes present.

Table 1 Chemical composition of malleable iron

Element	Composition,%
Carbon	**2.16-2.90**
Silicon	**0.90-1.90**
Manganese	**0.15-1.25**
Sulfur	**0.02-0.20**
Phosphorus	**0.02-0.15**

Five-digit designations are assigned in ASTM A 47 (Ref 1), which covers two grades of ferritic malleable iron, and in A 220 (Ref 2), which deals with pearlitic malleable iron. The first three digits indicate the minimum yield strength (in kips per square inch), and the last two indicate the minimum percentage of elongation in 50 mm (2 in.). Another standard, ASTM A 602 (Ref 3), covers both types of malleable iron; it assigns an "M" and four digits. The first two digits are typical yield strength in kips per square inch, and the last two are typical percentage of elongation in 50 mm (2 in.) test specimens cut from actual cast parts.

Melting Practices

Melting can be accomplished by batch cold melting or by duplexing. Cold melting is done in coreless or channel-type induction furnaces, electric arc furnaces, or cupola furnaces. In duplexing, the iron is melted in a cupola or electric arc furnace, and the molten metal is transferred to a coreless or channel-type induction furnace for holding and pouring. Charge materials (foundry returns, steel scrap, ferroalloys, and, except in cupola melting, carbon) are carefully selected, and the melting operation is well controlled to produce metal having the desired composition and properties. Minor corrections in composition and pouring temperature are made in the second stage of duplex melting, but most of the process control is done in the primary melting furnace. Detailed information on induction furnaces, electric arc furnaces, and cupolas is available in the articles "Melting Furnaces: Electric Arc Furnaces," "Melting Furnaces: Induction Furnaces," and "Melting Furnaces: Cupolas" in this Volume.

Molds are produced in green sand, silicate CO_2 bonded sand, or resin bonded sand (shell molds) on equipment ranging from highly mechanized or automated machines to that required for floor or hand molding methods, depending on the size and number of castings to be produced (see the article "Sand Molding" in this Volume). In general, the technology of molding and pouring malleable iron is similar to that used to produce gray iron (see the article "Gray Iron" in this Volume). Heat treating is done in high-production controlled-atmosphere continuous furnaces or batch-type furnaces, again depending on production requirements.

After it solidifies and cools, the metal is in a white iron state, and gates, sprues, and feeders can be easily removed from the castings by impact. This operation, called spruing, is generally performed manually with a hammer because the diversity of castings produced in the foundry makes the mechanization or automation of spruing very difficult. After spruing, the castings proceed to heat treatment, while gates and risers are returned to the melting department for reprocessing.

Malleable iron castings are produced from the white iron by a two-stage annealing process. First- and second-stage annealing processes are described in detail in the section "Control of Annealing" in this article.

After heat treatment, ferritic or pearlitic malleable castings are cleaned by shotblasting, gates are removed by shearing or grinding, and, where necessary, the castings are coined or punched. Close dimensional tolerances can be maintained in ferritic malleable iron and in the lower-hardness types of pearlitic malleable iron, both of which can be easily straightened in dies. The harder pearlitic malleable irons are more difficult to press because of higher yield strength and a greater tendency toward springback after die pressing. However, even the highest-strength pearlitic malleable can be straightened to achieve good dimensional tolerances.

Control of Melting. Metallurgical control of the melting operation is designed to ensure that the molten iron will have a certain composition and will:

- Solidify white in the castings to be produced
- Anneal on an established time-temperature cycle set to minimum values in the interest of economy
- Produce the desired graphite distribution (nodule count) upon annealing

Changes in melting practice or composition that would satisfy the first requirement listed above are generally opposed to satisfaction of the second and third, while attempts to improve annealability beyond a certain point may result in an unacceptable tendency for the as-cast iron to be mottled instead of white.

The common elements in malleable iron are generally controlled within about ±0.05 to ±0.15%. A limiting minimum carbon content is required in the interest of mechanical quality and annealability because decreasing carbon content reduces the fluidity of the molten iron, increases shrinkage during solidification, and reduces annealability. A limiting maximum carbon content is imposed by the requirement that the casting be white as-cast. The range in silicon content is limited to ensure proper annealing during a short-cycle high-production annealing process and to avoid the formation of primary graphite during solidification. Manganese and sulfur contents are balanced to ensure that all sulfur is combined with manganese and that only a safe, minimum quantity of excess manganese is present in the iron. An excess of either sulfur or manganese will retard annealing in the second stage and therefore increase annealing costs. The chromium content is kept low because of the carbide-stabilizing effect of this element and because it retards both the first-stage and second-stage annealing reactions.

A mixture of gray iron and white iron in variable proportions that produces a mottled (speckled) appearance is particularly damaging to the mechanical properties of the annealed casting, whether ferritic or pearlitic malleable iron. Primary control of mottle is achieved by maintaining a balance of carbon and silicon contents.

Because economy and castability are enhanced when the carbon and silicon contents of the base iron are in the higher portions of their respective ranges, some malleable iron foundries produce iron with carbon and silicon contents at levels that might produce mottle and then add a balanced, mild carbide stabilizer to prevent mottle during casting. Bismuth and boron in balanced amounts accomplish this control. A typical addition is 0.01% Bi (as metal) and 0.001% B (as ferroboron). Bismuth retards graphitization during solidification; small amounts of boron have little effect on graphitizing tendency during solidification, but accelerate carbide decomposition during annealing. The balanced addition of bismuth and boron permits the production of heavier sections for a given base iron or the utilization of a higher-carbon higher-silicon base iron for a given section thickness.

Tellurium can be added in amounts of 0.0005 to 0.001% to suppress mottle. Tellurium is a much stronger carbide stabilizer than bismuth during solidification, but also strongly retards annealing if the residual exceeds 0.003%. Less than 0.003% residual tellurium has little effect on annealing, but has a significant influence on mottle control. Tellurium is more effective if added together with copper or bismuth.

Residual boron should not exceed 0.0035% in order to avoid nodule alignment and carbide formation. Also, the addition of 0.005% Al to the pouring ladle significantly improves annealability without promoting mottle.

Microstructure

Malleable iron is characterized by microstructures consisting of uniformly dispersed fine particles of free carbon in a matrix of ferrite or tempered martensite. These microstructures can be produced in base metal of essentially the same composition. Structural differences between ferritic malleable iron and the various grades of pearlitic or martensitic malleable iron are achieved through variations in heat treatment. The microstructure of a casting of any type of malleable iron is derived by controlled annealing of white iron of suitable composition. During the annealing cycle, carbon that exists in combined form, either as massive carbides or as a microconstituent in pearlite, is converted to a form of free graphite known as temper carbon.

Ferritic malleable iron requires a two-stage annealing cycle. The first stage converts primary carbides to temper carbon, and the second stage converts the carbon dissolved in austenite at the first-stage annealing temperature to temper carbon and ferrite.

The microstructure of ferritic malleable iron is shown in Fig. 1. A satisfactory structure consists of temper carbon in a matrix of ferrite. There should be no flake graphite and essentially no combined carbon in ferritic malleable iron. Pearlitic and martensitic malleable irons contain a controlled quantity of combined carbon, which, depending on heat treatment, may appear in the metallic matrix as lamellar pearlite, tempered martensite, or spheroidite.

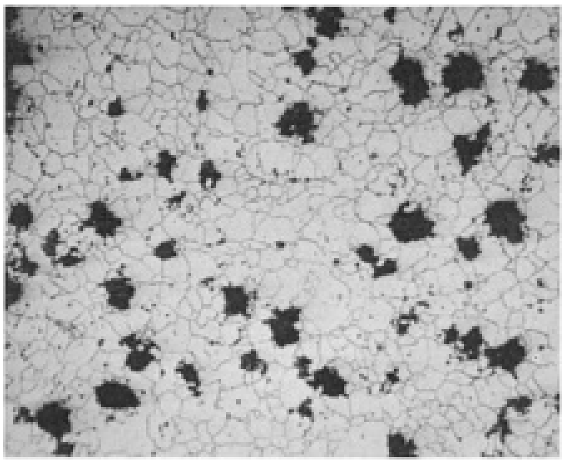

Fig. 1 Structure of annealed ferritic malleable iron showing temper carbon in ferrite. 100×

Molten iron produced under properly controlled melting conditions solidifies with all carbon in the combined form, producing the white iron structure fundamental to the manufacture of either ferritic or pearlitic malleable iron (Fig. 2). The base iron must contain balanced quantities of carbon and silicon to simultaneously provide castability, white iron in even the thickest sections of the castings, and annealability; therefore, precise metallurgical control is necessary for quality production. Thick metal sections cool slowly during solidification and tend to graphitize, producing mottled or gray iron. This is undesirable, because the graphite formed in mottled iron or rapidly cooled gray iron is generally of the type D configuration, a flake form in a dense, lacy structure, which is particularly damaging to the strength, ductility, and stiffness characteristics of both ferritic and pearlitic malleable iron.

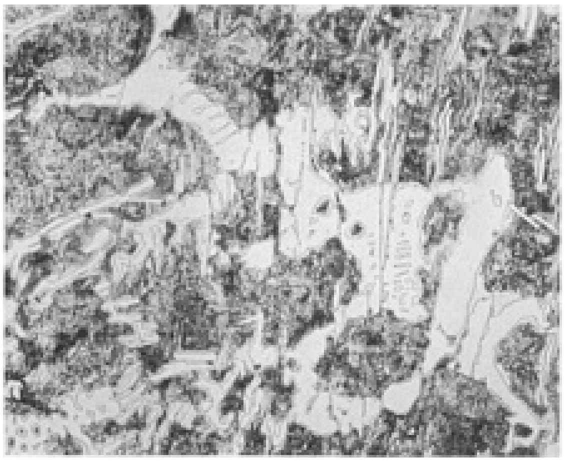

Fig. 2 Structure of as-cast malleable white iron showing a mixture of pearlite and eutectic carbides. 400×

Control of Nodule Count. Proper annealing in short-term cycles and the attainment of high levels of casting quality require that controlled distribution of graphite particles be obtained during first-stage heat treatment. With low nodule count (few graphite particles per unit area or volume), mechanical properties are reduced from optimum, and second-stage annealing time is unnecessarily long because of long diffusion distances. Excessive nodule count is also undesirable, because graphite particles may become aligned in a configuration corresponding to the boundaries of the original primary cementite. In martensitic malleable iron, very high nodule counts are sometimes associated with low hardenability and nonuniform tempering. Generally, a nodule count of 80 to 150 discrete graphite particles per square millimeter (80 to 150 in 15.5 in.^{2} of a photomicrograph at 100×) appears to be optimum. This produces random particle distribution, with short distances between particles.

Temper carbon is formed predominantly at the interface between primary carbide and saturated austenite at the first-stage annealing temperature, with growth around the nuclei taking place by a reaction involving diffusion and carbide decomposition, Although new nuclei undoubtedly form at the interfaces during holding at the first-stage annealing temperature, nucleation and graphitization are accelerated by the presence of nuclei that are created by appropriate melting practice. High silicon and carbon contents promote nucleation and graphitization, but these elements must be restricted to certain maximum levels because of the necessity that the iron solidify white.

Control of Annealing. The rate of annealing of a hard iron casting depends on chemical composition, nucleation tendency (as discussed above), and annealing temperature. With the proper balance of boron content and graphitic materials in the charge, optimum number and distribution of graphite nuclei are developed in the early part of first-stage annealing, and growth of the temper carbon particles proceeds rapidly at any annealing temperature. An optimum iron will anneal completely through the first-stage reaction in approximately $3\frac{1}{2}$ h at 940 °C (1720 °F). Irons with lower silicon contents or less-than-optimum nodule counts may require as much as 20 h for completion of first-stage annealing.

The temperature of first-stage annealing exercises considerable influence on the rate of annealing and the number of graphite particles produced. Increasing the annealing temperature accelerates the rate of decomposition of primary carbide and produces more graphite particles per unit volume. However, high first-stage annealing temperatures can result in excessive distortion of castings during annealing, which leads to straightening of the casting after heat treatment. Annealing temperatures are adjusted to provide maximum practical annealing rates and minimum distortion and are therefore controlled within the range of 900 to 970 °C (1650 to 1780 °F). Lower temperatures result in excessively long annealing times, while higher temperatures produce excessive distortion.

After first-stage annealing, the castings are cooled as rapidly as practical to 740 to 760 °C (1360 to 1400 °F) in preparation for second-stage annealing. The fast cooling step requires 1 to 6 h, depending on the equipment being employed. Castings are then cooled slowly at a rate of about 3 to 11 °C (5 to 20 °F) per hour. During cooling, the carbon dissolved in the austenite is converted to graphite and deposited on the existing particles of temper carbon. This results in a fully ferritic matrix.

In the production of pearlitic malleable iron, the first-stage heat treatment is identical to that used for ferritic malleable iron. However, some foundries then slowly cool the castings to about 870 °C (1600 °F). During cooling, the combined carbon content of the austenite is reduced to about 0.75%, and the castings are then air cooled. Air cooling is accelerated by an air blast to avoid the formation of ferrite envelopes around the temper carbon particles (bull's-eye structure) and to produce a fine pearlitic matrix (Fig. 3). The castings are then tempered to specification, or they are reheated to reaustenitize at about 870 °C (1600 °F), oil quenched, and tempered to specification. Large foundries usually eliminate the reaustenitizing step and quench the castings in oil directly from the first-stage annealing furnace after stabilizing the temperature at 845 to 870 °C (1550 to 1600 °F).

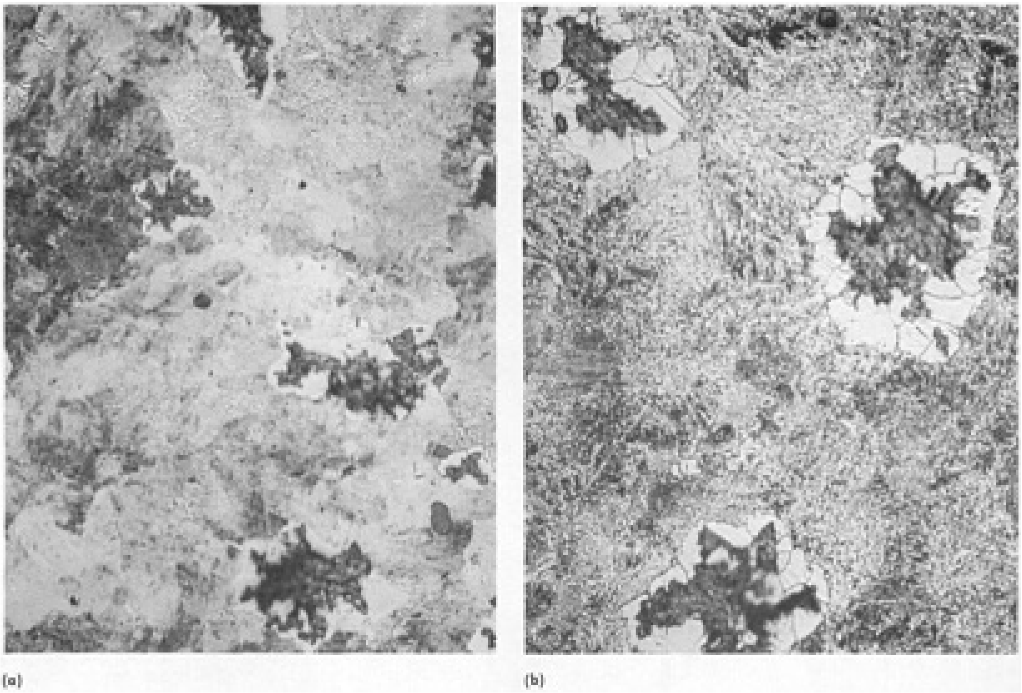

Fig. 3 Structure of air-cooled pearlitic malleable iron. (a) Slowly air cooled. 400×. (b) Cooled in an air blast. 400×

The furnace atmosphere for producing malleable iron in continuous furnaces is controlled so that the ratio of CO to CO_2 is between 1:1 and 20:1. In addition, any sources of water vapor or hydrogen are eliminated; the presence of hydrogen is thought to retard annealing, and it produces excessive decarburization of casting surfaces. Proper control of the gas atmosphere is important for avoiding an undesirable surface structure. A high ratio of CO to CO_2 retains a high level of combined carbon on the surface of the casting and produces a pearlitic rim, or picture frame, on a ferritic malleable iron part. A low ratio of CO to CO_2 permits excessive decarburization, which forms a ferritic skin on the casting with an underlying rim of pearlite. The latter condition is produced when a significant portion of the subsurface metal is decarburized to the degree that no temper carbon nodules can be developed during first-stage annealing. When this occurs, the dissolved carbon cannot precipitate from the austenite, except as the cementite plates in pearlite.

The rate of cooling after first-stage annealing is important in the formation of a uniform pearlitic matrix in the air-cooled casting, because slow rates permit partial decomposition of carbon in the immediate vicinity of the temper carbon nodules, which results in the formation of films of ferrite around the temper carbon (bull's-eye structure). When the extent of these films becomes excessive, a carbon gradient is developed in the matrix. Air cooling is usually done at a rate not less than about 80 °C (150 °F) per minute.

Air-quenched malleable iron castings have hardnesses ranging from 269 to 321 HB, depending on casting size and cooling rate. Such castings can be tempered immediately after air cooling to obtain pearlitic malleable iron with a hardness of 241 HB or less.

High-strength malleable iron castings of uniformly high quality are usually produced by liquid quenching and tempering, using any of the three procedures. The most economical procedure is direct quenching after first-stage annealing. In this procedure, castings are cooled in the furnace to the quenching temperature of 845 to 870 °C (1550 to 1600 °F) and held for 15 to 30 min to homogenize the matrix. The castings are then quenched in agitated oil to develop a matrix microstructure of martensite having a hardness of 415 to 601 HB. Finally, the castings are tempered at an appropriate temperature between 590 and 725 °C (1100 and 1340 °F) to develop the specified mechanical properties. The final microstructure consists of tempered martensite plus temper carbon, as shown in Fig. 4. In heavy sections, higher-temperature transformation products such as fine pearlite are usually present.

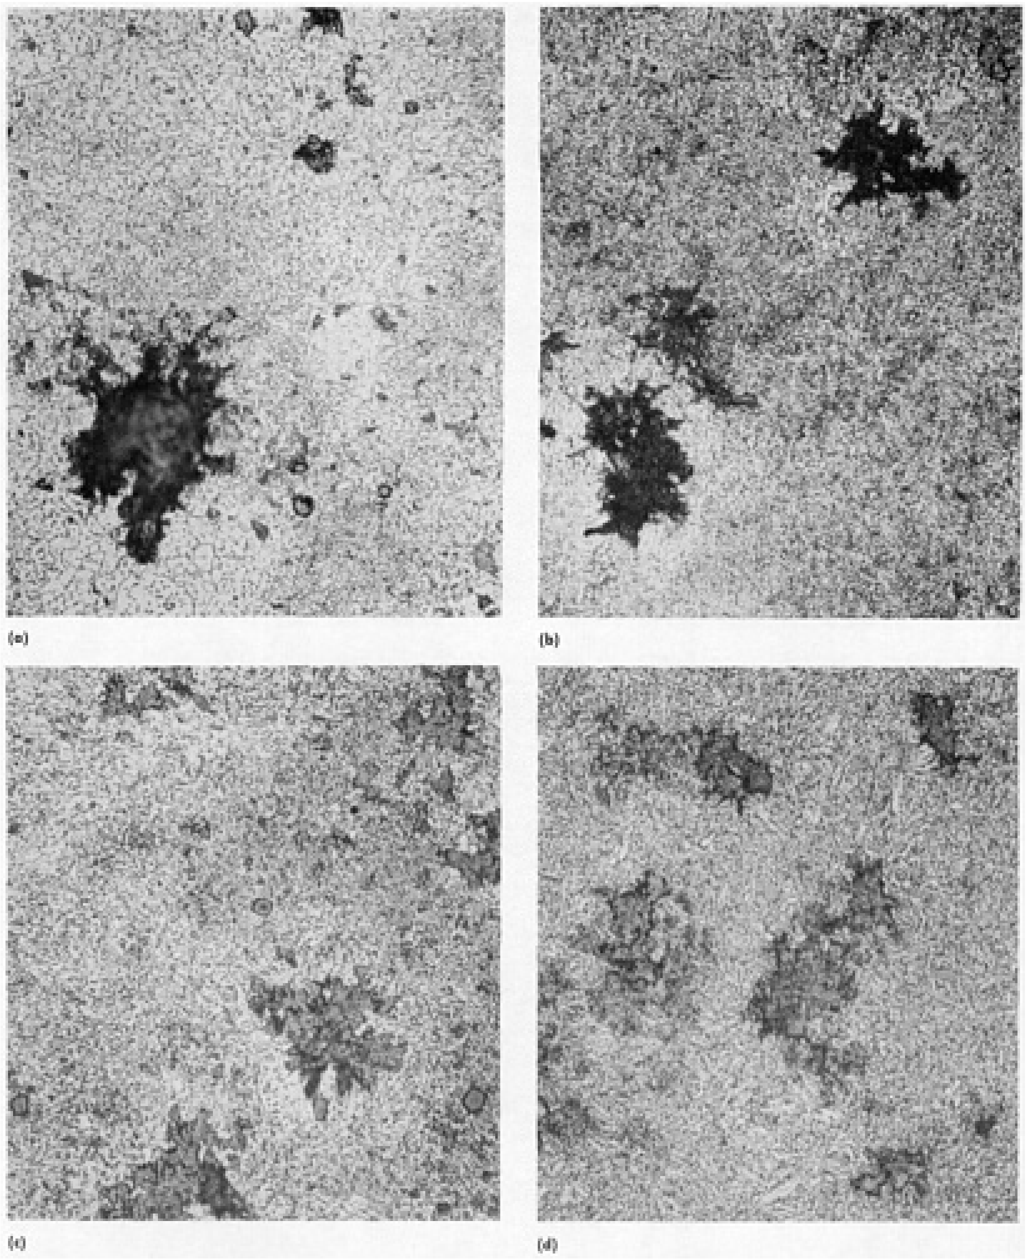

Fig. 4 Structure of all-quenched and tempered martensitic malleable iron. (a) 163 HB. 500×. (b) 179 HB. 500×. (c) 207 HB. 500×. (d) 229 HB. 500×

Some foundries produce high-strength malleable iron by an alternative procedure in which the castings are forced-air cooled after first-stage annealing, retaining about 0.75% C as pearlite, and then reheated to 840 to 870 °C (1545 to 1600 °F) for 15 to 30 min, followed by quenching and tempering as described above for the direct-quench process.

Rehardened-and-tempered malleable iron can also be produced from fully annealed ferritic malleable iron with a slight variation from the heat treatment used for arrested-annealed (air-quenched) malleable. The matrix of fully annealed ferritic malleable iron is essentially carbon free, but can be recarburized by heating at 840 to 870 °C (1545 to 1600 °F) for 1 h. In general, the combined carbon content of the matrix produced by this procedure is slightly lower than that of arrested-annealed pearlitic malleable iron, and the final tempering temperatures required for the development of specific hardnesses are lower. Rehardened malleable iron made from ferritic malleable may not be capable of meeting certain specifications.

Tempering times of 2 h or more are needed for uniformity. In general, control of final hardness of the castings is precise, with process limitations approximately the same as those encountered in the heat treatment of medium- or high-carbon steels. This is particularly true when specifications require hardnesses of 241 to 321 HB where control limits of ±0.2 mm

Brinell diameter can be maintained with ease. At lower hardnesses, a wider process control limit is required because of certain unique characteristics of the pearlitic malleable iron microstructure. The relationships between tempering conditions and properties (yield strength and hardness) are illustrated in Fig. 5.

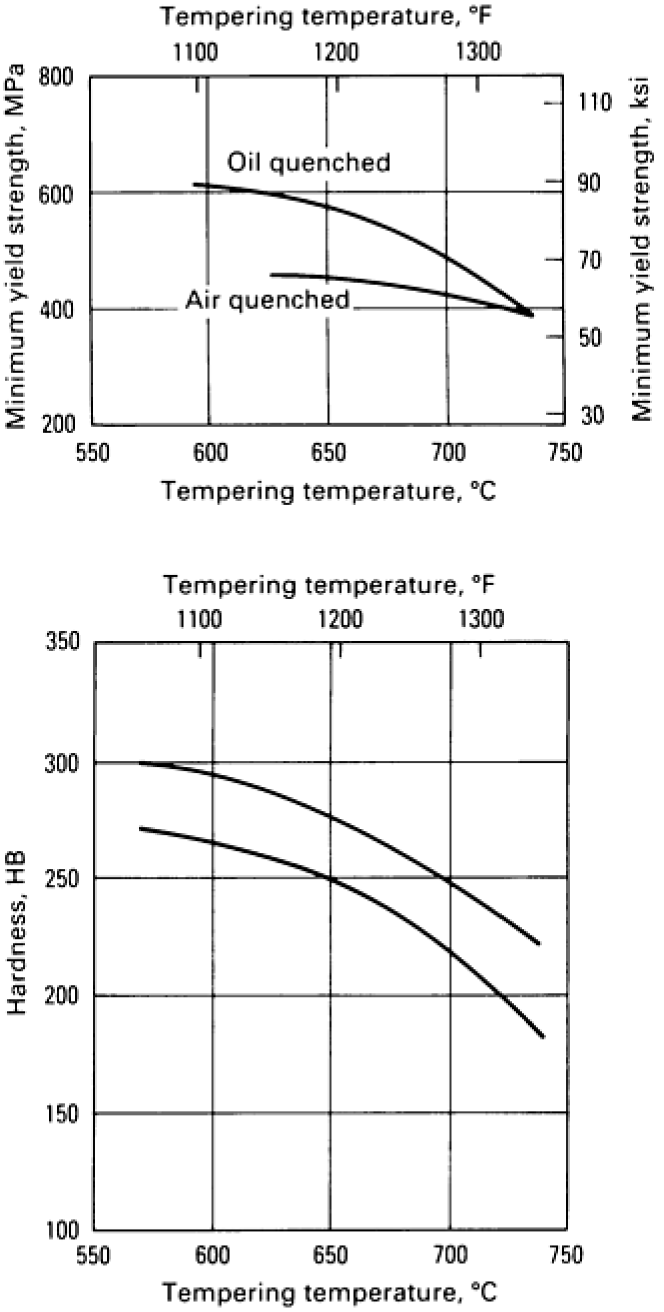

Fig. 5 Hardness and minimum yield strength of pearlitic malleable iron. Relationships of tempering time and temperature to hardness and minimum yield strength are given.

Applications

The requirement that any iron produced for conversion to malleable iron must solidify white places definite section thickness limitations on the malleable iron industry. Thick metal sections can be produced by melting a base iron of low carbon and silicon contents or by alloying the molten iron with a carbide stabilizer. However, when carbon and silicon are maintained at low levels, difficulty is invariably encountered in annealing, and the time required to convert primary and pearlitic carbides to temper carbon becomes excessively long. High-production foundries are usually reluctant to produce castings more than about 40 mm ($1\frac{1}{2}$ in.) thick. Some foundries, however, routinely produce castings as thick as 100 mm (4 in.).

Automotive and associated applications of ferritic and pearlitic malleable irons include many essential parts in vehicle power trains, frames, suspensions, and wheels. A partial list includes differential carriers, differential cases, bearing caps, steering-gear housings, spring hangers, universal-joint yokes, automatic-transmission parts, rocker arms, disc brake calipers, wheel hubs, and many other miscellaneous castings. Examples are shown in Fig. 6. Ferritic and pearlitic malleable irons are also used in the railroad industry and in agricultural equipment, chain links, ordnance material, electrical pole line hardware, hand tools, and other parts requiring section thicknesses and properties obtainable in these materials.

Malleable iron castings are often selected because the material has excellent machinability in addition to significant ductility. In other applications, malleable iron is chosen because it combines castability with good toughness and machinability. Malleable iron is often chosen because of shock resistance alone. Table 2 lists some of the typical applications of malleable iron castings.

Table 2 Applications of malleable iron castings

Mechanical properties are given in Table 3.

Specification No.	**Class or grade**	**Microstructure**	Typical applications
Ferritic			
ASTM A 47, ANSI G48.1, FED QQ-1-666c	32510, 35018	Temper carbon and ferrite	**General engineering service at normal and elevated temperatures for good machinability and excellent shock resistance**

Ferritic Malleable Iron

Because ferritic malleable iron consists of only ferrite and temper carbon, the properties of ferritic malleable castings depend on the quantity, size, shape, and distribution of the temper carbon particles and on the composition of the ferrite. Fully annealed ferritic malleable iron castings contain 2.00 to 2.70% graphitic carbon by weight, which is equivalent to about 6 to 8% by volume. Because the graphitic carbon contributes nothing to the strength of the castings, those with the lesser amount of graphite are somewhat stronger and more ductile than those containing the greater amount (assuming equal size and distribution of graphite particles). Elements such as silicon and manganese in solid solution in the ferritic matrix contribute to the strength and reduce the elongation of the ferrite. Therefore, by varying base metal composition, slightly different strength levels can be obtained in the fully annealed ferritic product. Table 3 lists specifications and properties applicable to malleable iron castings.

Table 3 Properties of malleable iron castings

Microstructures and typical applications are given in Table 2.

The mechanical properties that are most important for design purposes are tensile strength, yield strength, modulus of elasticity, fatigue strength, and impact strength. Hardness can be considered no more than an approximate indicator that the ferritizing anneal was complete, and it is seldom used for any other purpose. The hardness of ferritic malleable iron almost always ranges from 110 to 156 HB.

The tensile properties of ferritic malleable iron (Table 3) are usually measured on unmachined test bars. Machined test bars are normally used for pearlitic malleable iron.

The fatigue limit of unnotched ferritic malleable iron is about 50% of the tensile strength, or from 170 to 205 MPa (25 to 30 ksi). Figure 7 summarizes the effects of notches on fatigue strength. Notch radius generally has little effect on fatigue strength, but fatigue strength decreases with increasing notch depth.

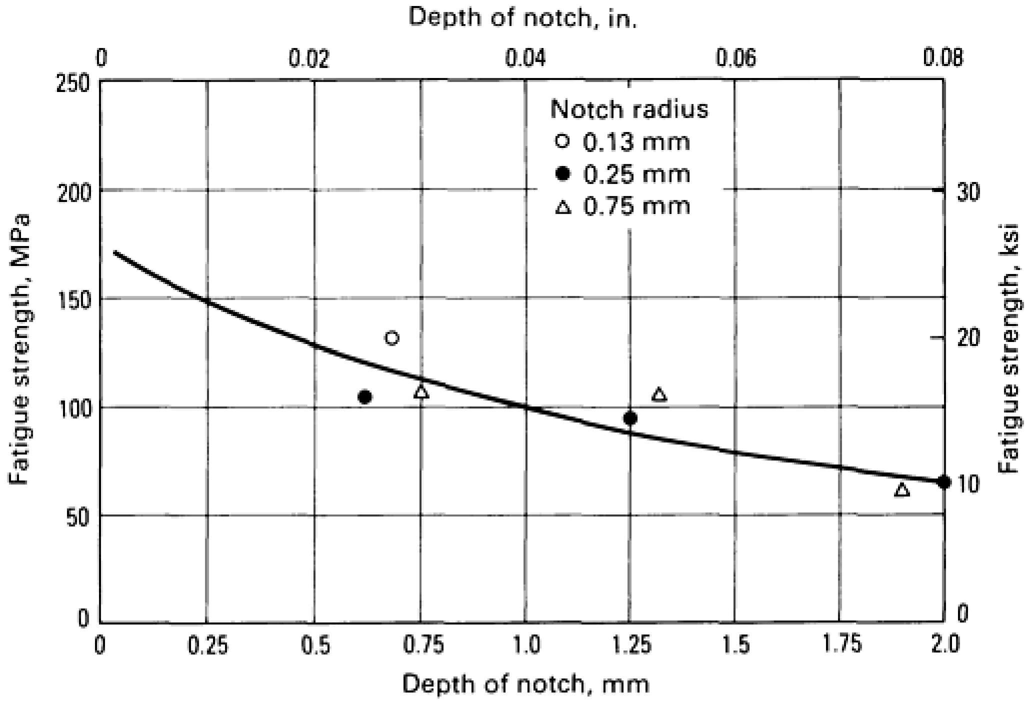

Fig. 7 Effects of notch radius and notch depth on the fatigue strength of ferritic malleable iron

Modulus of elasticity in tension is about 170 GPa (25 × 10^6 psi). The modulus in compression ranges from 150 to 170 GPa (22 × 10^6 to 25 × 10^6 psi); in torsion, from 65 to 75 GPa (9.5 × 10^6 to 11 × 10^6 psi).

Because brittle fractures are most likely to occur at high strain rates, at low temperatures, and with a high restraint on metal deformation, notch tests such as the Charpy V-notch test are conducted over a range of test temperatures to establish the toughness behavior and the temperature range of transition from a ductile to a brittle fracture. Figure 8 illustrates the behavior of ferritic malleable iron and several types of pearlitic malleable iron in the Charpy V-notch test. This shows that ferritic malleable iron has a higher upper shelf energy and a lower transition temperature to a brittle fracture than pearlitic malleable iron does. Additional information on fracture toughness of malleable irons can be found later in the discussion of "Pearlitic and Martensitic Malleable Iron" in this article.

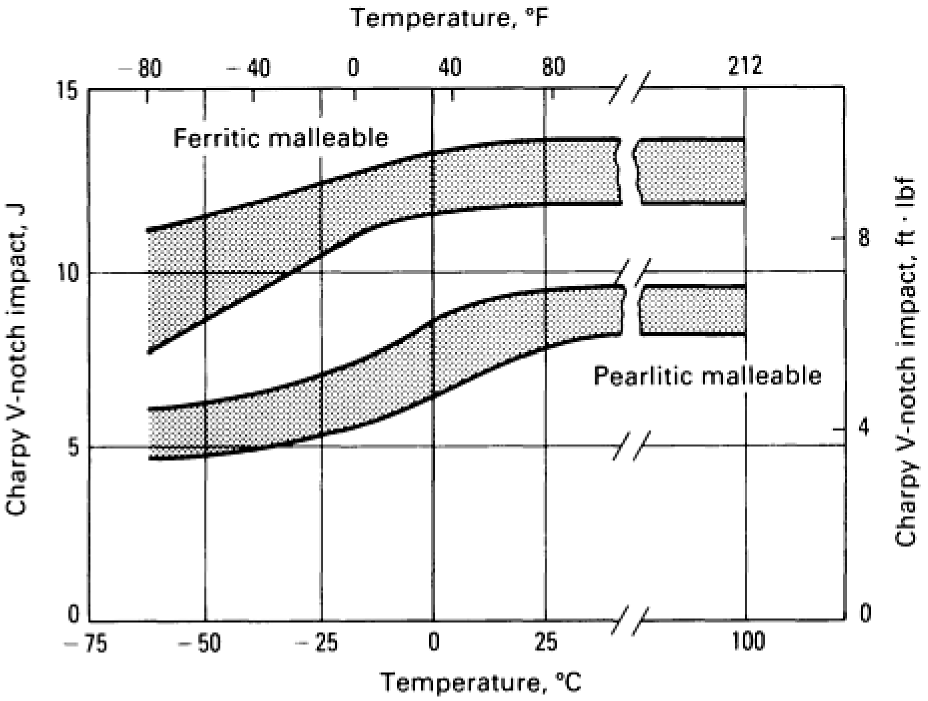

Fig. 8 Charpy V-notch transition curves for ferritic and pearlitic malleable irons. Source: Ref 4

Short-term tensile properties show no significant change to 370 °C (700 °F). Sustained-load stress rupture data from 425 to 650 °C (800 to 1200 °F) are given in Fig. 9.

The solid lines are curves determined by the method of least squares from the existing data and are least squares fit to data. The dashed lines define the 90% symmetrical tolerance interval. The lower dashed curve defines time and load for 95% survivors, and the upper dashed curve is the boundary for 5% survivors. Normal distribution is assumed. Source: Ref 1

The corrosion resistance of ferritic malleable iron is increased by the addition of copper, usually about 1%, in certain applications, for example, conveyor buckets, bridge castings, pipe fittings, railroad switch stands, and freight-car hardware. One important use for copper-bearing ferritic malleable iron is chain links. Ferritic malleable iron can be galvanized to provide added protection. The effects of copper on the corrosion resistance of ferrous alloys are well documented in Volume 13 of the 9th Edition of *Metals Handbook.*

Welding and Brazing. Welding of ferritic malleable iron almost always produces brittle white iron in the weld zone and the portion of the heat-affected zone immediately adjacent to the weld zone. During welding, temper carbon is dissolved, and upon cooling it is reprecipitated as carbide rather than graphite. In some cases, welding with a cast iron electrode may produce a brittle gray iron weld zone. The loss of ductility due to welding may not be serious in some applications. However, welding is usually not recommended unless the castings are subsequently annealed to convert the carbide to temper carbon and ferrite. Ferritic malleable iron can be fusion welded to steel without subsequent annealing if a completely decarburized zone as deep as the normal heat-affected zone is produced at the faying surface of the malleable iron part before welding. Silver brazing and tin-lead soldering can be satisfactorily used. Additional information on welding can be found in the article "Welding of Cast Irons and Steels" in this Volume.

Pearlitic and Martensitic Malleable Iron

Pearlitic malleable iron is produced either by controlled heat treatment of the same base white iron used to produce ferritic malleable iron or by alloying to prevent the decomposition of carbides dissolved in austenite during cooling from the first-stage annealing temperature. It can be produced by air cooling after first-stage annealing and subsequent tempering to develop specified properties. Martensitic malleable iron is produced by liquid quenching and tempering to develop specified properties (see the section "Control of Annealing" in this article). Variations in heat treatment, coupled

with variations in base composition and melting practice, make it possible to obtain a wide range of properties in pearlitic or martensitic malleable iron.

The mechanical properties of pearlitic and martensitic malleable iron vary in a substantially linear relationship with Brinell hardness (Fig. 10 and 11). In the low hardness ranges, below about 207 HB, the properties of air-quenched and tempered pearlitic malleable are essentially the same as those of oil-quenched and tempered martensitic malleable. This results from the fact that attaining the low hardnesses requires considerable coarsening of the matrix carbides and partial second-stage graphitization. Either an air-quenched pearlitic structure or an oil-quenched martensitic structure can be coarsened and decarburized to meet this hardness requirement.

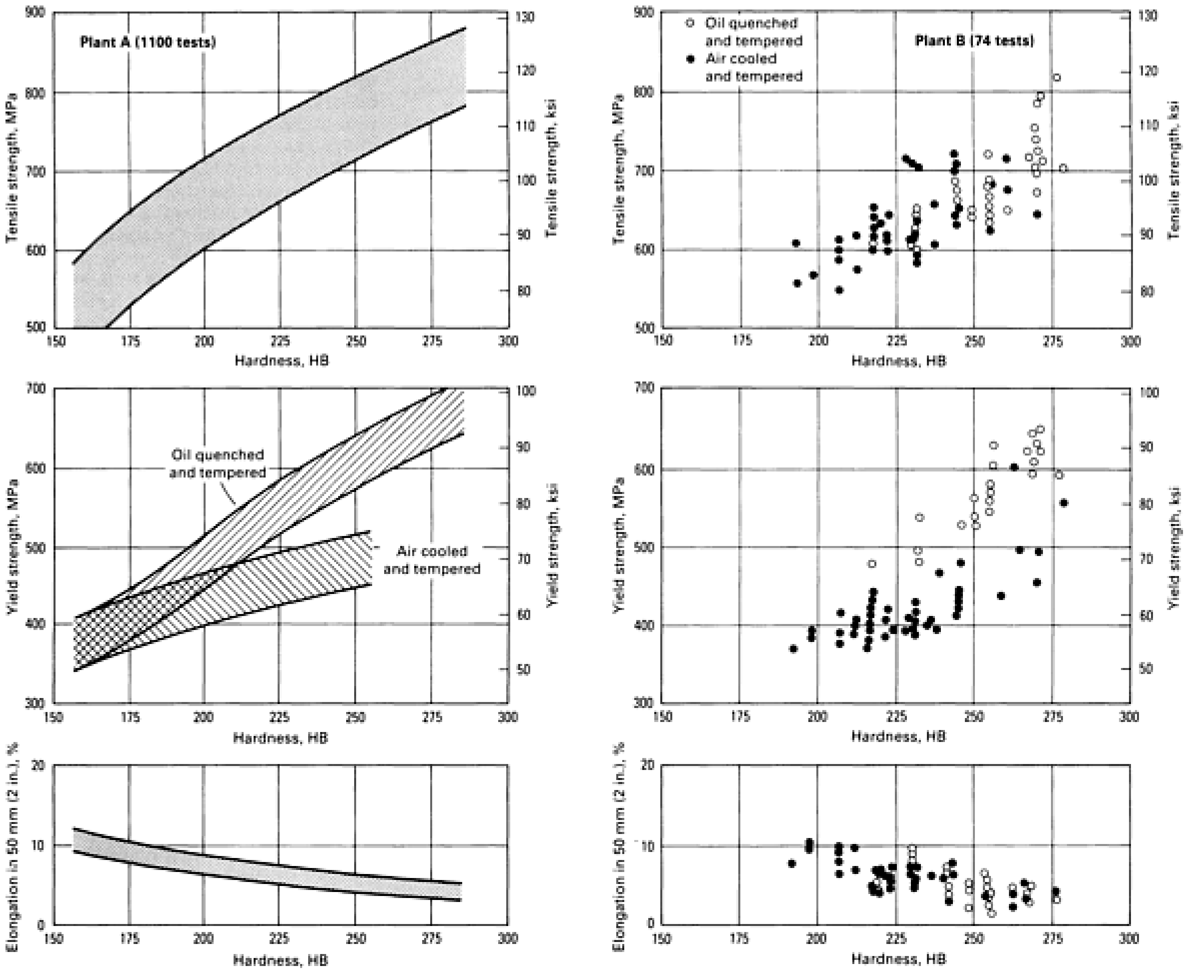

Fig. 10 Relationships of tensile properties to Brinell hardness for pearlitic malleable irons from two foundries. The mechanical properties of these irons vary substantially in a linear relationship with Brinell hardness, and in the low hardness ranges (below about 207 HB), the properties of air-quenched and tempered material are essentially the same as those produced by oil quenching and tempering.

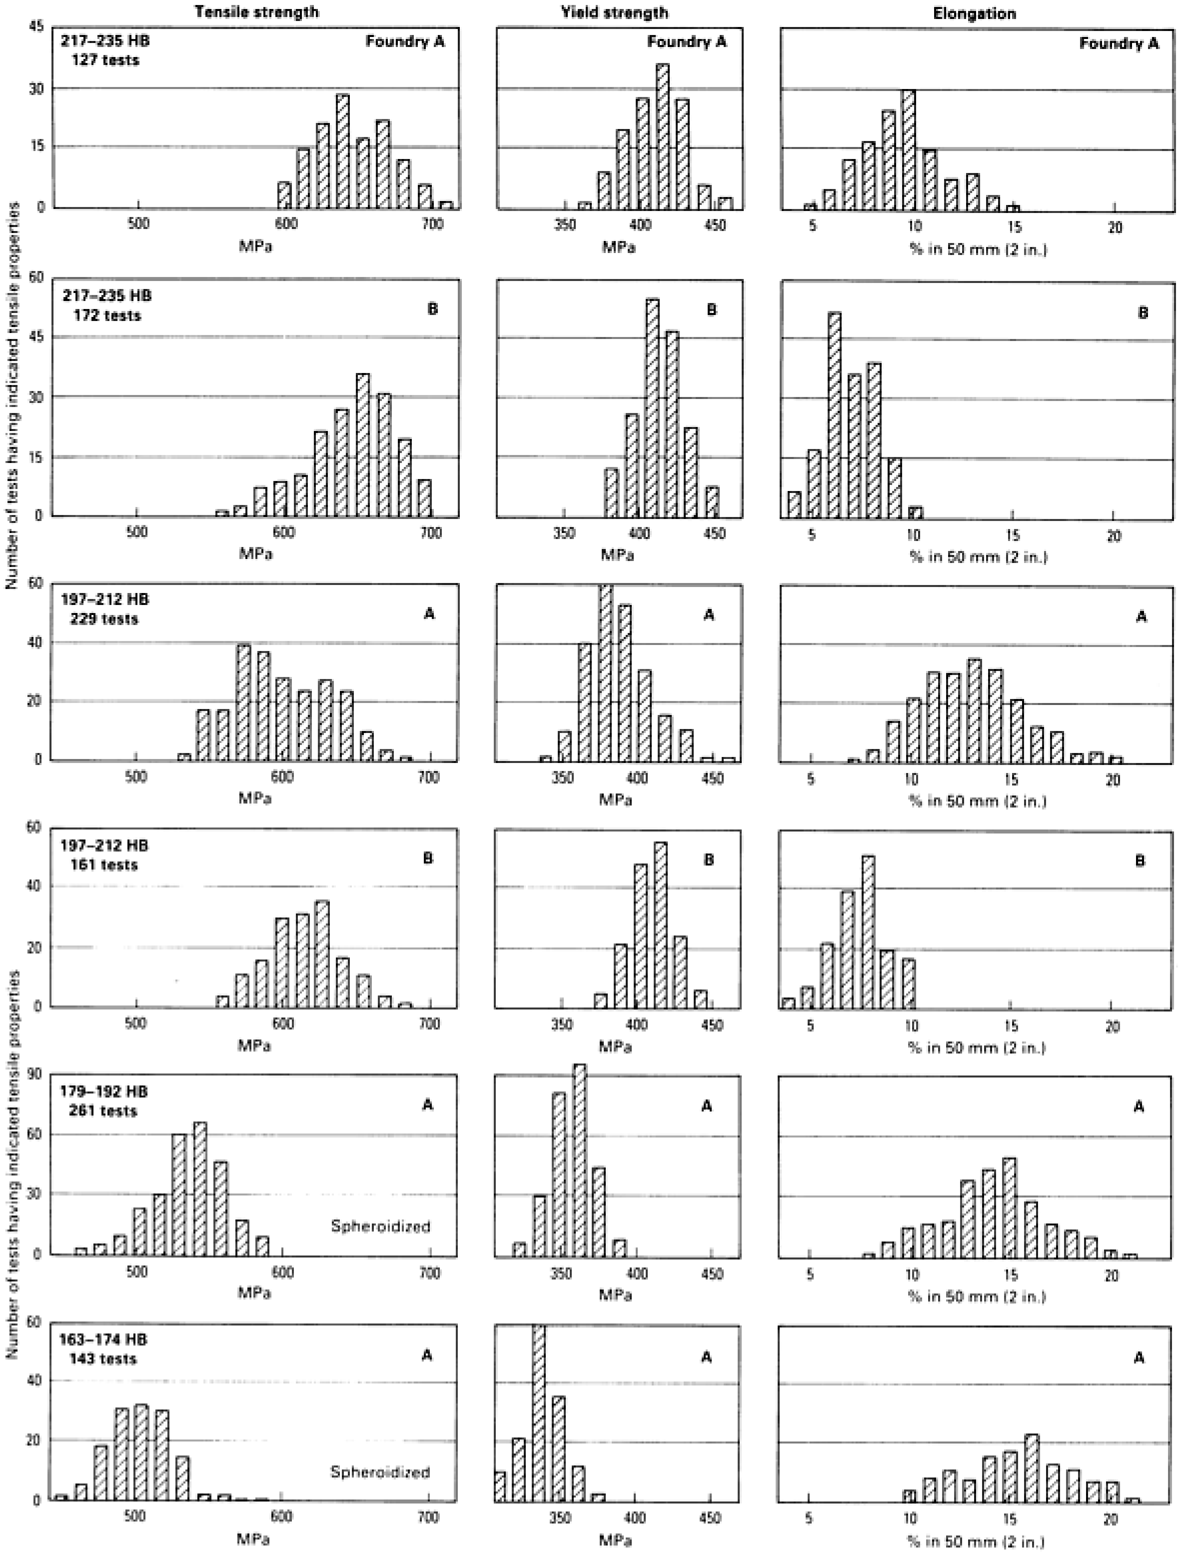

Fig. 11 Tensile properties of pearlitic malleable iron at various hardness levels. At foundry A, the iron was made by alloying with manganese, with completion of first-stage graphitization, air cooling under air blast from 938 °C (1720 °F), and subcritical tempering for spheroidizing.

At higher hardnesses, oil-quenched and tempered malleable iron has higher yield strength and elongation than air-quenched and tempered malleable because of greater uniformity of matrix structure and finer distribution of carbide particles. Oil-quenched and tempered pearlitic malleable iron is produced commercially to hardnesses as high as 321 HB, while the maximum hardness for high-production air-quenched and tempered pearlitic malleable iron is about 255 HB. The lower maximum hardness is applied to the air-quenched material for several reasons:

- Because hardness on air quenching normally does not exceed 321 HB and may be as low as 269 HB, attempts to temper to a hardness range above 255 HB produce nonuniform hardness and make the process control limits excessive
- Very little structural alteration occurs during the tempering heat treatment to a higher hardness, and the resulting structure is more difficult to machine than an oil-quenched and tempered structure at the same hardness
- There is only a slight improvement in other mechanical properties with increased hardness above 255 HB

Because of these considerations, applications for air-quenched and tempered pearlitic malleable iron are usually those requiring moderate strength levels, while the higher-strength applications need the oil-quenched and tempered material.

The modulus of elasticity in tension of pearlitic malleable iron is 175 to 195 GPa (25.5 × 10^6 to 28.0 × 10^6 psi). For automobile crankshafts, the modulus is important and must be determined with greater precision.

The results of Charpy V-notch tests on pearlitic malleable iron are presented in Fig. 8. The fracture toughness of ferritic and pearlitic malleable irons has not been widely studied, but one researcher has estimated K_{Ic} values for these materials by using a *J*-integral approach (Ref 5). Table 4 summarizes the fracture toughness values obtained for the various grades of malleable iron at various temperatures. All of the materials exhibited stable crack extension prior to fracture for 25 mm (1 in.) wide compact-tension specimens.

Source: Ref 5

As for ductile irons, fracture toughness testing indicates that malleable irons possess considerably more toughness than is indicated by Charpy impact toughness results. Although the fracture toughness values for pearlitic grades are similar to those obtained for ferritic grades, the higher yield strengths of the pearlitic grades indicate that their critical flaw sizes, which are proportional to $(K_{Ic}/\sigma_y)^2$, are less than those of the ferritic grades of malleable iron. Detailed information on the principles of fracture toughness and the nomenclature associated with fracture mechanics studies is available in the Section "Fracture Mechanics" and the article "Dynamic Fracture Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

The compressive strength of pearlitic and martensitic malleable irons is plotted in Fig. 12. Torsional strength values are presented in Table 5.

Normal distribution is assumed. Source: Ref 1.

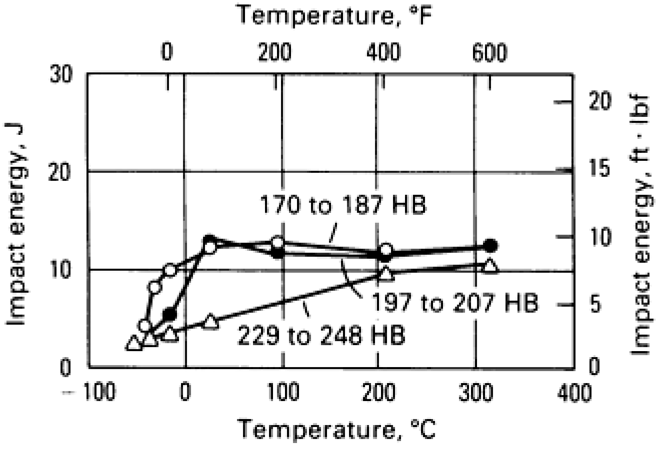

Fig. 14 Charpy V-notch impact energy of one heat of air-quenched and tempered pearlitic malleable iron

The fatigue limits of pearlitic and martensitic malleable irons are about 40 to 50% of tensile strength. Oil-quenched and tempered martensitic iron usually has a higher fatigue ratio than pearlitic iron made by the arrested anneal method.

Wear Resistance. Because of its structure and hardness, pearlitic and martensitic malleable irons have excellent wear resistance. In some moving parts where bushings are normally inserted at pivot points, heat-treated malleable iron has proved to be so wear resistant that the bushings have been eliminated. One example of this is the rocker arm for an overhead-valve automotive engine.

Welding and Brazing. Welding of pearlitic or martensitic malleable iron is difficult because the high temperatures used can cause the formation of a brittle layer of graphite-free white iron. Pearlitic and martensitic malleable iron can be successfully welded if the surface to be welded has been heavily decarburized.

Pearlitic or martensitic malleable iron can be brazed by various commercial processes. One application is the induction silver brazing of a pearlitic malleable casting and a steel shaft to form a planetary output shaft for an automotive transmission. In another automotive application, two steel shafts are induction copper brazed to a pearlitic malleable iron shifter shaft plate.

Selective Surface Hardening. Pearlitic malleable iron can be surface hardened by either induction heating and quenching or flame heating and quenching to develop high hardness at the heat-affected surface. Considerable research has been done to determine the surface-hardening characteristics of pearlitic malleable and its capability of developing high hardness over relatively narrow surface bands. Generally, little difficulty is encountered in obtaining hardnesses in the range of 55 to 60 HRC, with the depth of penetration being controlled by the rate of heating and by the temperature at the surface of the part being hardened (Fig. 15).

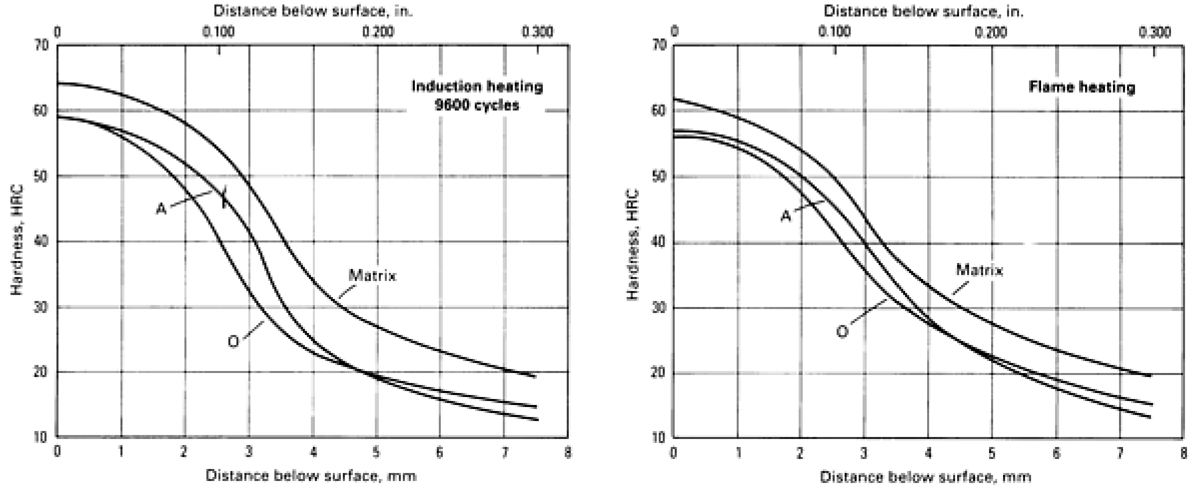

Fig. 15 Hardness versus depth for surface-hardened pearlitic malleable irons. Curves labeled "Matrix" show hardness of the matrix, converted from microhardness tests. O, oil quenched and tempered to 207 HB before surface hardening; A, air cooled and tempered to 207 HB before surface hardening

The maximum hardness obtainable in the matrix of a properly hardened pearlitic malleable part is 67 HRC. However, conventional hardness measurements made on castings show less than 67 HRC because of the presence of the graphite particles, which are averaged into the hardness. Generally, a casting with a matrix microhardness of 67 HRC will have about 62 HRC average hardness, as measured with the standard Rockwell tester. Similarly, a Rockwell or Brinell hardness test on softer structures will show less than matrix microhardness because of the presence of graphite.

Two examples of automobile production parts hardened by induction heating are rocker arms and clutch hubs. An example of a flame-hardened pearlitic malleable iron part is a pinion spacer used to support the cup of a roller bearing. To preclude service failures, the ends of the pinion spacer are flame hardened to file hardness to a depth of about 2.3 mm ($\frac{3}{32}$ in.).

Malleable iron can be carburized, carbonitrided, or nitrided to produce a surface with improved wear resistance. In addition, heat treatments such as austempering have been used in specialized applications.

High-Alloy Graphitic Irons

Richard B. Gundlach, Climax Research Services

Introduction

HIGH-ALLOY GRAPHITIC IRONS have found special use primarily in applications requiring corrosion resistance or strength and oxidation resistance in high-temperature service. They are commonly produced in both flake graphite and nodular graphite versions. Those alloys used in applications requiring corrosion resistance are the nickel-alloyed (13 to 36% Ni) gray and ductile irons (also called Ni-Resist irons) and the high-silicon (14.5% Si) gray irons. The alloyed irons produced for high-temperature service are the nickel-alloyed gray and ductile irons, the high-silicon (4 to 6% Si) gray and ductile irons, and the aluminum-alloyed gray and ductile irons. Two groups of aluminum-alloyed irons are recognized: the 1 to 7% Al irons and the 18 to 25% Al irons. Neither the 4 to 6% Si irons nor the aluminum-alloyed irons are covered by American Society for Testing and Materials (ASTM) standards. Although the oxidation resistance of the aluminum-alloyed irons is exceptional, problems in melting and casting the alloys are considerable, and commercial production of the aluminum-alloyed irons is uncommon.

In general, the molten metal processing of high-alloy graphitic irons follows that of conventional gray and ductile iron production. The same attention to chill control and inoculation practice is necessary, and the conditions for successful magnesium treatment for producing nodular graphite are similar or identical to those for conventional gray and ductile irons. The high alloy contents influence the eutectic carbon content; therefore, carbon levels in these alloys are lower. In many cases, hypereutectic compositions (high carbon contents) in the ductile irons are avoided because of a greater tendency toward the formation of graphite flotation and degenerate graphite forms in sections larger than 25 mm (1 in.).

The higher alloy contents affect the constitution of the irons, creating conditions that favor the formation of third phases and/or secondary eutectics during solidification. Therefore, many of the alloys commonly contain interdendritic carbides or silicocarbides in the as-cast structure. These constituents remain after heat treatment and are an accepted part of the microstructure.

High-Alloy Graphitic Irons

Richard B. Gundlach, Climax Research Services

High-Silicon Irons for High-Temperature Service

Graphitic irons alloyed with 4 to 6% Si provide good service and low cost in many elevated-temperature applications. These irons, whether gray or ductile, provide good oxidation resistance and stable ferritic matrix structures that will not go through a phase change at temperatures up to 900 °C (1650 °F). The elevated silicon contents of these otherwise normal cast iron alloys reduce the rate of oxidation at elevated temperatures because it promotes the formation of a dense, adherent oxide at the surface, which consists of iron silicate rather than iron oxide. This oxide layer is much more resistant to oxygen penetration, and its effectiveness improves with increasing silicon content. Detailed information on the corrosion-resistant properties of high-silicon cast irons is provided in the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

High-Silicon Gray Irons

The high-silicon gray irons were developed in the 1930s by BCIRA and are commonly called Silal. In Silal, the advantages of a high critical (A1) temperature, a stable ferritic matrix, and a fine, undercooled type D graphite structure are combined to provide good growth and oxidation resistance. Oxidation resistance is further improved with additions of chromium, which in these grades can approach levels of 2% Cr. An austenitic grade called Nicrosilal was also developed, but the Ni-Resist irons have replaced this alloy.

Applications. Although quite brittle at room temperature, the high-silicon gray irons are reasonably tough at temperatures above 260 °C (500 °F). They have been successfully used for furnace and stoker parts, burner nozzles, and heat treatment trays.

High-Silicon Ductile Irons

The advent of ductile iron led to the development of high-silicon ductile irons, which currently constitute the greatest tonnage of these types of iron being produced. Converting the eutectic flake graphite network into isolated graphite nodules further improves oxidation resistance and growth. The higher strength and ductility of the ductile iron version of these alloys qualify it for more rigorous service.

The high-silicon ductile iron alloys are designed to extend the upper end of the range of service temperatures for ferritic ductile irons. These irons are used to temperatures of 900 °C (1650 °F). Raising the silicon content to 4% raises the A1 temperature to 815 °C (1500 °F), and at 5% Si the A1 is above 870 °C (1600 °F). The mechanical properties of these alloyed irons at the lower end of the range (4 to 4.5% Si) are similar to those of standard ferritic ductile irons. At 5 to 6% Si, oxidation resistance is improved and critical temperature increased, but the iron can be very brittle at room temperature. At higher silicon levels, impact transition temperature rises well above room temperature, and upper shelf energy is dramatically reduced. Ductility is restored when temperatures exceed 425 °C (800 °F).

For most applications, alloying with 0.5 to 1% Mo provides adequate elevated-temperature strength and creep resistance (see Fig. 1). Higher molybdenum additions are used when maximum elevated-temperature strength is needed. High molybdenum additions (>1%) tend to generate interdendritic carbides of the Mo_2C type, which persist even through annealing, and tend to reduce toughness and ductility at room temperature.

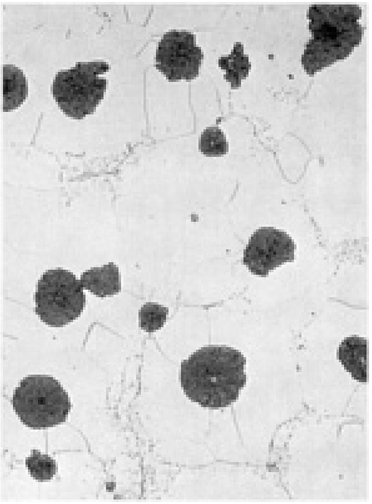

Fig. 1 Photomicrograph of a 4Si-Mo ductile iron showing nodular graphite structure. 400×

Silicon lowers the eutectic carbon content, which must be controlled to avoid graphite flotation. For 4% Si irons, carbon content should range from 3.2 to 3.5% C, depending on section size, and at 5% Si it should be around 2.9% C. The unique properties of each element and its contribution to the total alloy system of a ductile graphitic cast iron are described in the article "Ductile Iron" in this Volume.

Melting Practice. For the high-silicon ductile irons, standard ductile iron melting practices apply. Cupola melting is acceptable, but these irons are commonly electric melted. Acid, neutral, or basic linings are used. Conventional ductile iron charge materials are also used; however, care should be taken to minimize chromium, manganese, and phosphorus.

Manganese content should not exceed 0.5%, and it is preferable to keep it below 0.3%. Chromium should be no more than 0.1% and preferably below 0.6%. These elements promote as-cast embrittlement due to carbides and pearlite, which form networks in the interdendritic regions. These microstructural constituents are difficult to break down through subsequent heat treatment, and they degrade toughness and machinability. They are a particular problem in turbocharger applications, in which minimum ductility requirements must be met. Consequently, a larger proportion of pig iron in the charge is common.

Silicon additions can be made in the ladle, but it is highly recommended that all silicon be added to the furnace, except for that required for magnesium treatment and postinoculation. The same is true for molybdenum additions; either ferromolybdenum or molyoxide briquettes can be used.

Conventional magnesium treatment techniques are utilized, and the same rules for balancing sulfur and setting residual magnesium levels apply to the high-silicon irons. These irons are more susceptible to the formation of intercellular carbides when magnesium levels exceed those needed to balance sulfur and to nodularize the graphite. Although these irons respond like standard ductile irons to most inoculants, foundry grade ferrosilicon, containing 75 to 85% Si, is most often used for postinoculation.

Pouring Practice. Due to increased silicon contents, higher pouring temperatures (>1425 °C, or 2600 °F) are required to develop a clean melt surface in the ladle. Therefore, pouring temperatures somewhat higher than those for ductile irons should be used to minimize dross and slag defects.

Molds, Patterns, and Casting Design. These alloys are normally sand cast; sand molds can be made of green sand, shell mold, and air-set chemically bonded sands suitable for gray and ductile irons. As with any graphitic iron, high mold rigidity is necessary to minimize mold wall movement and shrinkage porosity. Softer molds will produce bigger castings, but in general little or no allowance for shrinkage is required in the pattern.

As with conventional ductile irons, the highly reactive magnesium dissolved in these irons, along with the high levels of silicon, gives rise to the formation of dross and inclusions due to the reaction with oxygen in the air during pouring and filling of the mold. Consequently, clean ladles with teapot designs or skimmers are recommended. Furthermore, measures must be taken in designing the runners and gating system to minimize turbulence and to trap dross before it enters the mold cavity (see the articles "Gating Design" and "Riser Design" in this Volume).

Shakeout Practice. As mentioned previously, room-temperature impact resistance is low; therefore, riser and gate removal is somewhat easier with these alloys than with standard ductile iron grades. These irons are quite ductile at elevated temperatures, and they should be allowed to cool before cleaning. They do exhibit a ductility trough in the temperature range of 315 to 425 °C (600 to 800 °F), and riser and gate removal is aided when performed upon cooling through this temperature range.

Heat Treatment. The high-silicon ductile irons are predominantly ferritic as-cast, but the presence of carbide-stabilizing elements will result in a certain amount of pearlite and often intercellular carbides. These alloys are inherently more brittle than standard grades of ductile iron and usually have higher levels of internal stress due to lower thermal conductivity and higher elevated-temperature strength. These factors should be taken into account when selecting heat treatment requirements.

High-temperature heat treatment is advised in all cases to anneal any pearlite and to stabilize the casting against growth in service. A normal graphitizing (full) anneal in the austenitic temperature range is recommended when undesirable amounts of carbide are present. For the 4 to 5% Si irons, this will require heating to at least 900 °C (1650 °F) for several hours, followed by slow cooling to below 705 °C (1300 °F). At higher silicon contents (>5%), in which carbides readily break down, and in castings that are relatively carbide free, subcritical annealing in the temperature range of 720 to 790 °C (1325 to 1450 °F) for 4 h is effective in ferritizing the matrix. Compared to full annealing, the subcritically annealed material will have somewhat higher strength, but ductility and toughness will be reduced.

Applications. The high-silicon and silicon-molybdenum ductile irons are currently produced as manifolds and turbocharger housings for trucks and some automobiles. They are also used in heat-treating racks.

High-Alloy Graphitic Irons

Richard B. Gundlach, Climax Research Services

Austenitic Nickel-Alloyed Gray and Ductile Irons

The nickel-alloyed austenitic irons are produced in both gray and ductile cast iron versions for high-temperature service. Austenitic gray irons date back to the 1930s, when they were specialized materials of minor importance. After the invention of ductile iron, austenitic grades of ductile iron were also developed. These nickel-alloyed austenitic irons have been used in applications requiring corrosion resistance, wear resistance, and high-temperature stablility and strength (see the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Additional advantages include low thermal expansion coefficients, nonmagnetic properties, and cast iron materials having good toughness at low temperatures. When compared with corrosion and heat-resistant steels, nickel-alloyed irons have excellent castability and machinability.

Applications of Nickel-Alloyed Irons

The nickel-alloyed (Ni-Resist) irons have found wide application in chemical process related equipment such as compressors and blowers; condenser parts; phosphate furnace parts; pipe, valves, and fittings; pots and retorts; and pump casings and impellers. Similarly, in food-handling equipment, the various alloy components include bottling and brewing equipment, canning machinery, distillery equipment, feed screws, metal grinders, and salt filters. In high-temperature applications, nickel-alloyed irons are used as cylinder liners, exhaust manifolds, valve guides, gas turbine housings, turbocharger housings, nozzle rings, water pump bodies, and piston rings in aluminum pistons. Figure 2 shows the typical microstructure obtained in Ni-Resist irons.

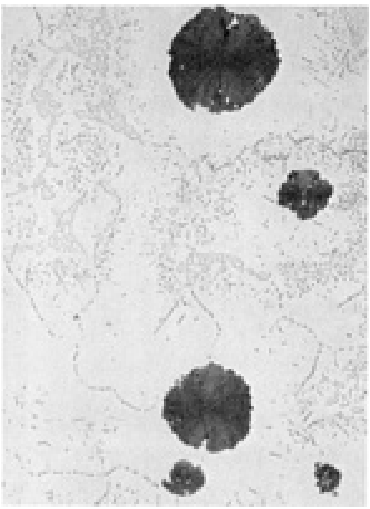

Fig. 2 Photomicrograph of a D5S Ni-Resist ductile iron showing nodular graphite structure. 400×

Austenitic Gray Irons

Specification ASTM A 436 defines eight types of austenitic gray iron alloys, four of which are designed to be used in elevated-temperature applications and four in applications requiring corrosion resistance (Table 1). The nickel produces a stable austenitic microstructure with good corrosion resistance and strength at elevated temperatures. The nickel-alloyed irons are also alloyed with chromium and silicon for wear resistance and oxidation resistance at elevated temperatures. Types 1 and 1b, which are designed for corrosion-resistant applications, are alloyed with 13.5 to 17.5% Ni and 6.5% Cu. Type 1 alloys are used to produce ring carriers utilized in conjunction with aluminum pistons in diesel engines. Types 2b, 3, and 5, which are principally used for high-temperature service, contain 18 to 36% Ni, 1 to 2.8% Si, and 0 to 6% Cr. With the development of ductile iron, most high-temperature applications shifted to similar Ni-Resist ductile iron grades. Type 4 alloys are alloyed with 29 to 32% Ni, 5 to 6% Si, and 4.5 to 5.5% Cr and are recommended for their stain-resistant properties.

(a) Where some machining is required, the 3.00-4.00% Cr range is recommended.

Austenitic Ductile Irons

Specification ASTM A 439 defines the group of austenitic ductile irons (Table 2). The austenitic ductile iron alloys have similar compositions to the austenitic gray iron alloys but have been treated with magnesium to produce nodular graphite irons. Ductile alloys are available in every type but type 1; this is because of its high copper content, which is not compatible with the production of nodular graphite. The ductile iron alloys have high strength and ductility, combined with the same desirable properties of the gray iron alloys. They provide frictional wear resistance, corrosion resistance, strength and oxidation resistance at high temperatures, nonmagnetic characteristics, and, in some alloys, low thermal expansivity at ambient temperatures.

Table 2 Compositions of austenitic nodular irons

Alloy	Composition, %					
	C	**Si**	**Mn**	**P**	**Ni**	Cr
Type D-2[(a)]	3.00 max	1.50-3.00	0.70-1.25	0.08 max	18.00-22.00	**1.75-2.75**
Type D-2B	3.00 max	1.50-3.00	0.70-1.25	0.08 max	18.00-22.00	**2.75-4.00**
Type D-2C	2.90 max	1.00-3.00	1.80-2.40	0.08 max	21.00-24.00	**0.50 max**
Type D-3[(a)]	2.60 max	1.00-2.80	1.00 max[(b)]	0.08 max	28.00-32.00	**2.50-3.50**
Type D3-A	2.60 max	1.00-2.80	1.00 max[(b)]	0.08 max	28.00-32.00	**1.00-1.50**
Type D-4	2.60 max	5.00-6.00	1.00 max[(b)]	0.08 max	28.00-32.00	**4.50-5.50**
Type D-5	2.40 max	1.00-2.80	1.00 max[(b)]	0.08 max	34.00-36.00	**0.10 max**
Type D-5B	2.40 max	1.00-2.80	1.00 max[(b)]	0.08 max	34.00-36.00	**2.00-3.00**
Type D-5S	**2.30 max**	**4.90-5.50**	**1.00 max[(b)]**	**0.08 max**	**34.00-37.00**	**1.75-2.25**

(a) Additions of 0.7-1.0% Mo will increase the mechanical properties above 425 °C (800 °F).

(b) Not intentionally added.

Melting Practice. In the past, these iron alloys were generally cupola melted, but today melting is almost exclusively done in electric furnaces. Choice of furnace linings is usually based on other alloys being melted in the shop; acid, neutral, or basic linings are used. Selection of charge materials is more critical in melting the higher-nickel alloys of the ductile iron versions because they are more sensitive to the tramp elements that affect graphite structure. The high nickel content causes the materials to be more prone to hydrogen gas defects; therefore, charge materials should be thoroughly dry, and melting times should be quick. The molten iron should only be superheated to the temperature necessary to treat and pour, and for as short a time as possible. Pouring is generally done above 1400 °C (2550 °F) to keep the molten iron surface clean and free of oxide.

Magnesium treatment of the ductile iron alloys is normally accomplished with nickel-magnesium alloys. The nickel-magnesium treatment alloy is often added in the furnace; there is no concern for pyrotechnics. The same rules for balancing sulfur and setting residual magnesium levels apply to these nickel-alloyed irons. These irons are more susceptible to the formation of intercellular carbides when magnesium levels exceed those needed to balance sulfur and to nodularize the graphite. Although these irons respond like standard ductile irons to most inoculants, foundry grade ferrosilicon, containing 75 to 85% Si, is most often used for postinoculation. Postinoculation is performed when tapping the furnace. Stream inoculation, where feasible, is also recommended for improved machinability.

Carbon content for the type D-5S alloy must be monitored carefully, because section sensitivity is high. Although the ASTM specification allows up to 2.4% C, sections over 25 mm (1 in.) are susceptible to exploded and chunky graphite formation. Carbon levels of 1.6 to 1.8% are recommended for heavy-section castings.

Molding and Casting Design. Conventional ferrous molding sands are used, including green sand, shell mold, and chemically bonded sands. The same precautions taken for high-strength irons apply to these alloys. Solidification should progress from thin to thick sections without interruption. Abrupt changes in section thickness should be avoided. Riser location should allow convenient access for riser removal. The shrinkage allowance is generally 21 mm/m ($\frac{1}{4}$ in./ft), or 2.1%.

Shakeout. These alloys can develop large thermal stresses upon cooling because of a relatively low thermal conductivity, combined with high elevated-temperature strength and high thermal expansion rates. Consequently, care should be taken in shaking out too hot, and mold cooling is recommended for intricately shaped castings and castings of widely varying section thickness.

Heat treatment of nickel-alloyed ductile irons serves to strengthen the casting and to stabilize the microstructure of the casting for increased durability. Additional information on the heat treatment of ductile iron is available in the article "Ductile Iron" in this Volume.

Stress relief heat treatments are typically conducted at temperatures between 620 and 675 °C (1150 and 1250 °F) to remove residual casting stresses. Mold cooling to 315 °C (600 °F) is a satisfactory alternative to furnace stress relief.

Annealing of some castings may be necessary to reduce hardness. Annealing is performed at 955 to 1040 °C (1750 to 1900 °F) for 30 min to 5 h, and this treatment will normally break down some of the carbides and spheroidize the rest.

Heat treatment for stability of the microstructure for service at temperatures of 480 °C (900 °F) and above is performed by heating at 760 °C (1400 °F) for a minimum of 4 h and furnace cooling to 540 °C (1000 °F), followed by air cooling. An alternative treatment is to heat at 900 °C (1650 °F) for 2 h and furnace cool to 540 °C (1000 °F). These treatments stabilize the microstructure and minimize growth and warpage in service. The treatments are designed to reduce carbon levels in the matrix and some growth and distortion often accompany heat treatment. Type 1 alloys are not generally amenable to this stabilizing treatment.

Dimensional stability, when truly critical, can be ensured by heat treating at 870 °C (1600 °F) or higher for 2 h plus an additional hour per 25 mm (1 in.) of cross section, furnace cooling not faster than 55 °C/h (100 °F/h) to 540 °C (1000 °F), and then holding for 1 h per 25 mm (1 in.) of cross section and cooling uniformly. After rough machining, the casting should be reheated to 455 to 480 °C (850 to 900 °F) and held 1 h per 25 mm (1 in.) of cross section.

Refrigeration and reaustenitization heat treatments are applied to type D-2 alloys to increase yield strength. Solution heat treating at 925 °C (1700 °F), refrigerating at -195 °C (-320 °F), and then reheating between 650 and 760 °C (1200 and 1400 °F) will increase yield strength considerably without materially affecting magnetic properties or corrosion resistance in seawater or dilute sulfuric acid. Detailed information on the heat treatment of ductile iron is available in the article "Ductile Iron" in this Volume.

Aluminum-Alloyed Irons

The aluminum-alloyed irons consist of two groups of gray and ductile irons. The low-alloyed group contains 1 to 7% Al, and the aluminum essentially replaces silicon as the graphitizing element in these alloys. The high-alloyed group contains

18 to 22% Al. Irons alloyed with aluminum in between these two ranges will be white irons as-cast and will have no commercial importance.

The aluminum greatly enhances oxidation resistance at elevated temperatures and also strongly stabilizes the ferrite phase to very high temperatures--up to and beyond 980 °C (1800 °F). Like the silicon-alloyed irons, the aluminum irons form a tight, adherent oxide on the surface of the casting that is very resistant to further oxygen penetration.

Unfortunately, the aluminum-alloyed irons are very difficult to cast without dross inclusions and laps (cold shuts). The aluminum in the iron is very reactive at the temperatures of the molten iron, and contact with air and moisture must be negligible. Care must be taken not to draw the oxide skin, which forms during pouring, into the mold in order to avoid dross inclusions. Methods for overcoming these problems in commercial practice are under development.

At present, there is no ASTM standard covering the chemistry and expected properties of these alloys, and commercial production is very limited. In the past, the 1.5 to 2.0% irons have been used in the production of truck exhaust manifolds.

High-Silicon Irons for Corrosion Resistance

Irons with high silicon contents (14.5% Si) constitute a unique corrosion-resistant ferritic cast iron group. These alloys are widely used in the chemical industry for processing and for transporting highly corrosive liquids. They are particularly suited to handling sulfuric and nitric acids (see the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). The three most common high-silicon iron alloys are covered in ASTM A 518M (Table 3). These alloys contain 14.2 to 14.75% Si and 0.7 to 1.15% C. Grades 2 and 3 are also alloyed with 3.25 to 5% Cr, and grade 2 contains 0.4 to 0.6% Mo. Other compositions are also commercially produced with up to 17% Si.

Table 3 Compositions of high-silicon iron alloys

Alloy	Composition, %					
	C	**Mn**	**Si**	**Cr**	**Mo**	Cu
Grade 1	0.70-1.10	1.50 max	14.20-14.75	0.50 max	0.50 max	**0.50 max**
Grade 2	0.75-1.15	1.50 max	14.20-14.75	3.25-5.00	0.40-0.60	**0.50 max**
Grade 3	**0.70-1.10**	**1.50 max**	**14.20-14.75**	**3.25-5.00**	**0.20 max**	**0.50 max**

Melting Practice. Induction melting is the preferred method for these alloys. Induction melting permits the very tight control of chemistry needed in melting these materials in order to minimize scrap losses due to cracking. The alloys have a very low tolerance for hydrogen and nitrogen; thus, charge materials must be carefully controlled to minimize the levels of these gases. Vacuum treatment can be used to increase strength and density.

The melting point of the eutectic 14.3% Si cast iron is approximately 1180 °C (2160 °F), and the alloy is generally poured at approximately 1345 °C (2450 °F). Because of the very brittle nature of high-silicon cast iron, castings are usually shaken out after cooling to ambient temperature. However, some casting geometries demand hot shakeout while the castings are still red hot, so that the castings can be immediately stress relieved and furnace cooled to prevent cracking.

Molding and Casting Design. These alloys are routinely cast in sand molds, investment molds, and permanent steel molds. Cores must have good collapsibility to prevent fracture during solidification. Flash must be minimized because it will be chilled iron and can readily become an ideal nucleation site for cracks that propagate into the casting.

Casting design for these high-silicon irons requires special considerations. To avoid cracking, sharp corners and abrupt changes in section size must be avoided. Casting designs should have tapered ingates to permit easy removal of gates and risers by impact and to minimize the amount of grinding required. Unless vacuum degassing is employed, conventional risers are not generally used or desired.

High-silicon cast irons are generally cast in sections ranging from 4.8 to 38 mm ($\frac{3}{16}$ to 1.5 in.). Thin sections fill well because of the excellent fluidity of these cast irons, but tend to chill and become extremely brittle white iron. Sections over 38 mm (1.5 in.) are prone to segregation and porosity, which reduce strength and corrosion resistance. Castings are generally designed with a patternmaker's rule of 18 mm shrink to the meter ($\frac{7}{32}$ in. shrink to the foot), or 1.8%.

Heat Treatment. High-silicon irons can be stress relieved by heating in the range of 870 to 900 °C (1600 to 1650 °F), followed by slow cooling to ambient temperatures to minimize the likelihood of cracking. Heat treatments have no significant effect on corrosion resistance.

Machinability. High-silicon cast irons have hardnesses of approximately 500 HB and are normally considered machinable only by grinding. Machinability can be improved with higher additions of carbon and/or phosphorus, but only at the expense of other properties, such as strength and corrosion resistance.

Applications. High-silicon irons are extensively used in equipment for the production of sulfuric and nitric acids, for sewage disposal and water treatment, for handling mineral acids in petroleum refining, and in the manufacture of fertilizer, textiles, and explosives. Specific components include pump rotors, agitators, crucibles, and pipe fittings in chemical laboratories.

Plain Carbon Steels

John M. Svoboda, Steel Founders' Society of America

Introduction

CARBON STEELS contain only carbon as the principal alloying element. Other elements are present in small quantities, including those added for deoxidation. Silicon and manganese in cast carbon steels typically range from 0.25 to about 0.80% Si, and 0.50 to about 1.00% Mn. Carbon steels can be classified according to their carbon content into three broad groups:

- *Low-carbon steels:* ≤0.20% C
- *Medium-carbon steels:* 0.20 to 0.50% C
- *High-carbon steels:* ≥0.50% C

Low-alloy steels contain alloying elements, in addition to carbon, up to a total alloy content of 8%. Cast steels containing more than the following amounts of a single alloying element are considered low-alloy cast steels:

Element	Amount, %
Manganese	**1.00**
Silicon	**0.80**
Nickel	**0.50**
Copper	**0.50**
Chromium	**0.25**
Molybdenum	**0.10**
Vanadium	**0.05**
Tungsten	**0.05**

Detailed information on cast low-alloy steels is available in the article "Low-Alloy Steels" in this Volume.

For the deoxidation of carbon and low-alloy steels (that is, for control of their oxygen content), aluminum, titanium, and zirconium are used. Of these, aluminum is used more frequently because of its effectiveness and low cost. Unless otherwise specified, the normal sulfur limit for carbon and low-alloy steels is 0.06%, and the normal phosphorus limit is 0.05%.

Plain Carbon Steels

John M. Svoboda, Steel Founders' Society of America

Structure and Property Correlations

Carbon steel castings are produced to a great variety of properties because composition and heat treatment can be selected to achieve specific combinations of properties, including hardness, strength, ductility, fatigue resistance, and toughness. Although selections can be made from a wide range of properties, it is important to recognize the interrelationships among these properties. For example, higher hardness, lower toughness, and lower ductility values are associated with

higher strength values. The relationships among these properties and mechanical properties are discussed further in this section.

Property trends among carbon steels are illustrated as a function of the carbon content in Fig. 1. Unless otherwise noted, the properties discussed refer to those obtained from specimens that have been removed from standard ASTM keel blocks, which are made with a 32 mm (1.25 in.) section size. The effect of larger section sizes on these properties is discussed in the section "Section Size and Mass Effects" in this article.

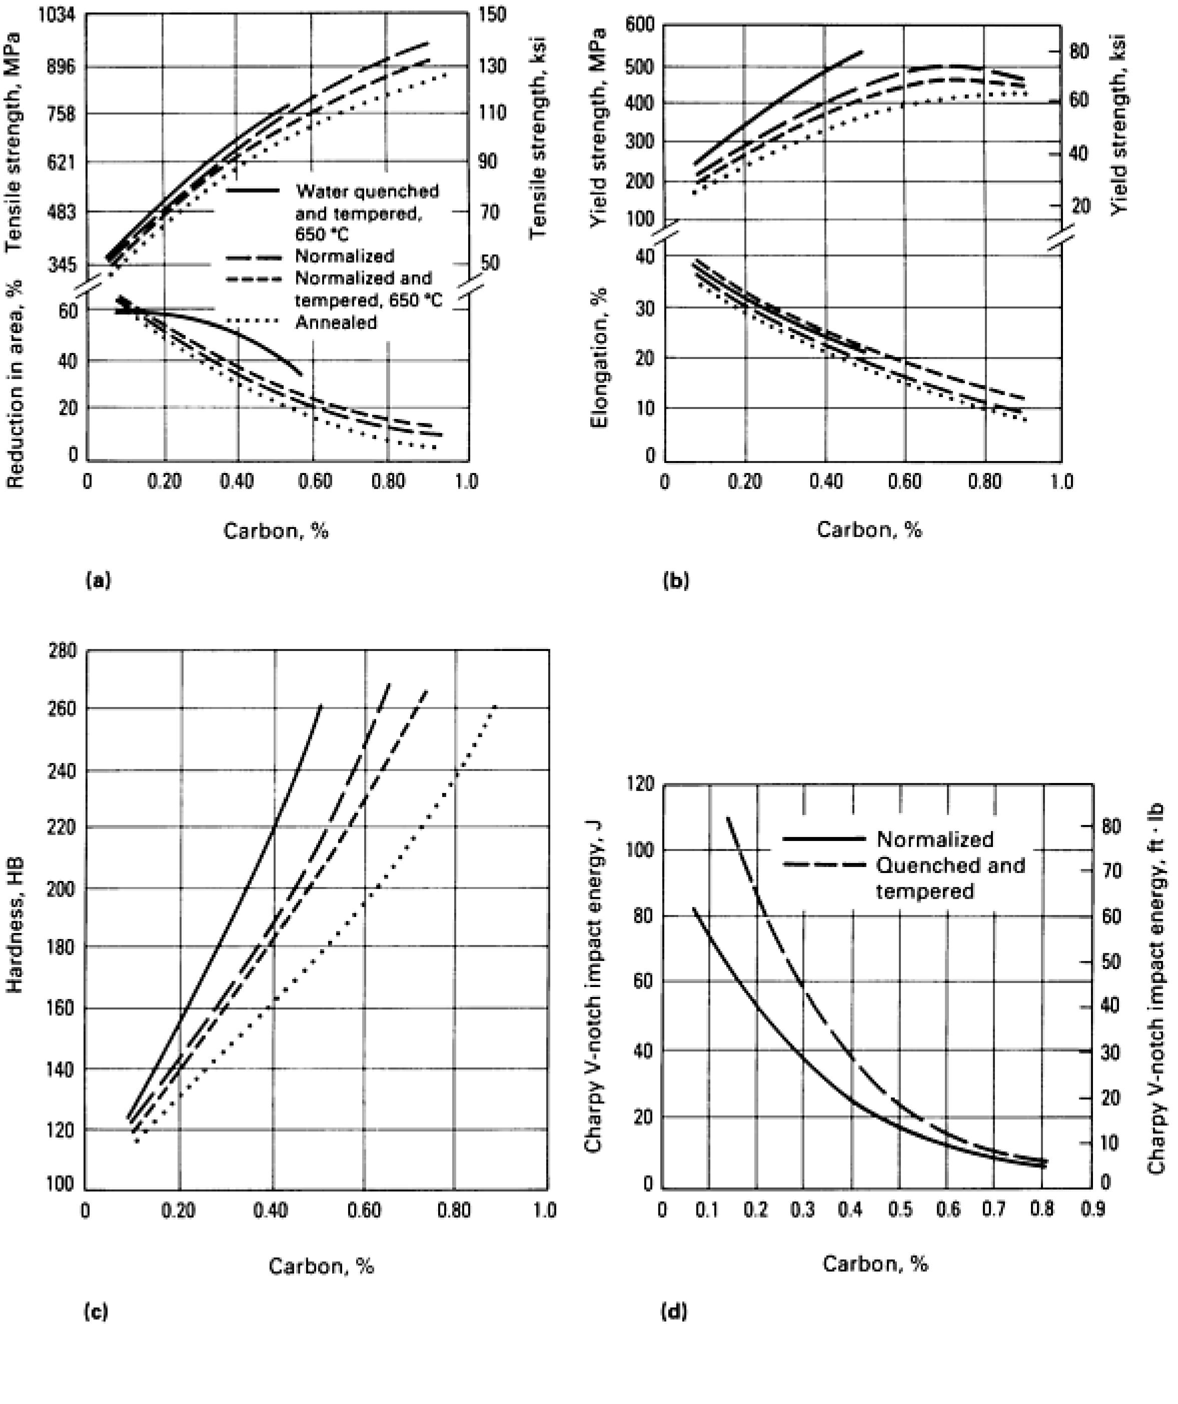

Fig. 1 Properties of cast carbon steels as a function of carbon content and heat treatment. (a) Tensile strength and reduction of area. (b) Yield strength and elongation. (c) Brinell hardness. (d) Charpy V-notch impact energy

Strength and Hardness. Depending on alloy choice and heat treatment, ultimate tensile strength levels from 414 to 1724 MPa (60 to 250 ksi) can be achieved with cast carbon and low-alloy steels. Figure 2 illustrates the tensile strength and tensile ductility values that can be expected from normalized and quenched-and-tempered cast carbon steels having a

range of Brinell hardness values. For carbon steels, the hardness and strength values are largely determined by carbon content and the heat treatment (Fig. 1c). The effect of tempering normalized carbon steel is shown in Fig. 3.

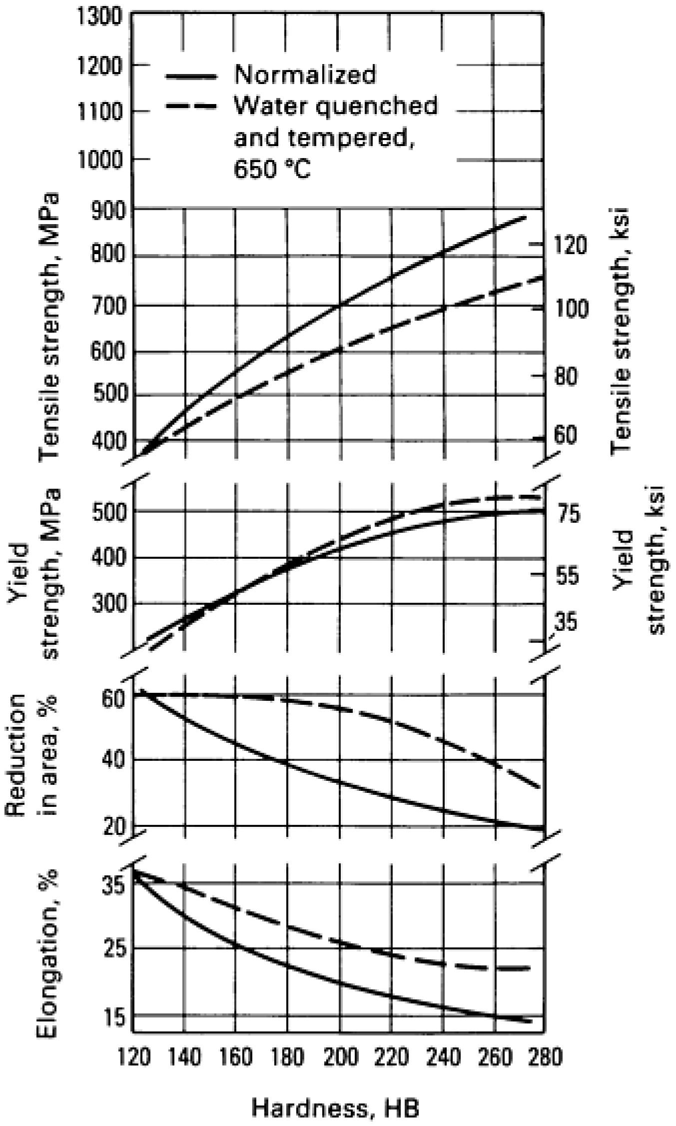

Fig. 2 Tensile properties of cast carbon steels as a function of Brinell hardness

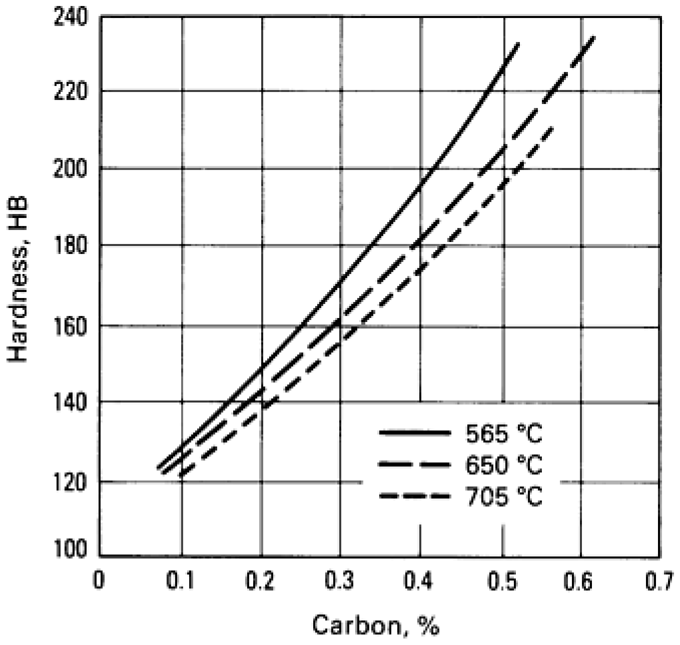

Fig. 3 Hardness versus carbon content of normalized cast carbon steels tempered at various temperatures for 2 h. Tempering temperatures are indicated on the graph.

Strength and Ductility. Ductility depends greatly on the strength, or hardness, of the cast steel (Fig. 2). Actual ductility requirements vary with the strength level and the specification to which a steel is ordered. Because yield strength is a primary design criterion for structural applications, the relationships shown in Fig. 1(a) and 1(b) are replotted in Fig. 4 to reveal the major trends for cast carbon steels. Quenched-and-tempered steels exhibit higher ductility values for a given yield strength level than normalized, normalized-and-tempered, or annealed steels.

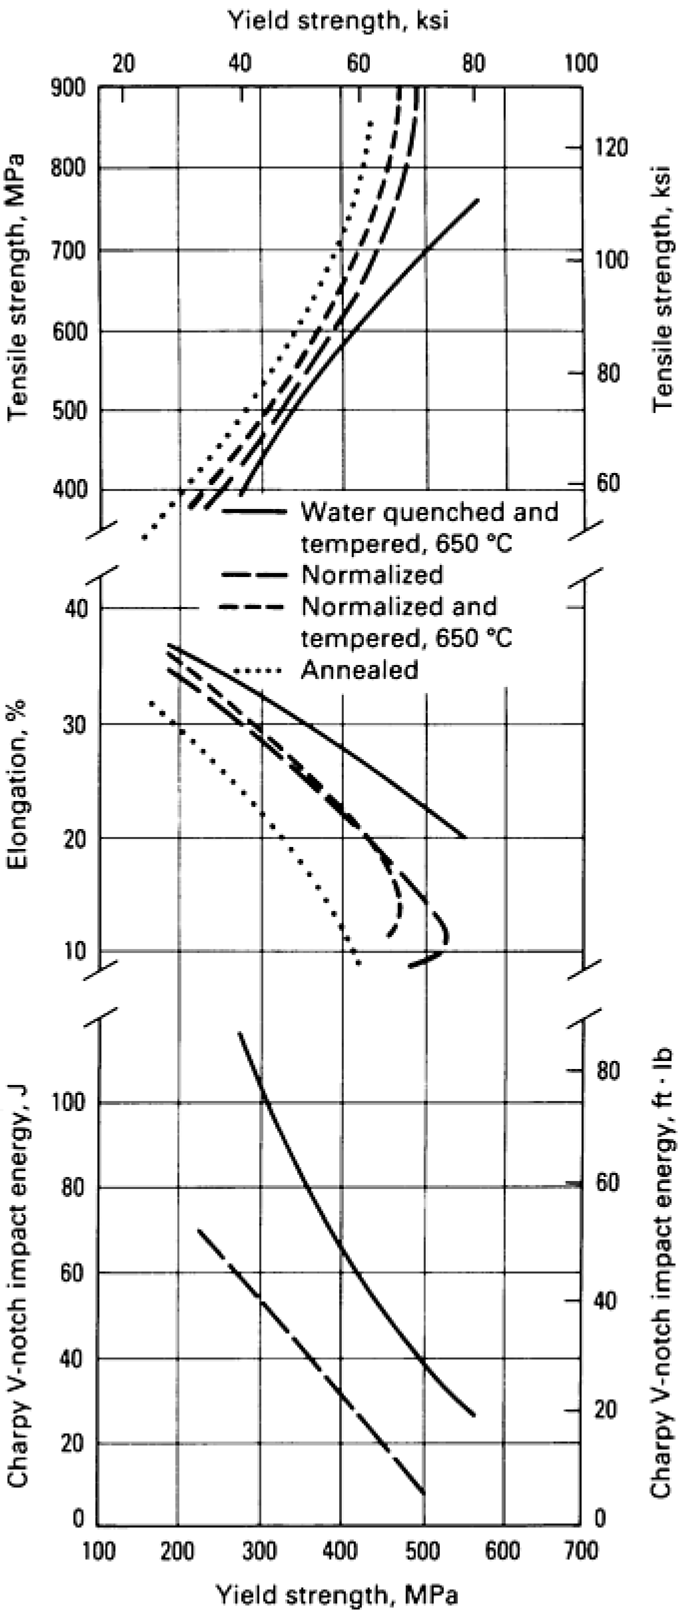

Fig. 4 Room-temperature properties of cast carbon steels after different heat treatments

Strength and Toughness. Several test methods are available for evaluating the toughness of steels or the resistance to sudden or brittle fracture. These include the Charpy V-notch impact test, the drop-weight test, the dynamic tear test, and specialized procedures to determine plane-strain fracture toughness. The results of all of these tests are in use and will be reviewed in this section because each of these tests offers specific advantages that are unique to the test method.

Charpy V-notch impact energy trends at room temperature (Fig. 4) reveal the distinct effect of strength and heat treatment on toughness. Higher toughness is obtained when a steel is quenched and tempered, rather than normalized and tempered. The effect of heat treatment and testing temperature on Charpy V-notch toughness is further illustrated in Fig. 5 for a carbon steel. Quenching, followed by tempering, produces superior toughness as indicated by the shift of the impact energy transition curve to lower temperatures.

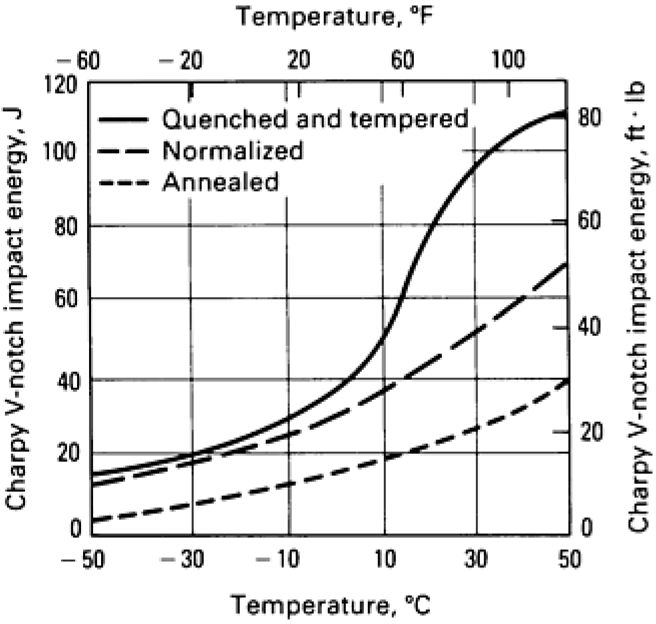

Fig. 5 Effect of various heat treatments on the Charpy V-notch impact energy of a 0.30% C steel

Nil ductility transition temperatures (NDTT) ranging from 38 °C (100 °F) to as low as -90 °C (-130 °F) have been recorded in tests on normalized-and-tempered cast carbon and low-alloy steels in the yield strength range of 207 to 655 MPa (30 to 95 ksi) (Fig. 6). Comparison of the data in Fig. 6 with those of Fig. 7 shows the superior toughness values at equal strength levels that low-alloy steels offer compared to carbon steels. When cast steels are quenched and tempered, the range of strength and of toughness is broadened. Depending on alloy selection, NDTT values of as high as 10 °C (50 °F) to as low as -107 °C (-160 °F) can be obtained in the yield strength range of 345 to 1345 MPa (50 to 195 ksi) (Fig. 7).

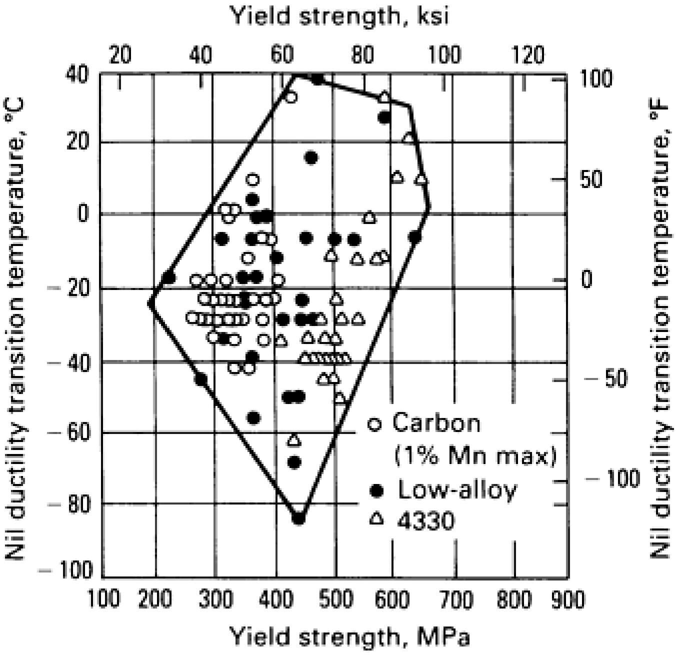

Fig. 6 Nil ductility transition temperatures and yield strengths of normalized-and-tempered commercial cast steels

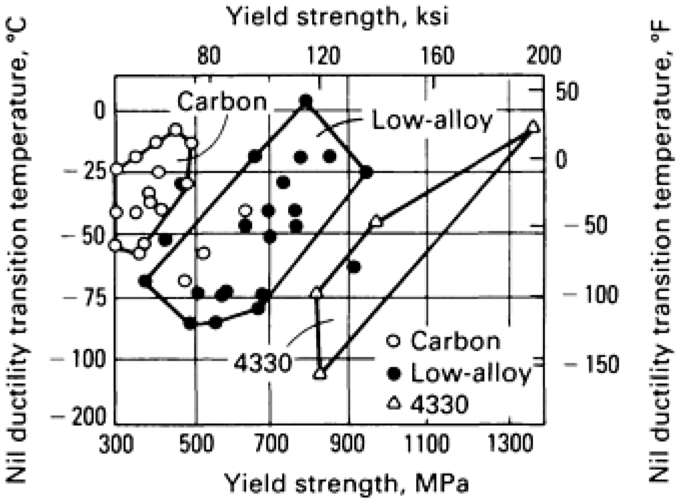

Fig. 7 Nil ductility transition temperatures and yield strengths of quenched-and-tempered commercial cast steels

An approximate relationship exists between the Charpy V-notch impact energy-temperature behavior and the NDTT value. The NDTT value frequently coincides with the energy transition temperature determined in Charpy V-notch tests.

Plane-strain fracture toughness (K_{Ic}) data for a variety of steels reflect the important strength-toughness relationship. Fracture mechanics tests have the advantage over conventional toughness tests of being able to yield material property values that can be used in design equations. Additional information is available in the Selected References at the end of this article.

Strength and Fatigue. The most basic method of presenting engineering fatigue data is by means of the *S-N* curve, which relates the dependence of the life of the fatigue specimen in terms of the number of cycles to failure *N* to the

maximum applied stress *S*. Other tests have been used, and the principal findings for cast carbon steels are highlighted in the following sections.

Constant Amplitude Tests. The endurance ratio (endurance limit divided by the tensile strength) of cast carbon and low-alloy steels as determined by rotating-beam bending fatigue tests (mean stress = 0) is generally taken to be approximately 0.40 to 0.50 for smooth bars. The data given in Table 1 indicate that this endurance ratio is largely independent of strength, alloying additions, and heat treatment.

The fatigue notch sensitivity factor, *q*, determined in rotating-beam bending fatigue tests is related to the microstructure of the steel (composition and heat treatment) and the strength. Table 2 shows that *q* generally increases with strength--from 0.23 for annealed carbon steel at a tensile strength of 577 MPa (83.5 ksi) to 0.68 for the higher-strength normalized-and-tempered low-alloy steels. The quenched-and-tempered steels with a martensitic structure are less notch sensitive than the normalized-and-tempered steels with a ferrite-pearlite microstructure. Similar results and trends in notch sensitivity have been reported for tests with sharper notches.

Cast steels suffer less degradation of fatigue properties due to notches than equivalent wrought steels. When the ideal laboratory test conditions are replaced with more realistic service conditions, the cast steels exhibit much less notch sensitivity to variations in the values of the test parameters than wrought steels. Table 3 shows that the *q* values for wrought steels are 1.4 to 2.3 times higher than those for cast steels. Under laboratory test conditions (uniform specimen section size, polished and honed surfaces, and so on), the endurance limit of wrought steel is higher than that of cast steel. The same fatigue characteristics as those of cast steel, however, are obtained when a notch is introduced or when standard lathe-turned surfaces are employed in the rotating-beam bending fatigue test. These effects are illustrated in Fig. 8 and 9.

Table 3 Fatigue notch sensitivity factors for cast and wrought steels at various strength levels

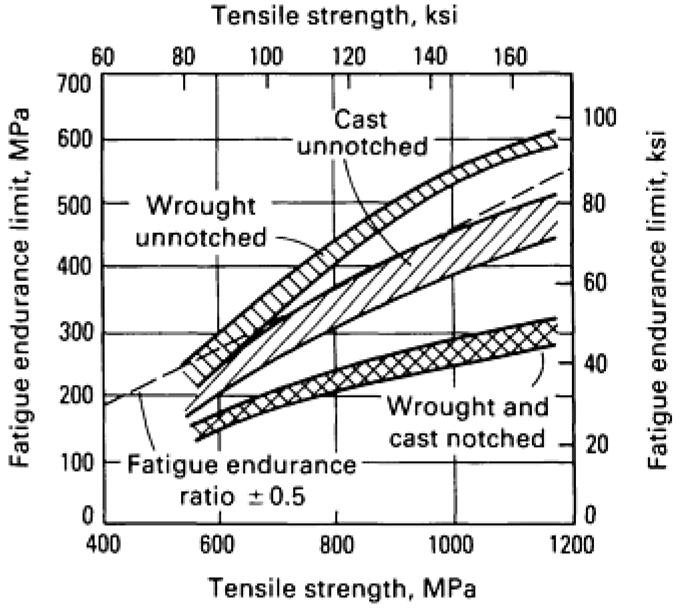

Fig. 9 Fatigue endurance limit versus tensile strength for notched and unnotched cast and wrought steels with various heat treatments. Data obtained in R.R. Moore rotating beam fatigue tests; theoretical stress concentration factor = 2.2

The cyclic stress-strain characteristics shown in Fig. 10 and Table 4 indicate a reduction of the strain-hardening exponent *n* of the normalized-and-tempered cast carbon steel (SAE 1030) from 0.3 in monotonic tension to 0.13 under cyclic-strain-controlled tests. Figure 11 shows that the strain life characteristics of normalized-and-tempered cast carbon steel (SAE 1030) and wrought steel are similar. These data were obtained from strain-controlled constant-amplitude low-cycle fatigue tests (0.001 to 0.02 strain range amplitudes, with a constant strain rate triangle wave form of 2.5×10^{-4} s^{-1} at 0.5 to 3.3 Hz).

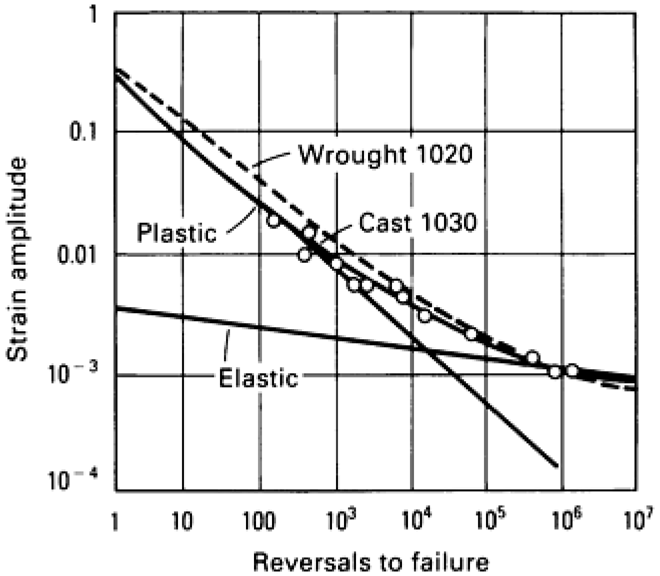

Fig. 11 Low-cycle strain-control fatigue behavior of cast and wrought carbon steels in the normalized-and-tempered condition

Constant load amplitude fatigue crack growth properties for load ratios of $R = 0$ (Fig. 12a) indicate comparable properties for cast and wrought steel and slightly better properties for normalized-and-tempered cast carbon steel (SAE 1030) under

load ratios of R = -1 (Fig. 12b). These tests were conducted in air at 10 to 30 Hz, depending on load ratio, initial stress intensity, and crack length.

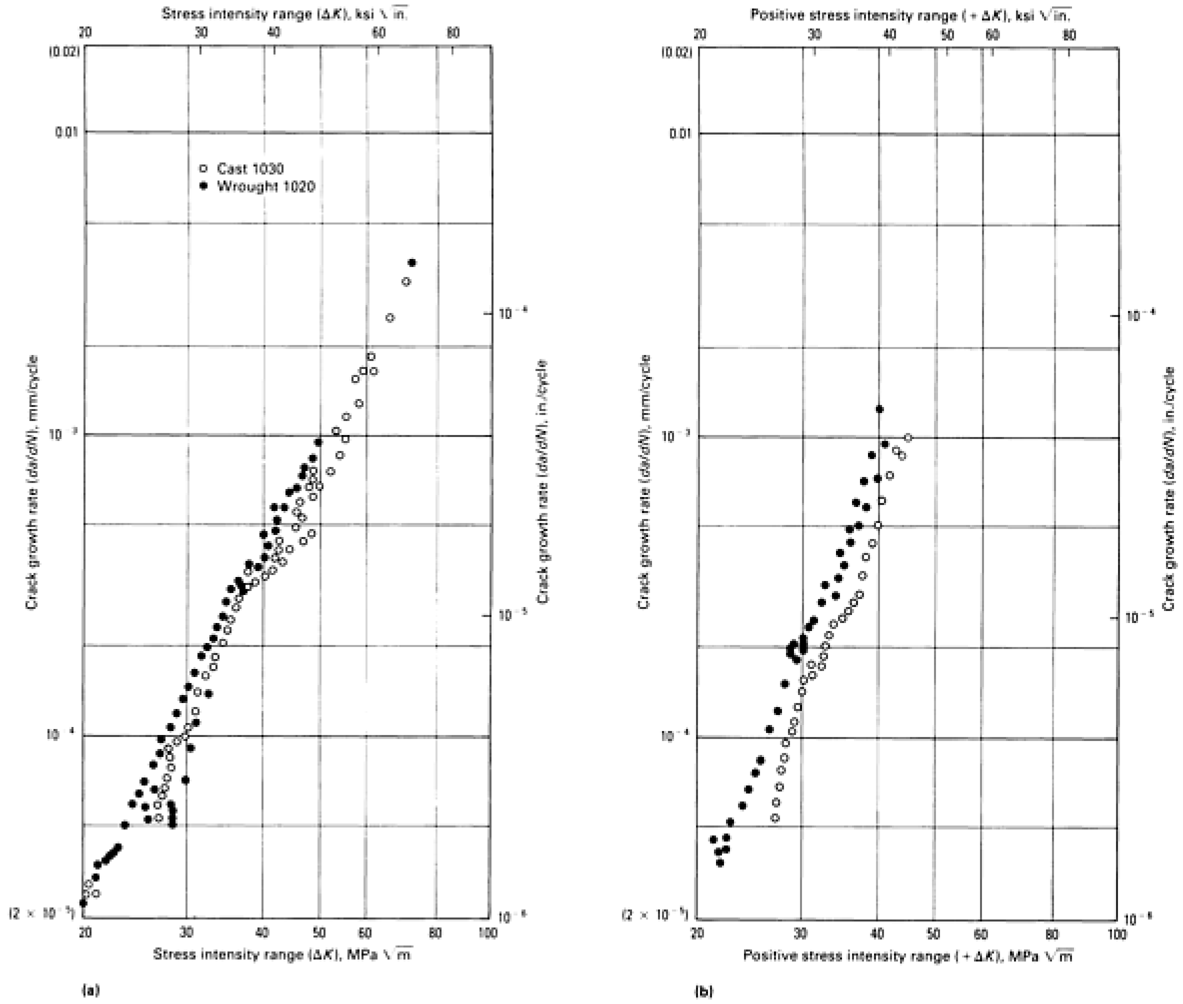

Fig. 12 Constant-amplitude fatigue behavior of normalized-and-tempered cast and wrought carbon steels. (a) Load ratio *R* = 0. (b) *R* = -1

Variable load amplitude fatigue tests indicate equal total life for cast and wrought carbon steels (cast 1030 and wrought 1020, respectively) (Fig. 13). The slower crack growth rate in the cast material compensated for the longer crack initiation life of the wrought carbon steel.

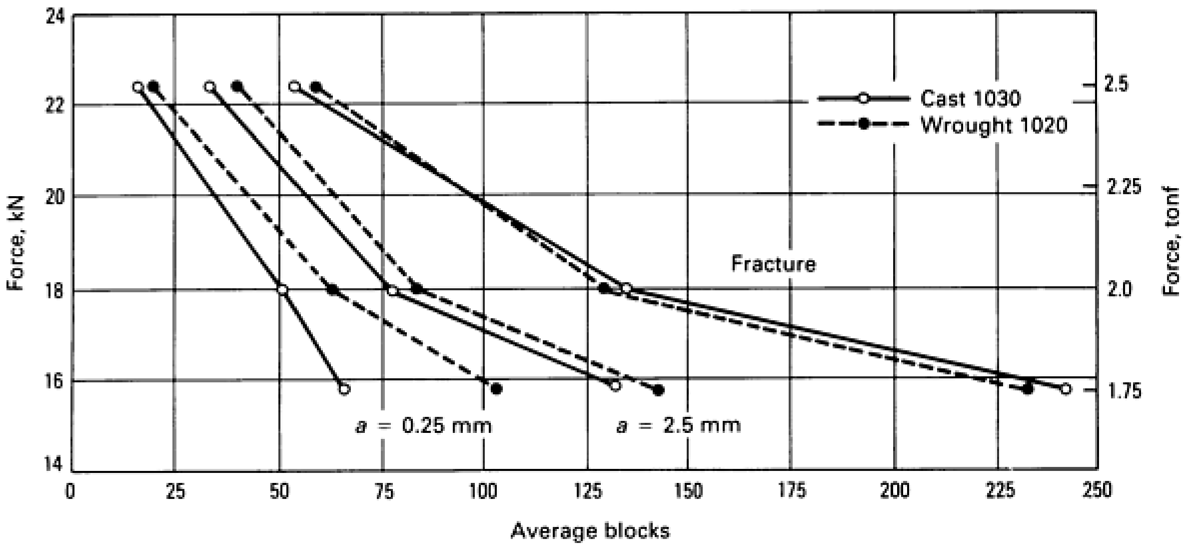

Fig. 13 Average blocks to specific crack lengths and fracture for comparable cast and wrought carbon steels in the normalized-and-tempered condition

Section Size and Mass Effects. Mass effects are common to steels, whether rolled, forged, or cast, because the cooling rate during heat treating varies with section size and because the microstructure constituents, grain size, and nonmetallic inclusions increase in size from surface to center. Mass effects are metallurgical in nature and are distinct from the effect of discontinuities, which are discussed in the following section in this article.

The section size or mass effect is of particular importance in steel castings because mechanical properties are typically assessed from test bars machined from standardized coupons having fixed dimensions and are cast separately from or attached to the castings. The removal of test bars from the casting is impractical because removal of material for testing would destroy the usefulness of the component.

Test specimens removed from a casting will not routinely exhibit the same properties as test specimens machined from the standard test coupon designs for which minimum properties are established in specifications. The mass effect discussed above, that is, the difference in cooling rate between the test coupons and the part being produced, is the fundamental reason for this situation. Several specifications provide for the mass effect by permitting the testing of coupons that are larger than normal and that have cooling rates more representative of those experienced by the part being produced. Among these specifications are ASTM E 208, A 356, and A 757.

Discontinuity Effects. The treatment of discontinuities in design is undergoing major changes because of the wider use of fracture mechanics in the industry. If the plane-strain fracture toughness K_{Ic} of a material is known at the temperature of interest, designers can determine the critical combination of flaw size and stress required to cause failure in one load application. In addition, designers can calculate the remaining life of a component having a discontinuity, or they can compute the largest acceptable flow from knowledge of the crack growth rate da/dN of a material and other fracture mechanics parameters. In the absence of suitable plane-strain fracture mechanics data, approximations can be made on the basis of results obtained from various tensile, impact, and fatigue tests.

Test Coupon Versus Casting Properties. Coupon properties refer to the properties of specimens cut and machined from a separately cast coupon or a coupon that is attached to and cast integrally with the casting. Typically, the legs of the ASTM standard double-leg keel block (A 370) serve as the coupons; the legs are 32 mm (1.25 in.) thick.

Test Coupons. The ASTM double-leg keel block is the most prominent design for test coupons. Table 5 provides information on the reliability of tensile test results obtained from the double-leg keel block. The data indicate that for two tests there is 95% assurance that the actual strength is within ±6.9 MPa (±1 ksi) of the actual ultimate tensile strength and within ±11 MPa (±1.6 ksi) of the actual yield strength. For tensile ductility, the data show that two tests produce, with 95% assurance, the elongation results within ±3% and the reduction in area value within ±5%. When 32 mm (1.25 in.)

thick test coupons are suitably attached to the casting and cast integrally with the production casting, the tensile properties determined for the coupon will be comparable to those from a separately cast keel block.

Table 5 Number of tests required for various degrees of accuracy using double-leg keel block test specimens

Property tested	**Acceptable variation**		Tests required for indicated probability

The properties determined from keel block legs with dimensions exceeding those of the ASTM double-leg keel block, that is, thicker than 32 mm (1.25 in.), may differ, especially if the steel involved is of insufficient hardenability for the heat treatment employed to produce a microstructure similar to that in 32 mm (1.25 in.) section keel block legs. The data given in Table 6 show slightly decreasing strength and ductility with increasing keel block section size of annealed 0.26% C steel.

The weldability of carbon steels is primarily a function of composition and heat treatment. Carbon steels having low manganese and silicon contents and carbon contents below 0.30% can be welded without any special precautions. When the carbon content exceeds 0.30%, preheating of the casting prior to welding may be advisable. The low-temperature preheat (120 to 205 °C, or 250 to 400 °F) reduces the rate at which heat is extracted from the heat-affected zone (HAZ) adjacent to the weld. Preheating also helps to relieve mechanical stresses and to prevent underbead cracking, because hydrogen is still relatively mobile and can diffuse away from the last areas to undergo a metallurgical transformation. Preheating minimizes the chances of a hardening transformation occurring in the HAZ and therefore reduces the hardness adjacent to the weld. Stress raisers that could result from the hardened area can be eliminated in this manner. Generally, if the hardness of the HAZ after welding does not exceed 35 HRC or 327 HB, preheating of the casting for welding is not required.

Plain Carbon Steels

John M. Svoboda, Steel Founders' Society of America

Melting Practice

One major difference between melting practice in a steel foundry and in a steel mill is the higher tapping temperature used for foundry melting to attain better fluidity of the molten steel. The producer of ingots for rolling is less concerned with fluidity because mold filling is simpler in ingot molds than in the molds used for producing relatively complex shapes.

The melting furnaces used in steel foundries are essentially the same as those used for the production of steel ingots except that most foundry melting units are smaller. Although the equipment is the same, the processes are often different. Steel ingots can be made as rimmed, semikilled, or killed steel. Only thoroughly killed steel is used for steel foundry products. The method of production of the killed steel used for castings may differ from that used for wrought products because of the fluidity requirement. However, the salient features of making steel in a foundry are the same as those for producing fully killed steel ingots.

Foundries that have access to a good grade of scrap, and therefore do not need to reduce the phosphorus and sulfur contents of the steel to meet specifications, usually prefer to use a furnace lined with silica refractories (acid lined). Foundries that do not have a good source of low-phosphorus, low-sulfur scrap use refractories such as magnesite and dolomite for furnace lining (basic lining). The compositions of certain steels, such as austenitic manganese steels, require that they be made in a furnace with a basic lining.

Direct Arc Melting

The direct arc furnace consists essentially of metal shell lined with refractories. This lining forms a melting chamber, the hearth of which is bowl shaped. Three carbon or graphite electrodes carry the current into the furnace. Steel, either solid or molten, is the common conductor for the current flowing between the electrodes. The metal is melted by arcs from the electrodes to the metal charge--both by direct impingement of the arcs and by radiation from the roof and walls. The electrodes are controlled automatically so that an arc of proper height can be maintained.

In acid electric practice, the furnace hearth is composed of silica sand or ganister rammed into place. The furnace is charged with selected scrap low in phosphorus and sulfur because the acid process cannot eliminate these elements. About 40% of the charge usually consists of foundry scrap (gates and risers). The general practice is to charge small pieces first in order to form a compact mass in the furnace, thus aiding electrical conductivity. The heavy, lumpy portion of the charge is placed over the smaller pieces, followed by the lightest portion.

The charge is melted down as quickly as possible. Small amounts of sand and limestone are occasionally added to the bath during the melting period to form a protective slag of proper consistency. Once melting is complete, oxygen is used as an oxidizing agent to produce excess oxygen. Iron oxide in slag reacts with silicon and manganese in the metal bath and produces oxides and silicates in the slag. After most of the silicon and manganese have been oxidized, the bath begins to boil. The boil is evidence of carbon elimination; it results from the interaction of dissolved carbon and free oxygen, giving rise to carbon monoxide bubbles.

In the oxidizing stage of melting, the slag is rich in iron oxide. As carbon is eliminated from the molten iron, the iron oxide content of the slag decreases. The finishing slag contains approximately 55 to 60% SiO_2, 12 to 16% MnO, 4 to 6% Al_2O_3, 7 to 10% CaO, and 12 to 20% FeO.

The carbon content is reduced to approximately 0.20 to 0.25% during the vigorous carbon boil. The boil is stopped by the addition of carbon in the form of a carburizing iron of low sulfur and phosphorus content. Further deoxidizers (ferromanganese and ferrosilicon) are then added to the bath. Next, the metal is tapped into the ladle. A small amount of aluminum is added to the ladle as a final deoxidizer.

For basic electric furnace melting, the furnace lining is a basic refractory such as magnesite or dolomite. The charge is usually composed of purchased scrap steel and foundry returns. During the melting period, small quantities of lime are occasionally added to form a protective slag over the molten metal. Iron ore is added to the bath just as melting is complete. The slag is then highly oxidizing and in the correct condition to take up phosphorus from the metal. Shortly after all of the steel has melted, this first slag is taken off (if a two-slag process is to be used), and a new slag composed of lime, fluorspar, and sometimes a little sand is added.

As soon as the second slag is melted, the current is reduced, and pulverized coke, carbon or ferrosilicon, or a combination of these is spread at intervals over the surface of the bath. This period of furnace operation is known as the refining period, and its purposes are to reduce the oxides of iron and manganese in the slag and to form a calcium carbide slag, which is essential to the removal of sulfur from the metal. The refining slag has approximately the following composition:

Element	Composition, %
CaO	**45-55**

SiO_2	**15-20**
FeO	**0.50-1.5**
CaF	**5-15**

Adjustments are made in the carbon content of the bath by the addition of a low-phosphorus pig iron. After the proper bath temperature is obtained, ferromanganese and ferrosilicon are added and the furnace is tapped. Aluminum is generally added in the ladle as a final deoxidizer.

Induction Melting

The high-frequency induction furnace is essentially an air transformer in which the primary is a coil of water-cooled copper tubing and the secondary is the metal charge. Inside the shell is placed the circular winding of copper tubing. Firebrick is placed on the bottom of the shell, and the space between that and the coil is rammed with grain refractory. The furnace chamber may be a refractory crucible or a rammed and sintered lining. General practice is to use ganister rammed around a steel shell that melts down with the first heat, leaving a sintered lining. Basic linings are often preferred; a rammed lining of magnesia grain or a clay-bonded magnesia crucible can be used.

The process consists of charging the furnace with steel scrap and then passing a high-frequency current through the primary coil, thus inducing a much heavier secondary current in the charge, which heats the furnace to the desired temperature. As soon as a pool of liquid metal is formed, a pronounced stirring action takes place in the molten metal, which helps to accelerate melting. In this process, melting is rapid, and there is only a slight loss of the easily oxidized elements. If a capacity melt is required, steel scrap is continually added during the melting-down period. Once melting is complete, the desired superheat temperature is obtained, and the metal is deoxidized and tapped.

Because only 10 to 15 min elapses from the time the charge is melted down until the heat is tapped, there is not sufficient time for chemical analysis. Therefore, the charge is usually carefully selected from scrap and alloys of known composition in order to produce the desired composition in the finished steel. Composition can be closely controlled in this manner.

In most induction furnaces, no attempt is made to melt under a slag cover, because the stirring action of the bath makes it difficult to maintain a slag blanket on the metal. However, slag is not required, because oxidation is slight. The induction furnace is especially valuable because of its flexibility in operation, particularly in the production of small lots of alloy steel castings. Induction melting is also well adapted to the melting of low-carbon steels because no carbon is picked up from electrodes, as may occur in an electric arc furnace.

Induction furnaces used in the steel foundry range in capacity from 14 to 22,680 kg (30 to 50,000 lb), but most have capacities of 45 to 4500 kg (100 to 10,000 lb).

Deoxidation Practice

Proper melting practice and, to a lesser degree, proper heat treatment can limit the gas content of conventionally melted steel to acceptable levels, regardless of the type of furnace equipment employed. Failure to control oxygen, hydrogen, and nitrogen contents may result in porosity or a serious decrease in ductility or both.

Gas content is largely adjusted during the oxygen boil. After the cold charge is melted and the bath is in the temperature range of 1510 to 1540 °C (2750 to 2800 °F), oxygen is introduced into the molten metal, usually by means of a piping arrangement. The oxygen combines with the dissolved carbon in the steel to form bubbles of carbon monoxide. As the bubbles form, dissolved hydrogen and nitrogen are caught up in the bubbles in much the same way that dissolved oxygen finds its way into bubbles of boiling water. Thus, the bubbles of gas contaminants are boiled out.

The normal hydrogen content in acid-melted steel is in the range of 2 to 4 ppm. Hydrogen content resulting from basic practice is slightly higher. Austenitizing and tempering treatments serve to lower the hydrogen content further in sections

of average thickness. However, these treatments may not suffice when very heavy sections are involved. The alternative is to degas the molten steel under vacuum, particularly when pouring heavy castings that will be subjected to severe dynamic loading.

The lowest nitrogen contents are obtained with either acid or basic open-hearth practice. Nitrogen contents in electric arc melted steels range from 3 to 10 ppm.

The primary role of deoxidation is to prevent pinholes due to carbon monoxide formation during solidification. Oxygen content should be less than 100 ppm to prevent porosity. Silicon and manganese are mild deoxidizers; they are added to stop the carbon boil and to adjust the chemistry. Manganese (>0.6%) and silicon (0.3 to 0.8%) additions are limited by other alloy effects and are normally inadequate alone to prevent pinholes.

Aluminum is the most common supplemental deoxidizer used to prevent pinholes. As little as 0.01% Al will prevent pinholes. Aluminum is normally added at the tap--about 1 kg/Mg (2 lb/ton) (0.10% added) with a recovery of 30 to 50% for a final content of about 0.03 to 0.05%. This is normally supplemented at the pour ladle with additional deoxidation, which could be more aluminum or calcium, barium, silicon, manganese, rare earths, titanium, or zirconium. More than the minimum amount of deoxidizer required for preventing porosity is needed to maintain sulfide inclusion shape control, but excessive amounts can cause intergranular failures or dirty metal. The second addition at the pour ladle is normally 1 to 3 kg/Mg (2 to 7 lb/ton). The commonly used elements for deoxidation are (in order of decreasing power) zirconium, aluminum, titanium, silicon, carbon, and manganese.

Inclusion Shape Control

Nonmetallic inclusions that form during solidification depend on the oxygen and sulfur contents of the casting. Deoxidation decreases the amount of nonmetallic inclusions by eliminating the oxides, and it affects the shape of the sulfide inclusions. High levels of oxygen (>0.012% in the metal) form FeO, which decreases the solubility of manganese sulfides and causes the manganese sulfides to freeze early in solidification as globules. The use of silicon deoxidation alone normally causes the formation of globular (Type I) sulfides.

Decreasing the oxygen to between 0.008 and 0.012% in the metal, through the use of aluminum, titanium, or zirconium increases the solubility of the manganese sulfides so that they solidify last as grain-boundary films. These grain-boundary sulfide films (Type II inclusions) are detrimental to the ductility and toughness of the steel and cause increased susceptibility to hot tearing. If the oxygen content is very low (<0.008% in the metal), then the deoxidizer forms complex sulfides that are crystalline and form early in solidification. These Type III inclusions are less harmful than Type II, but are more harmful than Type I.

The actual sulfide shape depends on the type and amount of deoxidizer. There are complex interactions, so care must be taken to avoid porosity and Type II sulfides. If a high level of rare-earth metals (RE/S > 1.5) is added, then galaxies of sulfides (Type IV inclusions) form; these are only for rare-earth additions. The most common inclusion modifier is calcium. Methods of addition will be covered later in this article.

Argon-Oxygen Decarburization (AOD)

Some foundries have recently installed AOD units to achieve some of the results that vacuum melting can produce. These units look very much like Bessemer converters with tuyeres in the lower sidewalls for the injection of argon or nitrogen and oxygen. They are processing units that must be charged with molten metal from an arc or induction furnace. Up to about 20% cold charge can be added to an AOD unit; however, the cold charge is usually less than 20% and consists of solid ferroalloys. The continuous injection of gases causes a violent stirring action and intimate mixing of slag and metal, which can lower sulfur values to below 0.005%. The gas contents approach or may be even lower than those of vacuum induction melted steel. The dilution of oxygen with inert gas, argon, or nitrogen causes the carbon-oxygen reaction to go to completion in favor of the oxidation reaction of iron and the oxidizable elements, notably, chromium in stainless steel. Therefore, superior chromium recoveries from less expensive high-carbon ferrochromium are obtained compared to those of electric arc melting practices.

Argon-oxygen decarburization units are used in the production of high-alloy castings, particularly of grades that are prone to defects due to high gas contents. Carbon and low-alloy steels for castings with heavy wall sections may be subject to hydrogen embrittlement and are also processed in these units with good results.

Powder Injection/Wire Injection

The powder injection or wire injection of reactive metals (calcium, magnesium, or rare earths) into liquid steel for desulfurization has come to the forefront of technology in the past decade. Ultralow levels of sulfur (<0.005%) can be obtained with this technique. Powder injection and wire injection operations are shown schematically in Fig. 14.

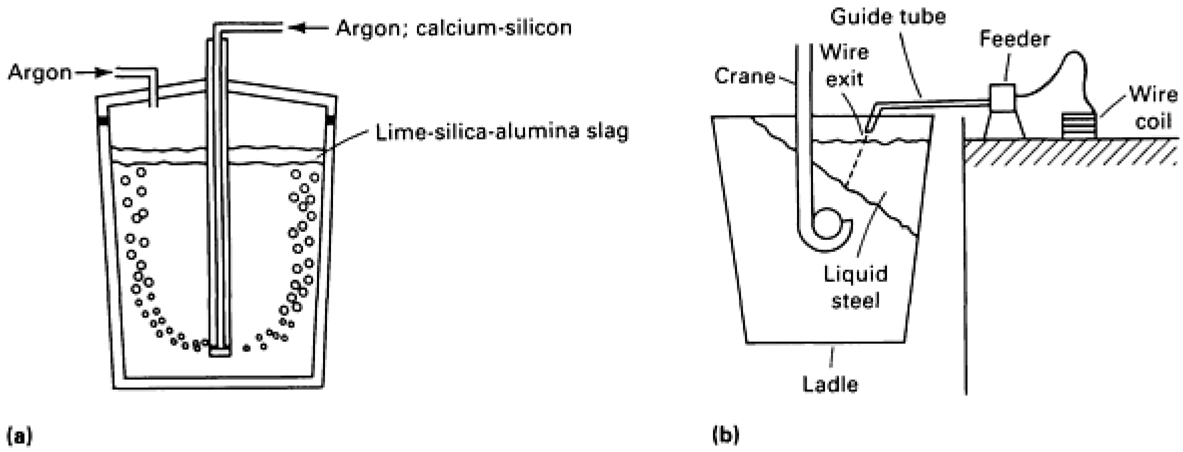

Fig. 14 Schematics showing powder injection and wire injection methods used for desulfurization. (a) Powder injection. (b) Wire injection

The basis of reactive metal injection desulfurization is the chemical combination of the reactive metal with sulfur dissolved in the liquid steel. Because the reactive metals are strong deoxidizers, it is necessary to have a low oxygen level in the liquid steel before the start of the injection process. Otherwise, the reactive metal would combine with the dissolved oxygen and not the dissolved sulfur. Aluminum is used to obtain the necessary low oxygen levels.

It is also necessary to have a slag present to hold the sulfur removed by the reactive metal. If such a slag is not present, the metal sulfide will be oxidized, and the sulfur will return to the liquid metal.

Plasma Refining

Steadily increasing requirements for steel cleanliness have led producers to adopt several novel refining technologies and process routes, many of which involve increased use of the ladle as a refining vessel. Such procedures require longer holding times in the ladle, which necessitate either increased superheats in the furnace or external heating in the ladle in order to avoid early solidification. Higher superheat, in addition to requiring excessive energy expenditure, can contribute to the problem of dirty steel. The preferred solution is to supply heat to the ladle, maintaining the steel at minimal superheat during refining. This can be accomplished by the transferred arc plasma torch, with the added benefit of enhanced refining reactions that aid in the production of clean steel with low levels of residual elements. In this work, experiments have been carried out in an induction furnace equipped with a gas-stabilized graphite electrode to investigate the control of oxygen and inclusion levels and the enhancement of desulfurization afforded by the transferred arc plasma.

Plain Carbon Steels

John M. Svoboda, Steel Founders' Society of America

Specifics of Foundry Practice

The foundry practice used for carbon and low-alloy steels is also used for cast stainless steels and cast nickel-base alloys (see the articles "High-Alloy Steels" and "Nickel and Nickel Alloys" in this Volume). Specific aspects of foundry practice

discussed in this article include pouring, gating, and risering. The cleaning and heat treatment of carbon steel castings will also be discussed.

Pouring Practice

Three types of ladles are used for pouring steel castings: bottom-pour, teapot, and lip-pour. Ladle capacities normally range from 45 kg to 36.3 Mg (100 lb to 40 tons), although ladles having much larger capacities are available.

The bottom-pour ladle (Fig. 15) has an opening in the bottom that is fitted with a refractory nozzle. A stopper rod, suspended inside the ladle, pulls the stopper head up from its seat in the nozzle, allowing the molten steel to flow from the ladle. When the stopper head is returned to the position shown in Fig. 15, the flow is cut off. The position of the stopper head is controlled manually by the slide-and-rack mechanism shown at left in Fig. 15.

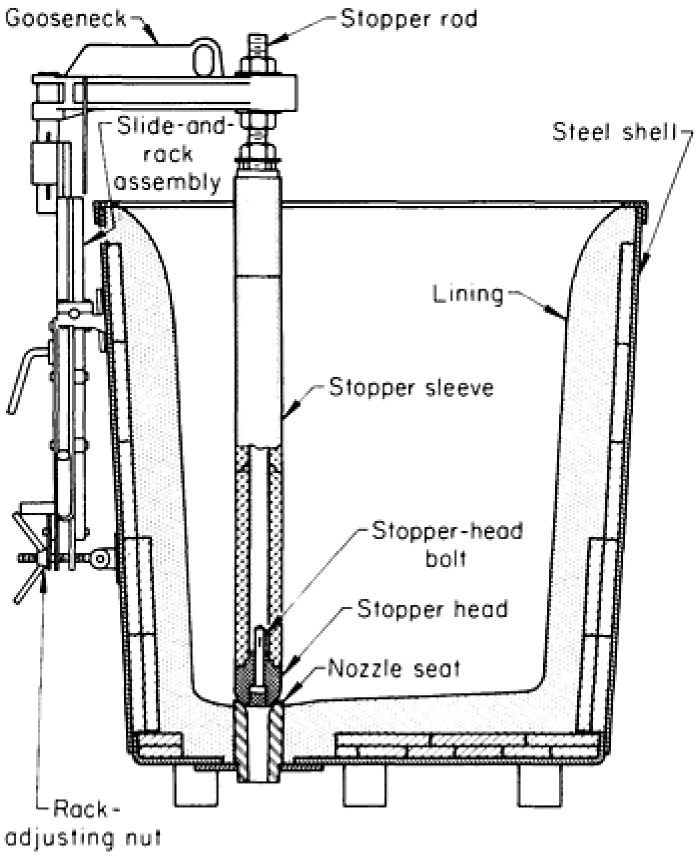

Fig. 15 Schematic of a bottom-pour ladle. This type of ladle is most often used to pour large castings.

Bottom pouring is preferred for pouring large castings from large ladles because it is difficult to tip a large ladle and still control the stream of molten steel. In addition, the bottom-pour ladle delivers cleaner metal to the mold. Inclusions, pieces of ladle lining, and slag float to the top of the ladle; therefore, pouring from the bottom greatly reduces the risk of passing nonmetallic particles into the mold cavity.

On the other hand, it is impractical to pour from a large bottom-pour ladle into small molds. The pressure head created by the metal remaining in the ladle delivers the molten steel too fast. The sand mold is not strong enough to withstand this heavy on-rush of molten steel. In addition, because little time is needed to fill a small mold, a large bottom-pour ladle must be opened and closed many times in order to empty it. This may cause the ladle to leak; however, special nozzles have been developed to minimize leakage. Although bottom-pour ladles could be scaled down in size for pouring smaller castings, this is unnecessary because of the almost equal ability of the teapot ladle to deliver clean metal.

The teapot ladle (Fig. 16) incorporates a ceramic wall, or baffle, that separates the bowl of the ladle from the spout. The baffle extends almost four-fifths of the distance to the bottom of the ladle. As the ladle is tipped, hot metal flows

from the bottom of the ladle up the spout and over the lip. Because the metal is taken from near the bottom of the ladle, it is free of slag and pieces of eroded refractory, although it may pick up foreign materials in the spout section or at the lip. The teapot design is feasible in various sizes, generally covering the entire range of casting sizes that are below the minimum size for which the bottom-pour ladle is used.

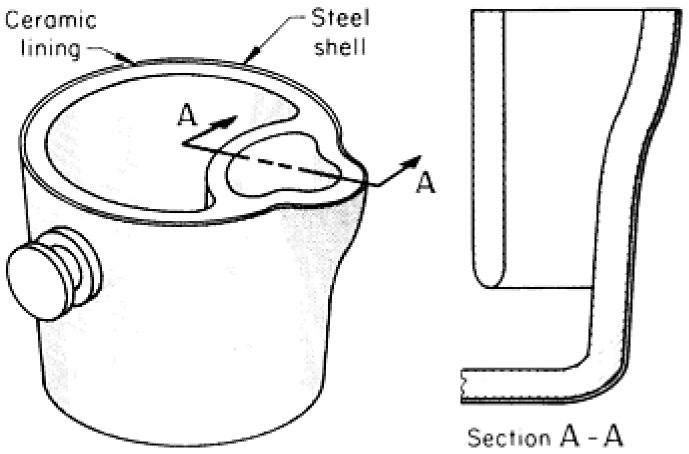

Fig. 16 Typical teapot ladle used for pouring small-to-medium size steel castings

Lip-pour ladles are similar in external form to the teapot type. Because lip-pour ladles have no baffles to hold back the slag and because the hot metal is not taken from the bottom of the ladle, this type of ladle pours a dirtier steel and is seldom used to pour steel castings. Nevertheless, it is widely used as a tapping ladle (at the melting furnace) and as a transfer ladle to feed smaller ladles of the teapot type.

Ladle Linings. Most ladle problems in the steel foundry are caused by deficiencies in preparing and maintaining the linings. Ladles with capacities above about 360 kg (800 lb) are lined with layers of firebrick covered with a thick refractory coating. When used to pour steel made by the acid process and when properly maintained, these linings will last for 60 to 75 heats. However, when pouring steel made by the basic process, the life of the lining is only 10 to 25 heats because of the erosion of refractory by the slag.

Smaller ladles are protected by monolithic linings prepared by ramming or by pouring and vibrating refractory mixtures around forms. The optimum refractory for this purpose is high-purity alumina, but because of the high cost of alumina, alternative materials such as olivine and zircon are more widely used. The service lives of these monolithic linings, which are most commonly used for small ladles, vary considerably, depending on the refractory mixture and the type of service. Thermal expansion and contraction can cause hairline cracks, into which hot metal enters. This results in erosion of the lining. Erosion not only shortens the life of the lining but also contributes to excessive dirt in the steel. Disposable fiber linings that do not require preheating are gaining acceptance.

Preheating the ladle helps to prolong the life of the ladle lining. Heating the lining to a temperature close to that of molten steel serves to lessen the thermal shock to the lining when the molten steel contacts it. Common practice is to preheat ladle linings to 815 to 1095 °C (1500 to 2000 °F) with oil-fired or gas-fired torches. Ladles lined with high-purity alumina can be preheated to temperatures as high as 1370 °C (2500 °F).

Pouring Time. Ideally, the optimum pouring time for a given steel casting would be established on the basis of the weight and shape of the casting, the temperature of the molten metal and its solidification characteristics, and the heat transfer characteristics and thermal stability of the mold. Most foundries, however, are required to pour many different castings from one heat, or even from one ladle. Therefore, these foundries do not attempt to control pouring time, but they do control the speed at which molten steel enters the mold cavity. This control is achieved through the design of the gating system.

Gating Design

An effective gating system for pouring steel and other metals into sand molds is one that fills the mold as rapidly as possible without developing pronounced turbulence. It is essential that the mold be filled rapidly, primarily because heat is radiated to the walls and top surface of the mold as the molten steel rises in the mold cavity; this heat can destroy the binder in the molding sand, causing the mold to collapse unless the metal rises rapidly to provide the necessary support.

Turbulent metal flow is harmful because it breaks up the metal stream, exposing more surface area to air and forming metallic oxides that rise to the top of the mold cavity; this produces a rough surface or inclusions in the casting. In addition, turbulent flow erodes the mold material. These eroded particles also float to the top of the mold cavity.

Preferred Metal Flow. According to preferred practice, the pourer directs the metal stream toward the pouring cup at the top of the mold, controlling the pouring rate to keep the cup full of molten steel throughout the pouring cycle. The opening in the bottom of the cup is directly over the sprue, or downgate, which is tapered with the large end up, thus reducing the diameter of the stream of descending metal. The taper prevents the stream from pulling away from the walls and drawing air into the gating system. The descending metal impinges on the sprue well at the bottom of the sprue, and the direction of flow changes from vertical to horizontal, with the metal flowing along runners to gates (ingates) and then to the main body of the casting. A gating system that incorporates these features is shown in Fig. 17.

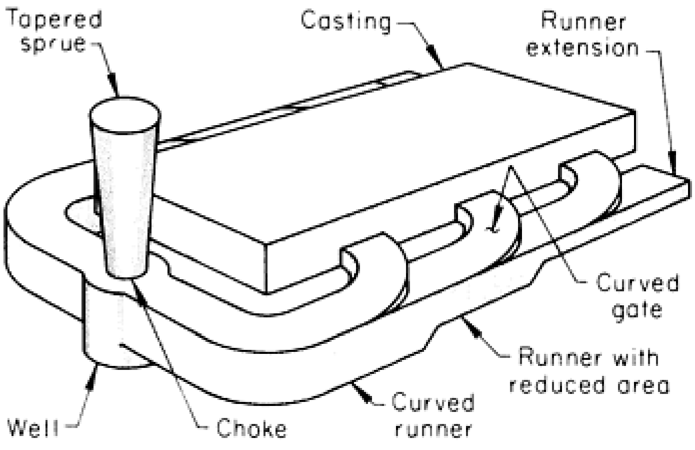

Fig. 17 Gating system that allows good metal flow. The desired metal flow is obtained in this system by proportioning the cross-sectional area of the choke of the spur to all the runners emanating from the sprue and to all of the gates in accordance with a 1:4:4 ratio.

The design of the gating system will largely determine the manner in which molten steel is fed into the mold, as well as the feed rate. Therefore, a system having several gates will influence the distribution of the flow between gates. A good design will have even distribution between gates, both initially and while the mold is filling. The distribution of flow during filling of the mold will affect the type of flow that occurs in the main body of the casting. A large difference in the flow between gates will create a swirl of metal in the mold about a vertical axis, in addition to that occurring about a horizontal axis.

The gating system shown in Fig. 17 is an example of a finger-type parting line system, in which the fingers feed metal to the casting just above the parting line. Other major types of gating systems used in steel foundries include the bottom gate, which feeds metal to the bottom of the casting, and the step gate, which feeds metal through a number of stepped gates, one above another. In the system shown in Fig. 17, the ratio of the cross-sectional area of the choke of the sprue to all of the runners emanating from the sprue basin and to all of the gates is 1:4:4. The runner area decreases progressively by an amount equal to the area of each gate it passes. This practice ensures that once the system is filled with metal it will remain full during the pouring cycle and will feed equally to each gate.

Further, the gates are located in the cope, while the runner, which extends beyond the last gate, is located in the drag. The extension of the runner serves as a trap for the first, and usually the dirtiest, metal to enter the system. The entire runner must fill before the metal will rise to the level of the gates. Thus, each gate begins feeding at the same time. The runners and gates are curved wherever a change in direction occurs. This streamlining reduces turbulence in the metal stream and minimizes mold erosion.

In contrast to the ratio of the system shown in Fig. 17 (1:4:4), if the total cross-sectional area of the gates is less than that of the runners (1:2:0.8, for example), the result is a pressurized system. With a pressurized system, the metal squirts into the mold cavity and flows turbulently over the mold bottom. This may cause roughening of the bottom surfaces.

Conversely, if the total cross-sectional area of the gates is significantly greater than that of the runners (1:2:3, for example), the gating system will be incompletely filled, and flow from the gates will be uneven. This condition increases the likelihood of mold erosion. When required, other more complicated additions to gating systems are used, including whirl gates, horn gates, strainer cores, tangential gates, and slit gates. However, any addition to the gating system usually increases the cost of the casting because all gating must be removed.

Mold Erosion. In addition to the contribution of gating design to a reduction in mold erosion, further reduction can be achieved by making the gating system out of tile, which is superior to green sand in resistance to erosion. However, the use of tile is generally limited to gating systems for large castings; in such cases, the quantity and speed of molten metal passing through the gating system would seriously erode green sand. The automated production of smaller molds is hampered by the addition of tile gates and runners. Thus, gating systems for these smaller castings are rammed in sand, usually with a semicircular or rectangular cross section for the gates and runners.

Riser Design

Molten steel contracts 0.9% per 55 °C (100 °F) as it cools from the pouring temperature to the solidification temperature. It then undergoes solidification contraction of 3% during freezing, and finally the solidified metal contracts 7.2% during cooling to room temperature. Therefore, when casting steel, an ample supply of molten metal must be available from risers (reservoirs) to compensate for the volume decrease, or shrinkage cavities will develop in the locations that solidify last.

Because feeding from the riser depends on gravity, risers are usually located at the top of the casting. Riser forms are placed on the pattern and molded into the cope half of the mold. The riser cavity is usually open to the top of the mold, although blind risers are sometimes used.

Riser Size and Shape. Formulas based on surface area, volume, and freezing time of the casting are used to determine riser size. Most risers are cylindrical, with their height approximately equal to their diameter. This configuration provides a low ratio of surface area to volume, which prolongs the time the steel remains liquid. A spherical riser would constitute an optimum design, but spherical shapes are difficult to mold.

The placement of a riser, in conjunction with its size, determines its effectiveness. The thicker sections of a casting act as reservoirs for feeding the thinner sections, which solidify first. Therefore, risers are placed over thick sections that cannot be fed by other areas of the casting.

Feeding Distance. Castings of uniform thickness present a different problem. Studies have established the feeding distances of a riser for various rectangular shapes in both the horizontal and vertical planes, with and without an end effect. An end effect is the additional cooling provided by the sand cover of an end surface.

The maximum feeding distance can be extended for a uniform section by adding a taper. The progressively thicker section solidifies in a progressively longer time, so that a favorable temperature gradient is established from the end of the section to the riser. A tapered pad of exothermic material placed in the mold along the length of the casting will also produce a favorable temperature gradient.

Plain Carbon Steels

Cleaning Operations

The choice of equipment and processing method for operations in the cleaning room of a steel foundry depends largely on the level of surface finish and dimensional accuracy required and on the cost that can be justified for the particular casting.

Cleaning of Small Castings. Figure 18 shows a flow chart for the cleaning (and other postshakeout operations) of small castings. This sequence of operations is suitable when the casting is small enough (up to about 18 kg, or 40 lb) to be processed on a floor-standing grinder rather than requiring a portable grinder.

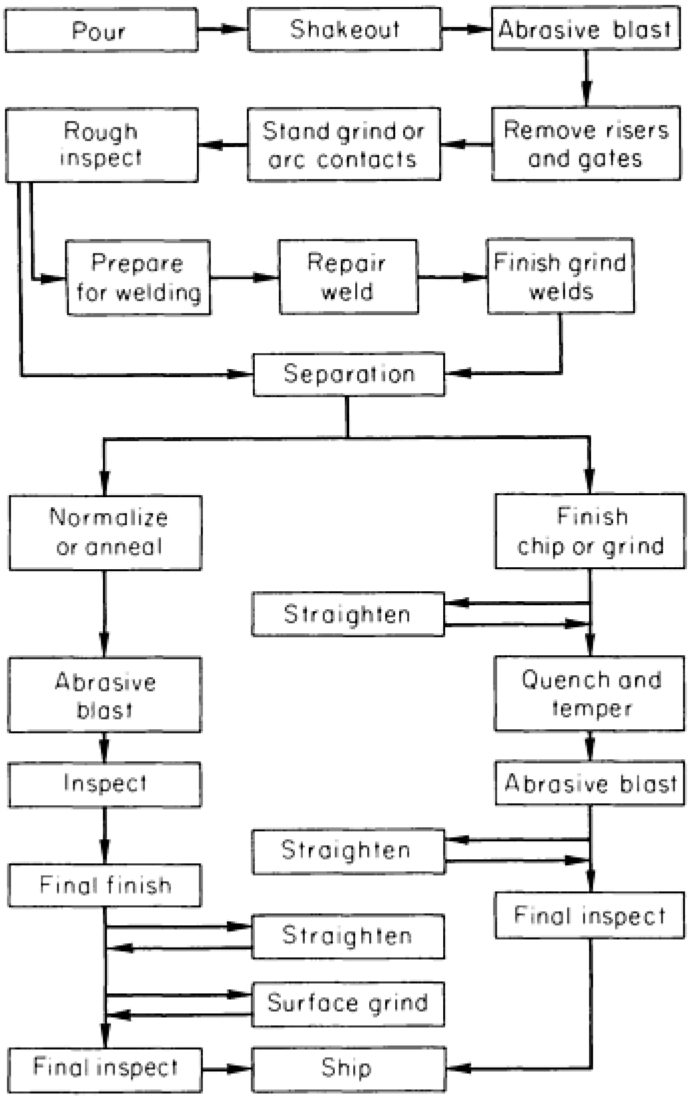

Fig. 18 Flow chart showing steps taken in the cleaning of small (up to 18 kg, or 40 lb) castings

Small castings are usually shaken out (removed from their molds) by a semiautomatic operation in which the molds are placed on a conveyor and taken to a vibrating grate. At the vibrating grate, sand from the broken molds and some of that adhering to the castings falls through the grate while the casting vibrates to the far end of a table and is removed. Certain very fragile castings may require special processing to prevent mechanical damage at this and subsequent stages in the cleaning operation. Castings are then allowed to cool to below about 205 °C (400 °F). At this point, the castings and the attached gates and risers still contain some adhering sand and a thin layer of scale.

The pressure abrasive blasting of small steel castings is generally accomplished in machines that repeatedly tumble the castings on a continuous belt in order to expose the surfaces to a stream of steel (or iron) shot or grit abrasive. Pressure abrasive blasting is a batch operation that usually requires 8 to 20 min per batch.

After the abrasive cleaning operation, gates and risers are removed by gas cutting, sawing, shearing, or breaking off. The equipment used for this operation includes gas-oxygen torches, abrasive cutoff wheels, friction or band saws, sledge hammers, or small power shears. The fuel gases used for gas cutting include acetylene, natural gas, propane, and special gases. The shape of the casting and the locations at which the gates and risers are attached exert a large influence in determining the method of removal.

Castings that are small enough to be readily handled by one man and manipulated manually (up to about 14 to 18 kg, or 30 to 40 lb) are sent to floor-standing grinders to finish contact areas, provided the shape of the casting at the contact

areas is such that extraneous metal can be removed by this type of equipment. Flat surfaces and convex curves that are accessible to the wheel can be shaped with the stand grinder. At the same time, parting line or core fins and other bumps or raised blemishes can also be removed from the castings. If the contours at the contact areas are complex or not readily accessible or if the casting is too heavy or awkward to handle, the contact areas can be smoothed down by the air carbon-arc cutting process. In this process, a carbon electrode approximately 9.5 to 25 mm ($\frac{3}{8}$ to 1 in.) in diameter strikes an arc with the surface of the contact area, and compressed air, issuing from jets in the electrode holder, continuously blows the steel droplets away as they are formed.

Castings can then be inspected, and those requiring weld repair can be removed from the flow and sent to weld preparation areas. Discontinuities are usually best removed prior to welding by using the air carbon-arc cutting process; other methods such as chipping, grinding, or torch scarfing are also employed. Welded areas are finished by grinding or by the air carbon-arc process.

Most carbon steel castings and some low-alloy steel castings require only normalizing or annealing heat treatment, rather than hardening and tempering. After normalizing or annealing, castings are again blast cleaned to remove the scale formed during heat treatment. Further finishing operations, such as grinding, may then be required. Castings that do not need additional finishing are ready for shipment or for machining.

Some castings require straightening, which is done by hydraulic press or hand hammer and die operations. Surface grinding may also be necessary on certain castings that require very flat or smooth surfaces in particular areas. If any of the above operations is performed after the inspection that follows the abrasive cleaning operation, another inspection is required in order to qualify castings for shipment.

Some carbon steel castings and most low-alloy steel castings must be quenched and tempered to achieve the specified strength. Castings so treated can be finished by chipping and grinding before heat treating (see alternate flow procedure in Fig. 18). Castings that are heat treated to only moderate strength levels and are simpler in design can be straightened after heat treatment, if straightening is required.

Cleaning of Large Castings. Figure 19 illustrates typical sequences of operation for cleaning large castings, for which portable equipment must be used while the casting rests on a worktable. These castings can be moved to the shakeout deck on a conveyor, or the individual flasks can be transported to the shakeout site with an overhead crane. When large castings must be shaken out while still at a red heat, the flask can be emptied by setting it on the edge of the shakeout deck so that the casting falls free of the deck and is allowed to cool before being placed on the shakeout deck for more complete removal of the adhering sand. This practice helps to prevent mechanical damage to the castings while they are red hot and soft.

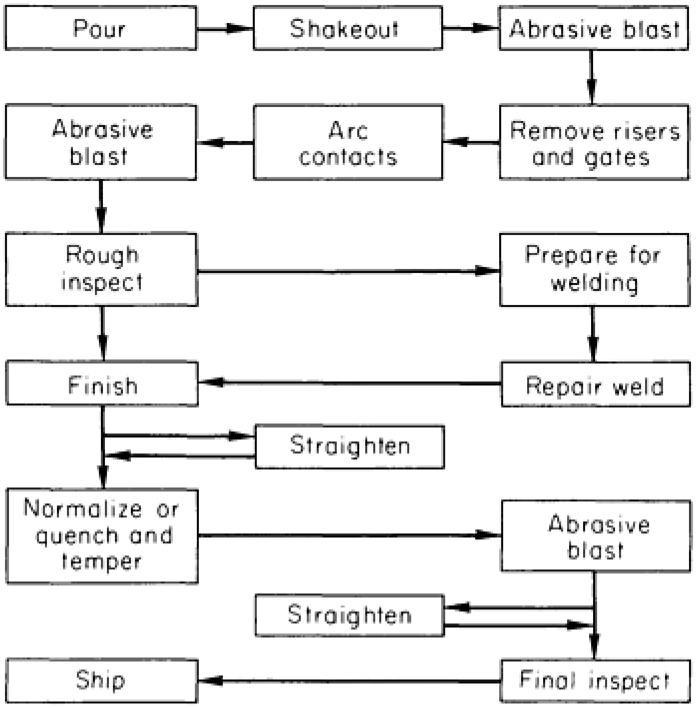

Fig. 19 Flow chart showing steps taken in the cleaning of medium and large castings

Abrasive blasting follows rough cleaning on the shakeout deck. The blasting equipment can be of the same type as that used for small castings but of larger capacity. Castings heavier than about 450 kg (1000 lb) each are usually blasted with a different type of equipment--a large room-type cabinet with a turntable. The casting is placed on the turntable in the desired position, and blasting begins with the turntable revolving to expose different surfaces of the casting to the blast. It may be necessary to reposition the casting once or twice in order to clean all of the surfaces. Blast cabinets equipped with hand-held hoses that propel shot in a high-velocity air stream are also common, especially for cleaning the cored internal cavities of castings. After blast cleaning, large castings are usually transported directly to the gate-and-riser removal area by overhead crane.

Risers and gates are usually removed by gas cutting. The stub of the contact remaining after cutting is removed by grinding with a portable grinder or by the air carbon-arc cutting process, depending on the contour of the surface that is contacted and the overall shape of the casting. The air carbon-arc method is preferred whenever possible because it is faster than grinding. Carbon electrodes 19 or 25 mm ($\frac{3}{4}$ or 1 in.) in diameter are usually used on castings of medium and large size. Following this operation, a short (about 3 min) blast-cleaning cycle can be used to remove slag, arc spatter, or oxide films from the casting surface, and discontinuities and blemishes can be marked for removal and weld repair. Weld preparation can be done by the air carbon-arc process or by chipping or grinding; the former is usually preferred.

After welding, castings are sent to finishing stations where blemishes, bumps, parting line fins, or core fins are removed and welded areas are dressed down. Portable grinding tools powered by compressed air or self-contained electric motors are generally used. Pneumatic chipping hammers and a variety of special chisels may also be required because of the shape of the casting and the location of the fins. Remaining spatter from gas cutting or carbon-arc cutting is also removed at this time.

Unless the castings require straightening, heat treatment is usually the next operation. After heat treatment, castings are blast cleaned to remove scale and then sent to the press area for straightening, if necessary, and on to final inspection.

Heat Treatment

Heat treatment is an important step in the production of steel castings because it develops the mechanical properties of a hardenable steel. Several types of heat treatment are available. The essential elements of any heat treatment are the heating cycle and the cooling cycle. Figure 20 shows schematically a heating cycle and three different cooling cycles. The length of time that a casting is held at temperature and the cooling rate are important factors. The holding time should be long enough to complete the desired microstructural transformation.

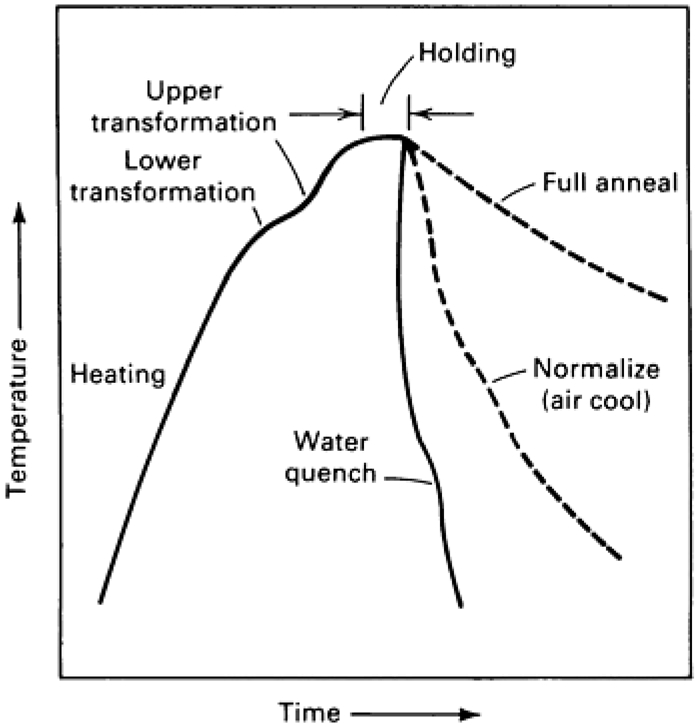

Fig. 20 Schematic showing heating/cooling cycles used for various heat treatments

Annealing is practiced on low-carbon steels to provide a soft, readily machinable structure. Annealed castings have relatively low strength but good ductility.

In a full anneal, the castings are heated above the upper critical temperature, held there long enough to complete the transformation to austenite, and then furnace cooled at a controlled rate to obtain a stress-relieved casting with a pearlite-ferrite structure that is ductile and readily machinable. There are variations of the annealing heat treatment for specialized purposes, for example, to achieve a spheroidized pearlite structure. The annealing temperatures of such specialized treatments may differ substantially from those of a full anneal. Full annealing and spheroidizing heat treatments are costly and should not be specified unless maximum ductility is actually required.

Cooling is accomplished by reducing or by simply turning off the heat input to the furnace. When the castings have cooled to below the lower critical temperature (about 425 °C, or 800 °F), the transformation of austenite is usually complete. The castings can then be removed from the furnace and air cooled or even quenched. Furnace cooling to lower temperatures merely wastes furnace time and requires additional heat to bring the furnace up to temperature for the next load.

Normalizing consists of heating the steel to a suitable temperature above the upper critical transformation temperature, holding long enough to complete the transformation to austenite, removing the work from the furnace, and cooling it in still air. Some castings are tempered after normalizing.

The castings must be placed so that the air can circulate freely around every casting. If air flow is restricted, the operation will be more like annealing. On the other hand, accelerated cooling by fans or forced-air flow may produce a result more like quenching.

The microstructure that results from normalizing is a mixture of ferrite and pearlite, associated with only low residual stresses and almost no distortion. Tensile strengths up to 655 MPa (95 ksi) can be obtained in this way. The normalizing and tempering operation is used to meet a number of standard specifications in this strength range. Because of the uniform structure obtained upon normalizing, machinability is good.

The cost of normalizing makes this heat treatment attractive. It requires less furnace time than annealing, and its cooling cycle is less expensive than quenching.

In hardening by quenching, the work is heated above the transition temperature (austenitized) as in annealing or normalizing (Fig. 20). The work is cooled more rapidly than in the other heat treatments--fast enough so that pearlite and ferrite do not have time to form.

Water and oil are the media most commonly used for quenching steel castings. Water is used whenever possible. Higher-carbon steels require oil quenching. Some complicated shapes also demand oil quenching to minimize quench cracking.

Oil quenches a little more slowly than water at all temperatures. At lower temperatures, the cooling curves for oil taper off; this means even slower rates than for water. Therefore, martensite forms more slowly in oil than in water.

Certain organic chemicals can be added to water to produce a quenching solution that resembles oil in its heat-removal characteristics. The main advantage of these solutions is that they have the behavior of oil without the fire hazard. Their greatest disadvantage is that they coat the work and so change the composition of the bath. The quench severity of these baths varies widely with small changes in composition. Tight control is necessary and sometimes difficult.

The quenching of carbon steels is always followed by tempering in order to adjust the mechanical properties of the quenched steel. The higher tensile strength levels of carbon steels can be obtained only by quenching and tempering. The quenching and tempering operation produces the optimum combination of strength and toughness.

Tempering is a heat treatment that follows quenching and sometimes normalizing. One purpose of tempering is to reduce the residual stresses that develop during cooling and transformation. Another objective of tempering is to modify the metallurgical structure of martensite and thus adjust strength and other mechanical properties to specified levels.

Tempering consists of heating the work to a temperature below the transformation range, holding for a specified time, and finally cooling. Carbon steels are tempered in the range of 175 to 705 °C (350 to 1300 °F). The holding time at temperature may vary from 30 min to several hours. A longer time at a given tempering temperature or a higher tempering temperature for a given time produces greater tempering.

Martensite softens more than pearlite at a given tempering temperature. Composition also affects the tempering response; carbide-forming elements cause the steel to exhibit greater resistance to tempering.

Tempering below 595 °C (1100 °F) may cause temper embrittlement in certain steels. Tempering is usually not done in this temper embrittlement range, and when higher tempering temperatures are used, the work can be quenched from the tempering temperature to minimize time in the embrittling zone during cooling.

Stress Relief. Because tempering is a stress-relief treatment, there is no need for a special stress relief after tempering. Stress relief is obtained by heating to temperatures above 260 °C (500 °F). A stress relief treatment is sometimes required when operations are performed after heat treatment that leave residual stresses in the casting. Welding, induction hardening, and grinding are examples of such operations. The maximum temperature for stress relief is generally limited to 30 °C (50 °F) below the tempering temperature that had been used in heat treating the casting to prevent it from softening.

Hydrogen Removal. Hydrogen has been found to cause low elongation and reduction in area in steel. If the steel contains 4 or 5 ppm of hydrogen, the ductility will be about 20% of that of a hydrogen-free steel. Hydrogen in steel is a mobile element. Above room temperature, the hydrogen will diffuse from the steel, and ductility will be restored.

Hydrogen removal can be accelerated by heating to 205 to 315 °C (400 to 600 °F). This heat treatment is commonly referred to as aging. The aging time is proportional to section thickness. Generally, 25 mm (1 in.) equals 20 h. For heavy sections (≥250 mm, or 10 in.), hydrogen removal by aging becomes impractical because of time requirements.

Plain Carbon Steels

John M. Svoboda, Steel Founders' Society of America

Applications

Two methods of identifying grades of cast steels are extensively used in the United States. The cast steel designations presented at the beginning of this article and the AISI designations for wrought steels are examples of the first method of identifying steel grades by alloy type. In this system, the first two digits indicate the alloy type, and the second two digits represent the carbon content. For example, a 1010 steel represents a carbon steel with 0.10% C, while a 1320 steel represents a manganese steel with 0.20% C. This system does not include mechanical properties or heat treatment. Accordingly, a cast 1040 steel (0.40% C) can exhibit a yield strength of 330 MPa (48 ksi) or of 496 MPa (72 ksi), depending on the choice of heat treatment.

In the second method, letters and numbers are arbitrarily assigned to steels with well-defined compositions, which index the heat treatment as well as the mechanical properties. Specification-writing bodies utilize this second system. Most specifications are written for specific end uses and identify each grade of steel by a unique set of letters and numbers. Because many steel grades are suitable for more than one end use, there are usually many steel grade designations that represent a single type of steel. For example, there are four ASTM specifications that together include 16 grades of chromium-molybdenum steels. These 16 grades, however, are made up of only three different steels. Although such a

system may appear confusing because of the redundancy of designations, the system does offer the advantage of characterizing the cast steel end product as thoroughly as is needed for its end use.

Low-carbon cast steels are those that have a carbon content less than 0.20%. The elements present in low-carbon cast steel, other than carbon, are manganese (0.50 to 1.00%), silicon (0.25 to 0.80%), and sulfur and phosphorus (up to 0.05% maximum each). Residual elements such as nickel, chromium, copper, and molybdenum will be present in small amounts. Cast carbon steels containing less than 0.10% C are mainly produced for electrical and magnetic equipment and are normally given a full anneal heat treatment.

Some castings for the railroad industry are produced from low-carbon cast steel. Castings for the automotive industry are also produced from this class of steel, as are annealing boxes and hot metal ladles. Steel castings in this class are also produced for case carburizing, by which process the castings are given a hard wear-resistant exterior and a tough, ductile core. The magnetic properties of cast low-carbon steels make them useful in the manufacture of electrical equipment.

The medium-carbon cast steels have carbon contents of 0.20 to 0.50%. This class of steels represents the bulk of steel casting production. A very large proportion of cast steel in the medium carbon class is heat treated by normalizing, which consists of cooling the castings in air from approximately 55 °C (100 °F) above the upper critical temperature. A stress-relief treatment can be used to relieve stresses set up in the casting by cooling conditions or welding operations and to soften the HAZ resulting from welding.

More than half of all the steel castings produced are of the medium-carbon type. These parts are used in a wide variety of ways, including applications in the railroad and other transportation industries, machinery and tools, equipment for rolling mills, mining and construction equipment, and many other miscellaneous applications.

High-Carbon Cast Steels. Cast steels containing more than 0.50% C are considered to be high-carbon cast steels. Other elements present in these grades are manganese (0.50 to 1.0%), silicon (0.30 to 0.80%), and phosphorus and sulfur (0.05% maximum each). Because of their high carbon contents, these grades are the most hardenable of the plain carbon cast steels. They are therefore used in applications that require relatively high strength levels.

Low-Alloy Steels

John M. Svoboda, Steel Founders' Society of America

Introduction

LOW-ALLOY STEELS contain alloying elements, in addition to carbon, up to a total alloy content of 8%. Cast steels containing more than the following amounts of a single alloying element are considered low-alloy cast steel:

Element	Amount, %

Manganese	**1.00**
Silicon	**0.80**
Nickel	**0.50**
Copper	**0.50**
Chromium	**0.25**
Molybdenum	**0.10**
Vanadium	**0.05**
Tungsten	**0.05**

Aluminum, titanium, and zirconium are used for the deoxidation of low-alloy steels. Of these elements, aluminum is used most frequently because of its effectiveness and low cost.

Numerous types of cast low-alloy steel grades exist to meet the specific requirements of the end use, such as structural strength and resistance to wear, heat, and corrosion. The designations of the American Iron and Steel Institute (AISI) and the Society of Automotive Engineers (SAE) have historically been used to identify the various types of steel by their principal alloy content. Cast steels, however, do not follow precisely the composition ranges specified by AISI and SAE designations for wrought steels. In most cases, the cast steel grades will contain 0.30 to 0.65% Si and 0.50 to 1.00% Mn unless otherwise specified. The principal low-alloy cast steel designations, their AISI and SAE equivalents, and their alloy type are:

Cast steel designation	**Nearest wrought equivalent**	Alloying elements
1300	1300	**Manganese**
8000, 8400	8000, 8400	**Manganese, molybdenum**
80B00	80B00	**Manganese, molybdenum, boron**
2300	2300	**Nickel**
8600, 4300	8600, 4300	**Nickel, chromium, molybdenum**

9500	9500	**Manganese, nickel, chromium, molybdenum**
4100	**4100**	**Chromium, molybdenum**

The 8000, 8400, 2300, and 9500 designations are no longer used by AISI. However, because these alloy types are extensively used as cast steels, their cast steel designation numbers are continued in the steel casting industry. There are additional alloy types that are infrequently specified as cast steels; namely, 3100 (nickel-chromium), 3300 (nickel-chromium), 4000 (molybdenum), 5100 (chromium), 6100 (chromium-vanadium), 4600 (nickel-molybdenum) and 9200 (silicon).

Hardenability

Hardenability is the property of steel that governs the depth to which hardening occurs in a section during quenching. It should not be confused with hardness, which is the resistance to penetration as measured by Rockwell, Brinell, or other hardness tests. Hardenability is of considerable importance because it relates directly to the strength of steel and to many other mechanical properties, notably, toughness and fatigue properties.

The principal method of hardening carbon and low-alloy steels consists of quenching the steel from the austenitizing temperature. Steels vary in their response to this quenching operation because the depth below the surface of a part to which the part hardens will depend on the composition of the steel and the severity of the quench. Because cooling during a quench is fastest at the surface of a part and slowest at its center and because the hardening reaction is time dependent, hardenability is a vital consideration in alloy selection. Figure 1 shows schematically the cooling curves for the center and surface of a hypothetical steel section superimposed on the continuous cooling transformation diagram. The curve labeled "50% martensite" intersects the pearlite area briefly; thus, half of the mass is transformed to pearlite and half transforms later to martensite. At some point closer to the surface, the cooling rate is given by the curve labeled "Critical cooling rate." This curve represents the cooling rate that is just fast enough to avoid transformation to any type of metallurgical structure except martensite.

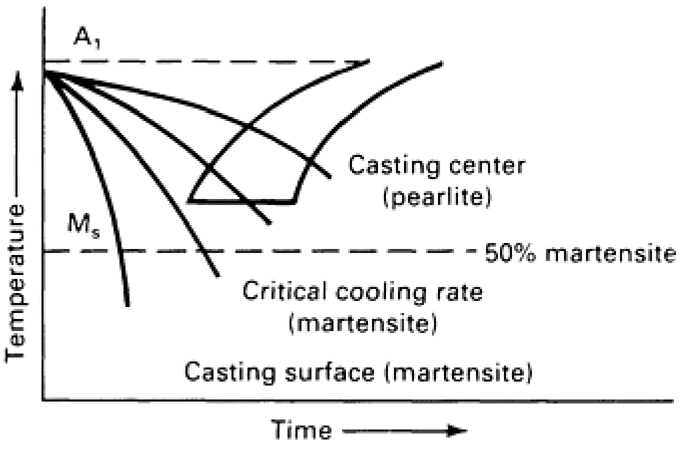

Fig. 1 Difference in cooling rates at the surface and center of a steel casting and the resulting microstructures obtained

Alloying Elements

The compositions of low-alloy cast steels are characterized by carbon contents primarily under 0.45% and by small amounts of alloying elements, which are added to produce certain definite properties. Low-alloy steels are applied when strength requirements are higher than those obtainable with carbon steels. Low-alloy steels also have better toughness and hardenability than carbon steels.

Carbon-Manganese Cast Steels. Cast steels containing 1.00 to 1.75% Mn and 0.20 to 0.50% C have received considerable attention from engineers in the past because of the excellent properties that can be developed with a single, relatively inexpensive alloying element and by a single normalizing or normalizing and tempering heat treatment.

Carbon-manganese steels are also referred to as medium-manganese steels and are represented by the cast 1300 series of steels (1.60 to 1.90% Mn).

Manganese-molybdenum cast steels are very similar to the medium-manganese steels with the added characteristics of high yield strength at elevated temperatures, higher ratio of yield strength to tensile strength at room temperature, greater freedom from temper embrittlement, and greater hardenability. Therefore, these steels have replaced medium-manganese steel for certain applications.

There are two general grades of manganese-molybdenum cast steels:

- 8000 series (1.0 to 1.35% Mn, 0.10 to 0.30% Mo)
- 8400 series (1.35 to 1.75% Mn, 0.25 to 0.55% Mo)

For both of these alloy types, the carbon content is frequently selected between 0.20 and 0.35%, depending on the heat treatment employed and the strength characteristics desired.

Manganese-Nickel-Chromium-Molybdenum Cast Steels. The cast 9500 series low-alloy steels are primarily produced for their high hardenability. Sections exceeding 127 mm (5 in.) in thickness can be quenched and tempered to obtain a fully tempered martensitic structure. The composition range employed for the 9500 series is:

Element	Composition, %
Manganese	**1.30-1.60**
Nickel	**0.40-0.70**
Chromium	**0.55-0.75**
Molybdenum	**0.30-0.40**

Nickel Cast Steels. Among the oldest alloy cast steels are those containing nickel. These steels are characterized by high tensile strength and elastic limit, good ductility, and excellent resistance to impact. The cast steels of the 2300 series contain 2.0 to 4.0% Ni, depending on the grade required.

Nickel-Chromium-Molybdenum Cast Steels. The addition of molybdenum to nickel-chromium steel significantly improves hardenability and makes the steel relatively immune to temper embrittlement. Nickel-chromium-molybdenum cast steel is particularly well suited to the production of large castings because of its deep-hardening properties. In addition, the ability of these steels to retain strength at elevated temperatures extends their usefulness in many industrial applications.

Chromium-Molybdenum Cast Steels. Chromium contents of about 1.00% or more provide a nominal improvement in elevated-temperature properties. The chromium cast steels (5100 series; 0.70 to 1.10% Cr) are not in common use in the steel casting industry. However, the chromium-molybdenum low-alloy cast steels are widely used.

Copper Bearing Cast Steels. There are several types of copper-containing steels. Selection among these various types is primarily based on either their atmospheric corrosion resistance (weathering steels) or the age-hardening characteristics that copper adds to steel.

High-strength cast steels cover the tensile strength range of 1207 to 2068 MPa (175 to 300 ksi). Cast steels with these strength levels and with considerable toughness and weldability were originally developed for ordnance applications. These cast steels can be produced from any of the above medium-alloy compositions by heat treating with liquid-quenching techniques and low tempering temperatures. Cast 4300 series steels or modifications thereof are usually employed.

Structure and Property Correlations

Carbon and low-alloy steel castings are produced to a great variety of properties because composition and heat treatment can be selected to achieve specific combinations of properties, including hardness, strength, ductility, fatigue, and toughness. Although selections can be made from a wide range of properties, it is important to recognize the interrelationships among these properties. For example, higher hardness, lower toughness, and lower ductility values are associated with higher strength values.

Figure 2 illustrates the range of properties that can be achieved with a single steel (in this case, nickel-chromium-molybdenum cast 8630) and the interrelationship of its mechanical properties. These relationships and mechanical property ranges will be further discussed in the following sections.

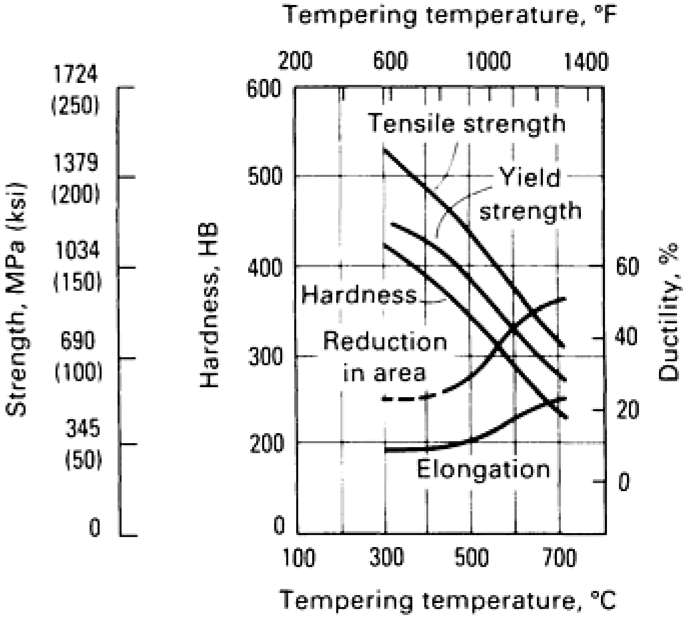

Fig. 2 Mechanical properties of water-quenched cast 8630 steel

Strength and Hardness. Depending on alloy selection and heat treatment, ultimate tensile strength levels ranging from 414 to 1724 MPa (60 to 250 ksi) can be achieved with cast low-alloy steels. The normally expected Brinell hardness-ultimate tensile strength combinations of cast low-alloy steels are shown in Fig. 3. As can be seen, these two properties are directly proportional.

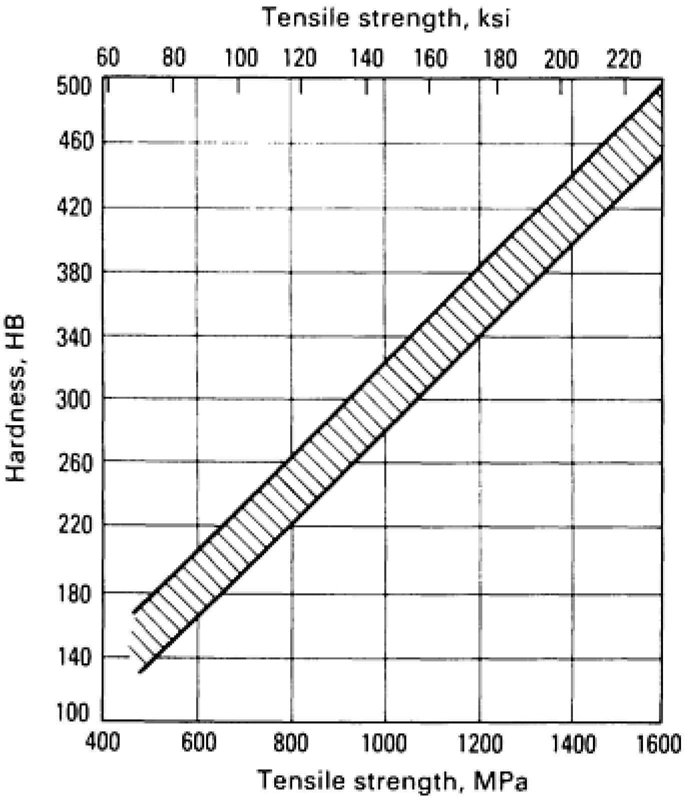

Fig. 3 Hardness versus tensile strength of low-alloy cast steels

Strength and Ductility. Ductility is inversely proportional to the strength, or hardness, of the cast steel. Actual ductility requirements vary with the strength level and the specification to which a steel is ordered. Yield strength is a primary design criterion for structural applications. Therefore, Fig. 4 plots tensile strength, ductility (as measured by elongation), and toughness (based on Charpy V-notch impact energy) in terms of yield strength. Quenched-and-tempered steels exhibit higher ductility values for a given yield strength level than normalized-and-tempered steels.

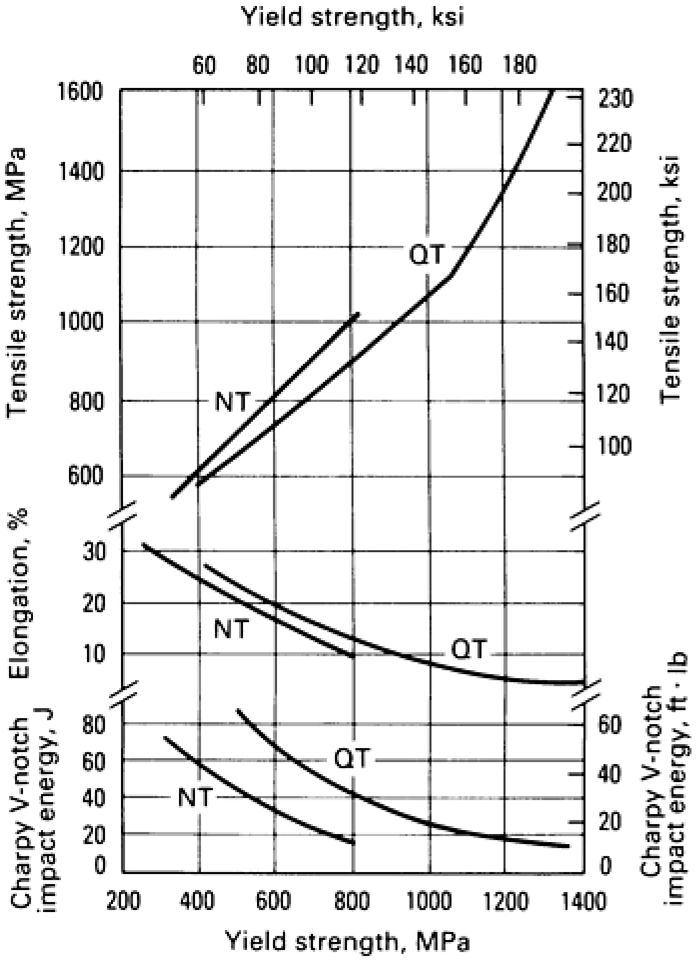

Fig. 4 Room-temperature properties of cast low-alloy steels. QT, quenched and tempered; NT, normalized and tempered

Strength and Toughness. Several test methods are available for evaluating the toughness of steel, or the resistance to sudden or brittle fracture. These include the Charpy V-notch impact test, the drop-weight tear test, the dynamic tear test, and specialized procedures to determine plane-strain fracture toughness.

Room-temperature Charpy V-notch impact energy trends (Fig. 4) reveal the distinct effect of strength and heat treatment on toughness. Higher toughness is obtained when a steel is quenched and tempered, rather than normalized and tempered; quenching, followed by tempering, produces superior toughness.

Nil ductility transition temperatures (NDTT) from 38 °C (100 °F) to as low as -90 °C (-130 °F) have been recorded in tests on normalized-and-tempered cast carbon and low-alloy steels in the yield strength range of 207 to 655 MPa (30 to 95 ksi). Nil ductility transition temperature values of as high as 10 °C (50 °F) to as low as -107 °C (-160 °F) can be obtained in the yield strength range of 345 to 1345 MPa (50 to 195 ksi), depending on alloy selection.

An approximate relationship exists between Charpy V-notch impact energy-temperature behavior and the nil ductility transition temperature. The nil ductility transition temperature frequently coincides with the energy transition temperature determined in Charpy V-notch tests. Applicable data for cast carbon-manganese steels are shown in Fig. 5.

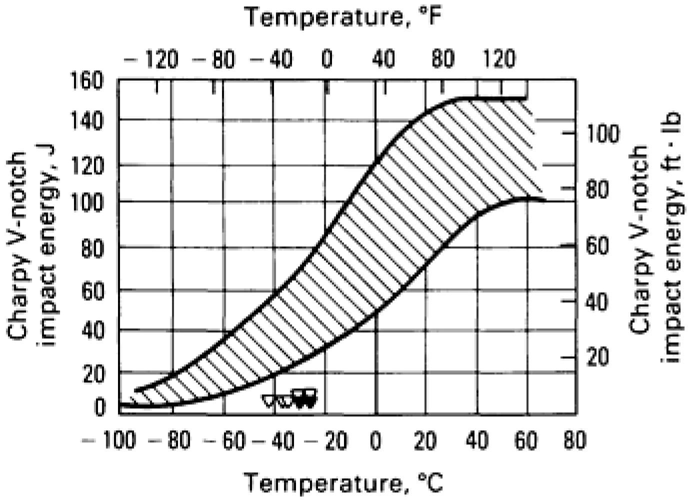

Fig. 5 NDTT values (triangles) and the scatter band of Charpy V-notch energy transition curves of several quenched-and-tempered carbon-manganese cast steels. Nominal ultimate tensile strength: 552 MPa (80 ksi)

Fracture Mechanics Tests. Plane-strain fracture toughness (K_{Ic}) data for the various steels listed in Table 1 reflect the important strength-toughness relationship. For quenched-and-tempered nickel-chromium-molybdenum steels, Fig. 6 indicates high K_{Ic} values of about 110 MPa$\sqrt{m}$ (100 ksi$\sqrt{in}$), at a 0.2% offset yield strength level of 1034 MPa (150 ksi). At a yield strength level of 1655 MPa (240 ksi), K_{Ic} values level off to about 66 MPa$\sqrt{m}$ (60 ksi$\sqrt{in}$). Data are also plotted in Fig. 6 for wrought plates made of comparable steel of somewhat higher carbon content.

Fracture mechanics tests have the advantage over conventional toughness tests of being able to yield material property values that can be used in design equations. Additional information is available in the Selected References at the end of this article.

Strength and Fatigue. The most basic method of presenting engineering fatigue data is by means of the *S-N* curve. The *S-N* curve shows the life of the fatigue specimen in terms of the number of cycles to failure *N* and the maximum applied stress *S*. Additional tests have been used, and the principal findings for cast steels are highlighted in the following sections.

Constant Amplitude Tests. The endurance ratio (fatigue endurance limit divided by the tensile strength) of cast carbon and low-alloy steels, determined in Moore rotating-beam bending fatigue tests (mean stress = 0), is generally taken to be about 0.40 to 0.50 for smooth bars. The data in Table 2 show that the endurance ratio is largely independent of strength, alloying elements, and heat treatment.

Fatigue notch sensitivity *q*, determined in rotating-beam bending fatigue tests, is related to the microstructure of the steel (composition and heat treatment) and to strength. Table 3 indicates that *q* generally increases with strength--from 0.23 for annealed carbon steel at a tensile strength of 577 MPa (83.5 ksi) to 0.68 for the higher-strength normalized-and-tempered low-alloy steels. The quenched-and-tempered steels with a martensitic structure are less notch sensitive than the normalized-and-tempered steels with a ferrite-pearlite microstructure. Similar results and trends on notch sensitivity have been reported for tests with sharper notches.

Cast steels suffer less degradation of fatigue properties due to notches than equivalent wrought steels. When laboratory test conditions are replaced with more realistic service conditions, the cast steels show much less notch sensitivity than wrought steels. Table 4 indicates that wrought steels are 1.5 to 2.3 times as notch sensitive as cast steels. Under laboratory test conditions and with specimen preparation, the unnotched endurance limit of wrought steels is higher. However, the same fatigue characteristics as those of cast steel are obtained when a notch is introduced (Fig. 7).

Section Size and Mass Effects

Mass effects are common to steel, whether rolled, forged, or cast, because the cooling rate during the heat-treating operation varies with section size and because microstructural components, grain size, and non-metallic inclusions vary from surface to center. Mass effects are metallurgical in nature and are distinct from the effect of discontinuities, which are discussed in the next section of this article. Figure 8 shows how the mass of a component lowers the strength properties of wrought AISI 8630 steel plate. The properties are plotted for the $\frac{1}{4}T$ location, halfway between the surface and the center of the plate.

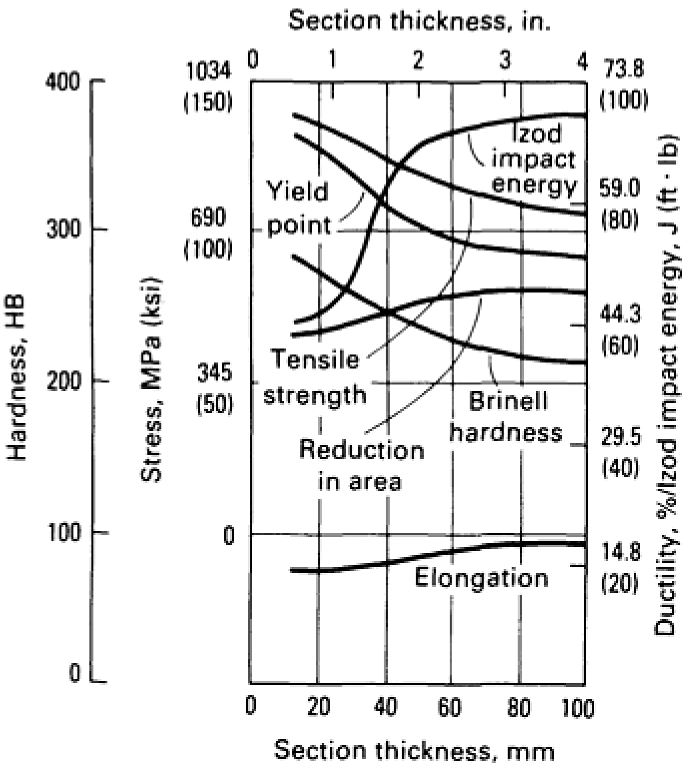

Fig. 8 Section size effects on water-quenched and tempered wrought AISI 8630 steel in sizes over 25 mm (1 in.). The properties reported are those at the $\frac{1}{4}T$ location (midway between surface and center).

The section size or mass effect is of particular importance in steel castings because mechanical properties are typically assessed from test bars machined from standardized coupons that have fixed dimensions and are cast separately from or attached to the castings (Fig. 9). Removal of the test bars from the casting is impractical, because removal of material for testing would destroy the usefulness of the component or would necessitate costly weld repairs for replacing the material removed for testing purposes.

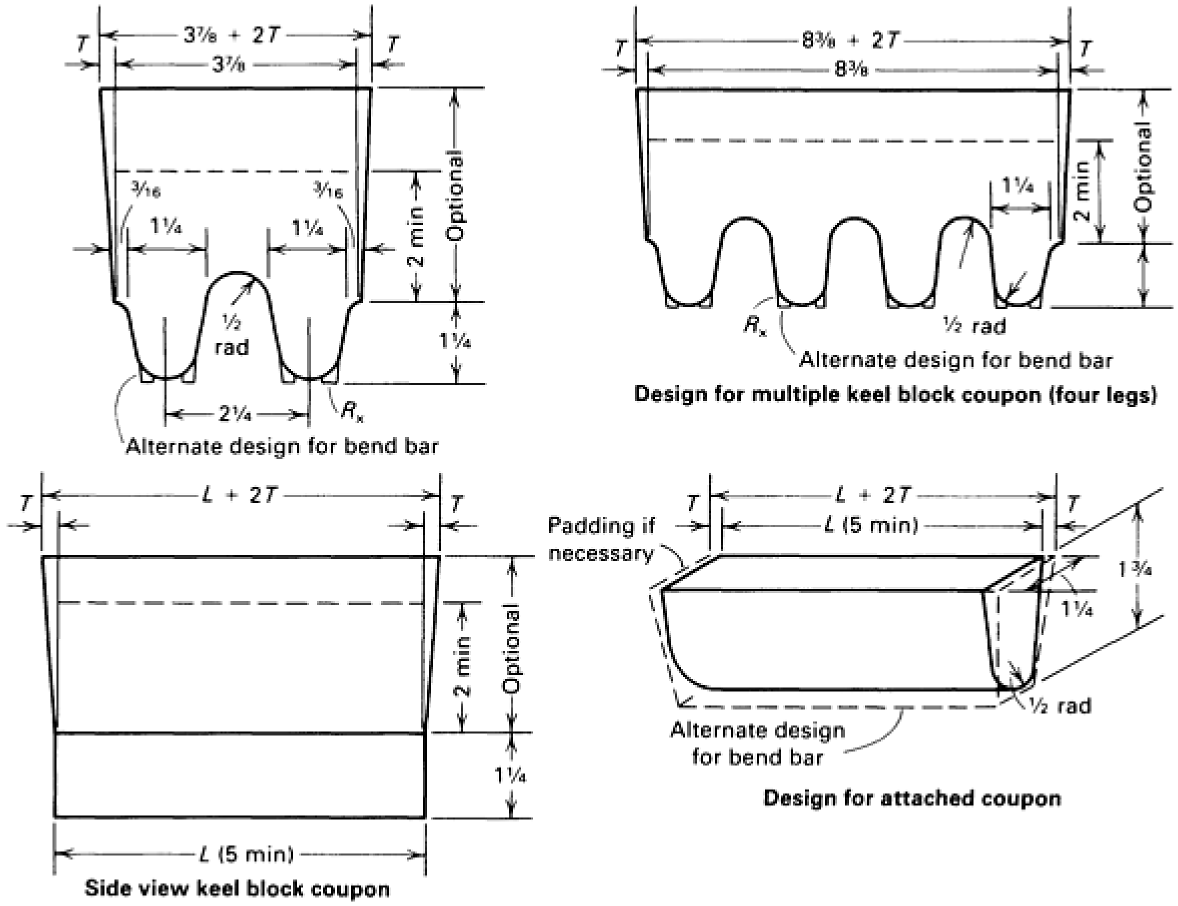

Fig. 9 Keel block coupon according to ASTM A 370. Dimensions given in inches

Specimens removed from a casting cannot be routinely expected to exhibit the same properties as test specimens machined from the standard test coupon designs for which minimum properties are established in specifications. The mass effect discussed above, that is, the differences in cooling rate between test coupons and the part being produced, is the fundamental reason for this situation. Several specifications, such as ASTM E 208, A 356, and A 757, provide for the mass effect by permitting test coupons that are larger than the basic keel block shown in Fig. 9 and whose cooling rate is therefore more representative of that experienced by the part being produced.

Discontinuity Effects

The treatment of discontinuities in design is undergoing major changes as a result of the wider use of fracture mechanics in the industry. If the plane-strain fracture toughness K_{Ic} of a material is known at the temperature of interest, designers can determine the critical combination of flaw size and stress required to cause failure in one load application. In addition, designers can calculate the remaining life of a component having a discontinuity, or they can compute the largest acceptable flaw from a knowledge of the crack growth properties (da/dN) and fracture mechanics parameters (K, n, and C) of a material. In the absence of suitable plane-strain fracture mechanics data, approximations can be made on the basis of test results obtained from a variety of tensile, impact, and fatigue tests.

Test Coupon Versus Casting Properties

Coupon properties refer to the properties of specimens cut and machined from either a separately cast coupon or a coupon that is attached to and cast integrally with the casting. Typically, the legs of the ASTM standard keel block (A 370) serve as the coupons. The legs of this keel block are 32 mm (1.25 in.) thick.

Casting properties refer to the properties of specimens cut and machined from the production casting itself. A casting from which properties are determined in this manner is either destroyed in the process or requires repair welding to replace the metal removed for testing.

Test Coupons. The ASTM double-leg keel block (Fig. 9) is the most prominent design for test coupons among those in use and among those recognized in ASTM A 370. Table 5 in the article "Plain Carbon Steels" in this Volume offers information on the reliability of tensile test results obtained from the double-leg keel block. The data indicate that for two tests there is 95% assurance that the strength is within 6.9 MPa (±1 ksi) of the actual ultimate tensile strength and within 11 MPa (±1.6 ksi) of the actual yield strength. For tensile ductility, the data show that two tests produce, with 95% assurance, the elongation results within ±3% and the reduction in area value within ±5%.

When 32 mm (1.25 in.) thick test coupons are suitably attached to the casting and cast integrally with the production casting, the tensile properties determined for the coupon will be comparable to those from a separately cast keel block. Table 5 contains data on this conclusion for several grades of cast steel.

Table 5 Comparison of properties of keel block and separately cast test specimens

Steel type	Coupon type	Tensile strength		Yield strength		Elongation, %	Reduction in area, %	Hardness, HB
		MPa	ksi	MPa	ksi			
No. 1 carbon steel	Keel block	524	76	317	46	34.5	54.4	**153**
	Attached	510	74	303	44	31.0	50.3	**148**
No. 2 Mn-Mo steel	Keel block	807	117	648	94	22.5	51.7	**241**
	Attached	800	116	641	93	21.0	47.2	**241**
No. 3 carbon steel	Keel block	503	73	338	49	34.0	57.8	. . .
	Attached	503	73	324	47	35.5	60.8	. . .
Grade B steel	Keel block	538	78	324	47	27.5	47.1	. . .

The properties determined from keel block legs whose dimensions exceed those of the ASTM double-leg keel block (that is, thicker than 32 mm, or 1.25 in.) may differ, especially if the steel involved is of insufficient hardenability for the heat treatment employed to produce a microstructure similar to that in 32 mm (1.25 in.) section keel block legs. Large mass effects are evident in Table 6 for several of the quenched-and-tempered materials and for the normalized-and-tempered materials. These data apply to low-alloy steels of similar carbon content.

Table 6 Effect of mass on the tensile and impact properties of cast low-alloy steels with similar carbon contents

Specimens were taken from the center of bars.

Weldability

The weldability of low-alloy steels is primarily a function of composition and heat treatment. Carbon steels having low manganese and silicon contents and a carbon content below 0.30% can be welded without any special precautions. When the carbon content exceeds 0.30%, preheating of the casting prior to welding may be advisable. The low-temperature preheat (120 to 205 °C, or 250 to 400 °F) reduces the rate at which heat is extracted from the heat-affected zone (HAZ) adjacent to the weld. Preheating also helps to relieve mechanical stresses and to prevent underbead cracking because hydrogen is still relatively mobile and can diffuse away from the last areas to undergo a metallurgical transformation. Preheating minimizes the chances of a hardening transformation occurring in the HAZ and thus reduces the hardness adjacent to the weld. The metallurgical notch that could result from the hardened area can be eliminated in this manner. Generally speaking, if the hardness of the HAZ after welding does not exceed 35 HRC or 327 HB, preheating of the casting for welding is not required.

As additional alloying elements are added to the steel, the need for preheating increases. Most of the low-alloy steels, such as the cast 8630, 8730, or 4130 steels, require some preheating. When properly preheated, such steels are readily welded. A comparison can be made between the weldability of two steels by comparing their carbon equivalents, CE. Of the various formulas available, one that appears to be quite useful is:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Cr + \%Mo + \%V}{5} + \frac{\%Cu + \%Ni}{15}$$

Steels having the same carbon equivalent will have approximately the same weldability and will require similar preheating and other precautions.

The alloy steels of higher hardenability, for example, the cast 4300 series, require more care and must be preheated in the range of 205 to 315 °C (400 to 600 °F). In fact, a few of the ASTM standards, such as A 217 and A 487, specify preheat temperatures that must be employed. The preheat temperatures specified are conservative and are based on the preheating temperatures normally used in the fabrication of piping assemblies, in which the stresses resulting from the shrinkage of the weld and restraint of the assembly must also be considered.

In the case of some low-alloy steels, especially those subject to toughness requirements, the interpass temperature (maximum or minimum temperature of the weld bead before additional beads are laid) must be maintained at a prescribed low level to prevent embrittlement of the parent metal.

Corrosion Properties

Low-alloy steels are generally not considered to be corrosion resistant, and casting compositions are not normally selected on the basis of corrosion resistance. In some environments, however, significant differences are observed in corrosion behavior such that the corrosion rate of one steel may be half that of another grade. In general, steels alloyed with small amounts of copper tend to have somewhat lower corrosion rates than copper-free alloys. As little as 0.05% Cu has been shown to exert a significant effect. In some environments, nominal levels of nickel, chromium, phosphorus, and silicon may also bring about modest improvements, but when these four elements are present, the presence of copper holds little if any additional advantage. Detailed information on the corrosion resistance of steels is available in the articles "Corrosion of Carbon Steels," "Corrosion of Alloy Steels," and "Corrosion of Cast Steels" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Elevated-Temperature Properties

Steels operating at temperatures above ambient are subject to failure by a number of mechanisms other than mechanical stress or impact. These include oxidation, hydrogen damage, sulfide scaling, and carbide instability, which manifests itself as graphitization.

The environmental factors involved in elevated-temperature service (370 to 650 °C, or 700 to 1200 °F) require that steels used in this temperature range be carefully characterized. As a consequence, four ASTM specifications have been developed for cast carbon and low-alloy steels for elevated-temperature service. One of these specifications, ASTM A 216, describes carbon steels; the other three, A 217, A 356, A 389, cover low-alloy steels.

The two alloying elements common to nearly all the steel compositions used at elevated temperatures are molybdenum and chromium. Molybdenum contributes strongly to creep resistance. Depending on microstructure, it has been shown that 0.5% Mo reduces the creep rate of steels by a factor of at least 10^3 at 600 °C (1110 °F).

Chromium also reduces the creep rate modestly at levels to approximately 2.25%. At higher chromium levels, creep resistance is somewhat reduced. Vanadium improves creep strength and is indicated in some specifications. Other elements that improve creep resistance include tungsten, titanium, and niobium. The effect of tungsten is similar to that of molybdenum, but on a weight percent basis more tungsten is required in order to be equally beneficial. Titanium and niobium have been shown to improve the creep properties of carbon-free alloys, but because they remove carbon from solid solution, their effect tends to be variable. None of the latter three elements appears in U.S. specifications for cast steels for elevated-temperature service.

Temper embrittlement is normally characterized by an increase in the Charpy V-notch impact transition temperature. It is generally associated with quenched-and-tempered steels, but it may also occur in normalized-and-tempered steels and may develop during either tempering or elevated-temperature service. The tempering or service temperature range in which embrittlement occurs is considered to be 425 to 595 °C (800 to 1100 °F). During heat treatment, embrittlement can be avoided by rapid cooling through this range.

The elements generally considered to cause embrittlement are phosphorus, tin, antimony, and arsenic; manganese and silicon enhance the effect of phosphorus. An addition of 0.05% Mo to alloy steels is very effective in reducing temper embrittlement. All of the alloy steels normally used for elevated-temperature service contain at least this quantity of molybdenum; therefore, temper embrittlement during heat treatment is seldom a problem. However, in those cases in which castings must be cooled from the tempering temperature at a rate below 20 °C (35 °F) per hour, it may be necessary to control the amount of temper-embrittling elements present in the steel. When embrittlement occurs during service, no reduction in impact properties at elevated temperature is apparent. Instead, diminished impact toughness may be observed during periods of shutdown when the equipment is at ambient temperatures.

Melting, Deoxidation, and Foundry Practices

Melting and deoxidation practices for low-alloy steels are the same as those employed for plain carbon steels and are discussed in detail in the article "Plain Carbon Steels" in this Volume. Pouring practice and gating and risering are also discussed in that article. Foundry practices, including the cleaning and heat treatment of steel castings, also are discussed "Plain Carbon Steels" in this Volume.

High-Alloy Steels

John M. Svoboda, Steel Founders' Society of America

Introduction

CAST HIGH-ALLOY STEELS are widely used for their corrosion resistance in aqueous media at or near room temperature and for service in hot gases and liquids at elevated temperatures (>650 °C, or 1200 °F). High-alloy cast steels are most often specified on the basis of composition using the designation system of the High Alloy Product Group of the Steel Founders' Society of America. (The High Alloy Product Group has replaced the Alloy Casting Institute (ACI), which formerly administered these designations.). These alloy designations (for example, CF-8M) have been adopted by the American Society for Testing and Materials (ASTM) and are preferred for cast high-alloy steels.

The first letter of the designation indicates whether the alloy is intended primarily for liquid corrosion service (C) or high-temperature service (H). The second letter denotes the nominal chromium-nickel type of the alloy (Fig. 1). As nickel content increases, the second letter of the designation is changed from A to Z. The numeral or numerals following the first two letters indicate maximum carbon content (percentage × 100) of the alloy. Finally, if further alloying elements are present, these are indicated by the addition of one or more letters as a suffix. Thus, the designation of CF-8M refers to an alloy for corrosion-resistant service (C) of the 19Cr-9Ni type (Fig. 1), with a maximum carbon content of 0.08% and containing molybdenum (M).

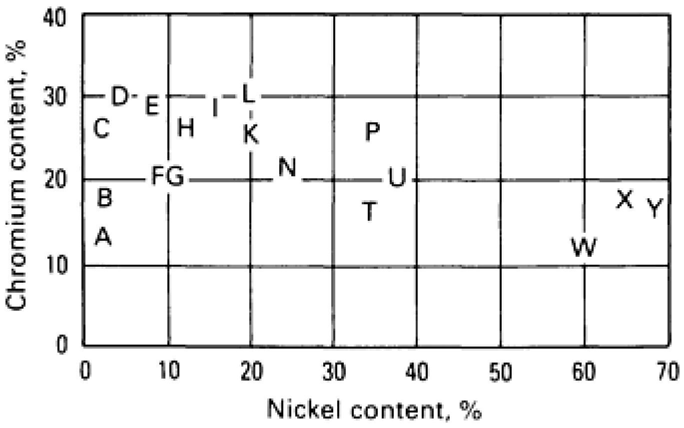

Fig. 1 Chromium and nickel contents in ACI standard grades of heat- and corrosion-resistant steel castings. See text for details.

Some of the high-alloy cast steels exhibit many of the same properties of cast carbon and low-alloy steels (see the articles "Plain Carbon Steels" and "Low-Alloy Steels" in this Volume). Some of the mechanical properties of these grades (for example, hardness and tensile strength) can be altered by suitable heat treatment. The cast high-alloy grades that contain more than 20 to 30% Cr + Ni, however, do not show the phase changes observed in plain carbon and low-alloy steels during heating or cooling between room temperature and the melting point. These materials are therefore nonhardenable, and their properties depend on composition rather than heat treatment. Therefore, special consideration must be given to each grade of high-alloy cast steel with regard to casting design, foundry practice, and subsequent thermal processing (if any).

Corrosion-Resistant High-Alloy Steels

Corrosion-resistant high-alloy cast steels, more commonly referred to as cast stainless steels, have grown steadily in technological and commercial importance during the past 40 years. The principal applications for these steels are as materials of construction for chemical-processing and power-generating equipment involving corrosion service in aqueous or liquid-vapor environments at temperatures normally below 315 °C (600 °F). These alloys are also used for special services at temperatures to 650 °C (1200 °F).

An appropriate definition for cast stainless steels is the familiar one based on the discovery in 1910 that a minimum of 12% Cr will impart resistance to corrosion and oxidation to steel. Cast stainless steels are defined as ferrous alloys that

contain a minimum of 12% Cr for corrosion resistance. Most cast stainless steels are of course considerably more complex compositionally than this simple definition implies. Stainless steels typically contain one or more alloying elements in addition to chromium (for example, nickel, molybdenum, copper, niobium, and nitrogen) to produce a specific microstructure, corrosion resistance, or mechanical properties for particular service requirements.

Corrosion-resistant high-alloy cast steels are usually classified on the basis of composition or microstructure. It should be recognized that these bases for classification are not completely independent in most cases; that is, classification by composition also often involves microstructural distinctions.

Table 1 lists the compositions of the commercial cast corrosion-resistant alloys. Alloys are grouped as chromium steels, chromium-nickel steels in which chromium is the predominant alloying element, and nickel-chromium steels in which nickel is the predominant alloying element. The service-ability of cast corrosion-resistant steels depends greatly on the absence of carbon, and especially precipitated carbides, in the alloy microstructure. Therefore, cast corrosion-resistant alloys are generally low in carbon (typically <0.08% C).

(a) Wrought alloy type numbers are AISI designations for grades most closely corresponding to casting alloys. Wrought alloy type numbers are given only as a guide for determining corresponding cast and wrought grades. Buyers should use cast alloy designations when specifying castings.

(b) Maximum unless range is given. All compositions contain balance of iron.

As shown in Table 1, the high-alloy cast steels can also be classified on the basis of microstructure. Structures may be austenitic, ferritic, martensitic, or duplex; the structure of a particular grade is primarily determined by composition. Chromium, nickel, and carbon contents are particularly important in this regard (see the section "Ferrite in Cast Stainless Steels" in this article). In general, straight chromium grades of high-alloy cast steel are either martensitic or ferritic, the chromium-nickel grades are either duplex or austenitic, and the nickel-chromium steels are fully austenitic.

Martensitic grades include Alloys CA-15, CA-40, CA-15M, and CA-6NM. The CA-15 alloy contains the minimum amount of chromium necessary to make it essentially rustproof. It has good resistance to atmospheric corrosion as well as to many organic media in relatively mild service. A higher-carbon modification of CA-15, CA-40 can be heat treated to higher strength and hardness levels. Alloy CA-15M is a molybdenum-containing modification of CA-15 that provides improved elevated-temperature strength. Alloy CA-6NM is an iron-chromium-nickel-molybdenum alloy of low carbon content.

Austenitic grades include CH-20, CK-20, and CN-7M. The CH-20 and CK-20 alloys are high-chromium, high-carbon, wholly austenitic compositions in which the chromium exceeds the nickel content. The more highly alloyed CN-7M has excellent corrosion resistance in many environments and is often used in sulfuric acid service.

Ferritic grades are designated CB-30 and CC-50. Alloy CB-30 is practically nonhardenable by heat treatment. As this alloy is normally made, the balance among the elements in the composition results in a wholly ferritic structure similar to wrought AISI type 442 stainless steel. Alloy CC-50 has substantially more chromium than CB-30 and has relatively high resistance to localized corrosion in many environments.

Austenitic-ferritic alloys include CE-30, CF-3, CF-3A, CF-8, CF-8A, CF-20, CF-3M, CF-3MA, CF-8M, CF-8C, CF-16F, and CG-8M. The microstructures of these alloys usually contain 5 to 40% ferrite, depending on the particular grade and the balance among the ferrite-promoting and austenite-promoting elements in the chemical composition (see the section "Ferrite in Cast Stainless Steels" in this article).

Duplex Alloys. Two duplex alloys--CD-4MCu and Ferralium--are currently of interest. Alloy CD-4MCu is the most highly alloyed duplex alloy. Ferralium was developed by Langley Alloys and is essentially CD-4MCu with about 0.15% N added. With high levels of ferrite (about 40 to 50%) and low nickel, the duplex alloys have better resistance to stress-corrosion cracking (SCC) than CF-3M. Alloy CD-4MCu, which contains no nitrogen and has a relatively low molybdenum content, has only slightly better resistance to localized corrosion than CF-3M. Ferralium, which has nitrogen and slightly higher molybdenum than CD-4MCu, exhibits better localized corrosion resistance than either CF-3M or CD-4MCu.

Improvements in stainless steel production practices (for example, electron beam refining, vacuum and argon-oxygen decarburization, and vacuum induction melting) have created a second generation of duplex stainless steels. These steels offer excellent resistance to pitting and crevice corrosion, significantly better resistance to chloride SCC than the austenitic stainless steels, good toughness, and yield strengths two to three times higher than those of type 304 or 316 stainless steels.

First generation duplex stainless steels, for example, AISI type 329 and CD-4MCu, have been in use for many years. The need for improvement in the weldability and corrosion resistance of these alloys resulted in the second generation alloys, which are characterized by the addition of nitrogen as an alloying element.

Second generation duplex stainless steels are usually about a 50-50 blend of ferrite and austenite. The new duplex alloys combine the near immunity to chloride SCC of the ferritic grades with the toughness and ease of fabrication of the austenitics. Among the second generation duplexes, Alloy 2205 seems to have become the general-purpose stainless. Table 2 lists the nominal compositions of first and second generation duplex alloys.

Table 2 Nominal compositions of first and second generation duplex stainless steels

(a) All compositions contain balance of iron.

Precipitation-Hardening Grades. The alloys in this group are CB-7Cu and CD-4MCu. Alloy CB-7Cu is a low-carbon martensitic alloy that may contain minor amounts of retained austenite or ferrite. The copper precipitates in the martensite when the alloy is heat treated to the hardened (aged) condition.

Heat-Resistant High-Alloy Steels

Heat-resistant high-alloy steel castings are extensively used for applications involving service temperatures in excess of 650 °C (1200 °F). Strength at these elevated temperatures is only one of the criteria by which these materials are selected, because applications often involve aggressive environments to which the steel must be resistant. The atmospheres most commonly encountered are air, flue gases, or process gases; such atmospheres may be either oxidizing or reducing and may be sulfidizing or carburizing if sulfur or carbon are present.

Carbon and low-alloy steels seldom have adequate strength and corrosion resistance at elevated temperatures in the environments for which heat-resistant cast steels are normally selected. Only heat-resistant steels exhibit the required mechanical properties and corrosion resistance over long periods of time without excessive or unpredictable degradation. In addition to long-term strength and corrosion resistance, some cast heat-resistant steels exhibit special resistance to the effects of cyclic temperatures and changes in the nature of the operating environment.

A number of cast high-alloy grades have been developed and successfully used for a variety of service requirements. There are three principal categories, based on composition:

- Iron-chromium alloys
- Iron-chromium-nickel alloys
- Iron-nickel-chromium alloys

These alloy types resemble high-alloy corrosion-resistant steels except for their higher carbon contents, which impart greater strength at elevated temperature. The higher carbon content and, to a lesser extent, alloy composition ranges distinguish cast heat-resistant steel grades from their wrought counterparts. Table 3 summarizes the compositions of standard cast heat-resistant grades.

Table 3 Compositions of cast heat-resistant high-alloy steels

(a) Wrought alloy type numbers are listed only as a guide for determining equivalent cast and wrought grades. Buyers should use cast alloy designations when specifying castings.

(b) Maximum unless range is given. All compositions contain balance of iron.

(c) Molybdenum not intentionally added

Iron-chromium alloys contain 8 to 30% Cr and little or no nickel. They are ferritic in structure and exhibit low ductility at ambient temperatures. Iron-chromium alloys are primarily used where resistance to gaseous corrosion is the predominant consideration because they possess relatively low strength at elevated temperatures. Examples of such alloys are the cast HA, HC, and HD grades listed in Table 3.

Iron-chromium-nickel alloys contain more than 18% Cr and more than 8% Ni, with the chromium content always exceeding that of nickel. They exhibit an austenitic matrix, although several grades also contain some ferrite. These alloys exhibit greater strength and ductility at elevated temperatures than those in the iron-chromium group and withstand moderate thermal cycling. Examples of these alloys are the HE, HF, HH, HI, HK, and HL grades listed in Table 3.

Iron-nickel-chromium alloys contain more than 10% Cr and more than 23% Ni, with the nickel content always exceeding that of chromium. These alloys are wholly austenitic and exhibit high strength at elevated temperatures. They can withstand considerable temperature cycling and severe thermal gradients and are well suited to many reducing, as well as oxidizing, environments. Examples of iron-nickel-chromium alloys are the HN, HP, HT, HU, HW, and HX grades listed in Table 3. Even though nickel is the major element in the HW and HX grades, these grades are ordinarily referred to as high-alloy steels rather than nickel-base alloys (see the article "Nickel and Nickel Alloys" in this Volume).

Ferrite in Cast Stainless Steels

The CF alloys constitute the most technologically important and highest-tonnage segment of corrosion-resistant casting production. These 19Cr-9Ni alloys are the cast counterparts of the AISI 300-series wrought stainless steels (Table 1). In general, the cast and wrought alloys possess equivalent resistance to corrosive media, and they are frequently used in conjunction with each other.

Important differences do exist, however, between the cast CF alloys and their wrought AISI counterparts. Most significant among these is the difference in alloy microstructure in the end-use condition. The CF grade cast alloys have duplex structures (Table 1) and usually contain 5 to 40% ferrite, depending on the particular alloy. Their wrought counterparts are fully austenitic. The ferrite in cast stainless with duplex structures is magnetic, a point that is often confusing when cast stainless steels are compared to their wrought counterparts by checking their attraction to a magnet. This difference in microstructures is attributable to the fact that the chemical compositions of the cast and wrought alloys are not identical by intent. The differences in composition will be discussed further in this section.

Significance of Ferrite. Ferrite is intentionally present in cast CF grade stainless steels for three principal reasons: to provide strength, to improve weldability, and to maximize resistance to corrosion in specific environments. Strengthening in the cast CF grade alloys is limited essentially to that which can be gained by incorporating ferrite into the austenite matrix phase. These alloys cannot be strengthened by thermal treatment, as with the cast ferritic or martensitic alloys, nor by hot or cold working, as with the wrought austenitic alloys. Strengthening by carbide precipitation is also out of the question because of the detrimental effect of carbides on corrosion resistance in most aqueous environments. Thus, the alloys are effectively strengthened by balancing alloy composition to produce a duplex microstructure consisting of ferrite (up to 40% by volume) distributed in an austenite matrix. It has been shown that the incorporation of ferrite into 19Cr-9Ni cast steels improves yield and tensile strengths substantially without loss of ductility or impact toughness at temperatures below 425 °C (800 °F). The magnitude of this strengthening effect for CF-8 and CF-8M alloys at room temperature is illustrated in Fig. 2.

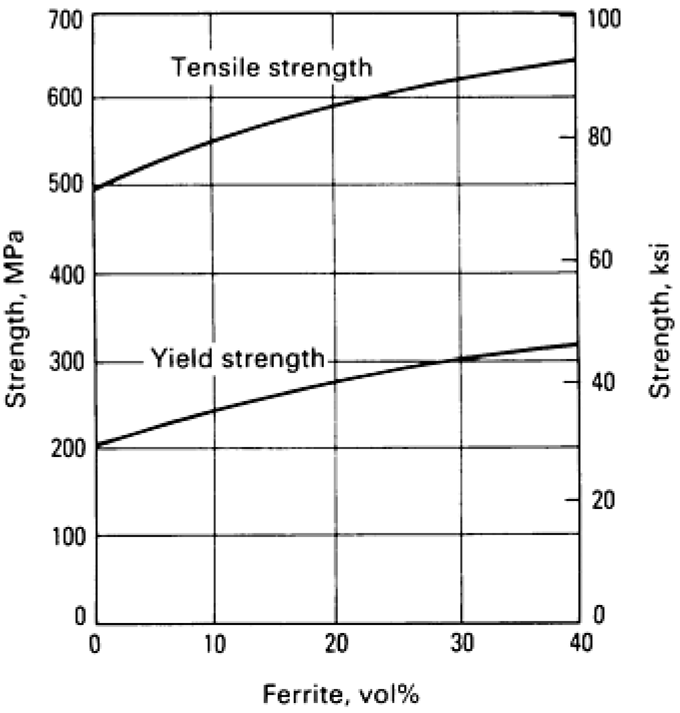

Fig. 2 Yield strength and tensile strength versus percentage of ferrite for CF-8 and CF-8M alloys. Curves are mean values for 277 heats of CF-8 and 62 heats of CF-8M.

Fully austenitic stainless steels are susceptible to a weldability problem known as hot cracking or microfissuring. The intergranular cracking occurs in the weld deposit and/or in the weld heat-affected zone and can be avoided if the composition of the filler metal is controlled to produce about 4% ferrite in the austenitic weld deposit. Duplex CF grade alloy castings are immune to this problem.

The presence of ferrite in duplex CF alloys improves resistance to SCC and generally to intergranular attack. Although failures of high-alloy castings due to these two types of corrosion are not common, SCC and intergranular attack are concerns because they can occur unexpectedly, particularly in castings that have been sensitized by welding in the field, where postweld heat treatment to restore corrosion resistance is impractical or impossible. In the case of SCC, the presence of ferrite pools in the austenite matrix is thought to block or make more difficult the propagation of cracks. In the case of intergranular corrosion, ferrite is helpful in sensitized castings because it promotes preferential precipitation of carbides in the ferrite phase rather than at the austenite grain boundaries, where they would increase susceptibility to intergranular attack.

The presence of ferrite also places additional grain boundaries in the austenite matrix, and there is evidence that intergranular attack is arrested at austenite-ferrite boundaries. The most comprehensive study of the effect of ferrite on the corrosion resistance of cast stainless steels indicates that ferrite:

- Improves the resistance of CF alloys to chloride SCC
- Improves resistance of these alloys to intergranular attack
- Affords greater operating safety for the CF alloys with respect to both types of attack at ferrite contents exceeding 10%

It is important to note, however, that not all studies have shown ferrite to be unconditionally beneficial to the general corrosion resistance of cast stainless steels. Whether or not corrosion resistance is improved by ferrite and to what degree depends on the specific alloy composition and heat treatment and the service conditions (environment and stress state).

Ferrite Control. From the preceding discussion, it is apparent that controlled ferrite contents in predominantly austenitic cast chromium-nickel steels, notably, the CF alloys, offer certain property advantages and that the amount of ferrite present will depend primarily on the compositional balance of the alloy. The underlying causes for the dependence of ferrite content on composition are found in the phase equilibria for the iron-chromium-nickel system. These phase equilibria have been exhaustively documented and related to commercial stainless steels.

The major elemental components of cast stainless steels are in competition to promote austenite or ferrite phases in the alloy microstructure. Chromium, silicon, molybdenum, and niobium promote the presence of ferrite in the alloy microstructure; nickel, carbon, nitrogen, and manganese promote the presence of austenite. By balancing the contents of ferrite- and austenite-forming elements within the specified ranges for the elements in a given alloy, it is possible to control the amount of ferrite present in the austenite matrix. The alloy can usually be made fully austenitic or with ferrite contents up to 30% or more in the austenite matrix.

The relationship between composition and microstructure in cast stainless steels permits the foundryman to predict and control the ferrite content of an alloy, as well as its resultant properties, by adjusting the composition of the alloy. This is accomplished with the Schoefer constitution diagram for cast chromium-nickel alloys (Fig. 3). This diagram was derived from an earlier diagram developed by Schaeffler for stainless steel weld metal. Use of Fig. 3 requires that all ferrite-

stabilizing elements in the composition be converted into chromium equivalents and that all austenite-stabilizing elements be converted into nickel equivalents by means of empirically derived coefficients representing the ferritizing or austenitizing power of each element. A composition ratio is then obtained from the total chromium equivalent Cr_e and nickel equivalent Ni_e, calculated for the alloy composition according to the following:

$$Cr_e = \%Cr + 1.5(\%Si) + 1.4(\%Mo) + \%Nb - 4.99 \quad \textbf{(Eq 1)}$$

$$Ni_e = \%Ni + 30(\%C) + 0.5(\%Mn) + 26(\%N - 0.02) + 2.77 \quad \textbf{(Eq 2)}$$

where the elemental concentrations are given in weight percent. Although similar expressions have been derived that take into account additional alloying elements and different compositional ranges in the iron-chromium-nickel alloy system, use of the Schoefer diagram has become standard for estimating and controlling ferrite content in stainless steel castings.

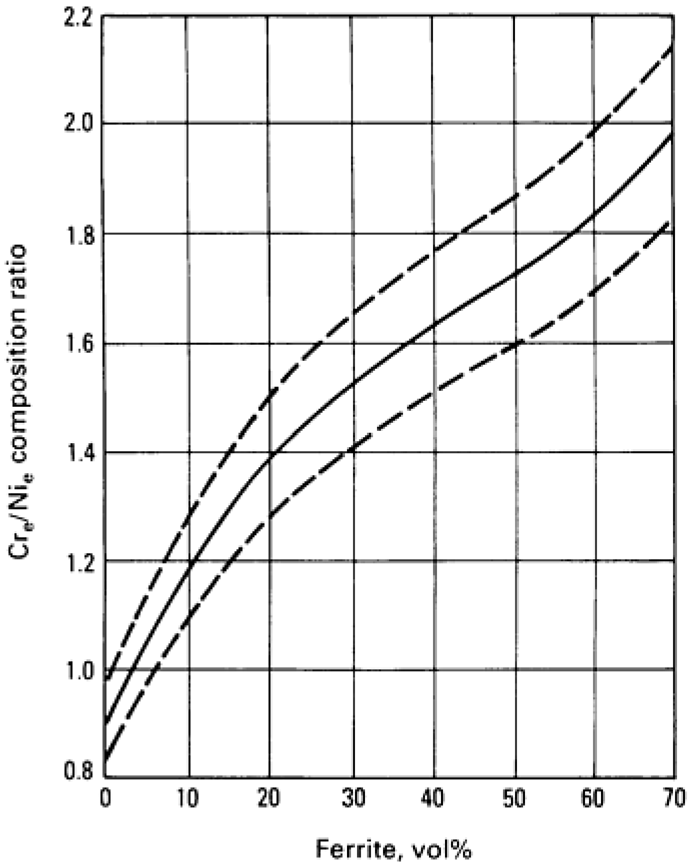

Fig. 3 Schoefer diagram for estimating the ferrite content of steel castings in the composition range 16 to 26% Cr, 6 to 14% Ni, 4% Mo (max), 1% Nb (max), 0.2% C (max), 0.19% N (max), 2% Mn (max), and 2% Si (max). Dashed lines denote scatter bands caused by the uncertainty of the chemical analysis of individual elements. See text for equations used to calculate Cr_e and Ni_e.

The Schoefer diagram possesses obvious utility for casting users and the foundryman. It is useful for estimating or predicting ferrite content if the alloy composition is known, and it is useful for setting nominal values for individual elements in calculating the furnace charge for an alloy in which a specified ferrite range is desired.

Limits of Ferrite Control. Although ferrite content can be estimated and controlled on the basis of alloy composition only, there are limits to the accuracy with which this can be done. The reasons for this are many. First, there is an unavoidable degree of uncertainty in the chemical analysis of an alloy (note the scatter band in Fig. 3). Second, the ferrite content depends on thermal history in addition to composition, although to a lesser extent. Third, ferrite contents at different locations in individual castings can vary considerably, depending on section size, ferrite orientation, presence of alloying element segregation, and other factors.

Measurements of ferrite content in stainless steel castings are also subject to significant limitations. Magnetic measurements of ferrite content are limited to small material volumes and require simple casting geometries. In addition, careful calibration with primary and secondary standards is required for accuracy of measurement. Quantitative metallographic determinations of ferrite content on polished surfaces are essentially impossible to conduct in a nondestructive fashion with respect to the casting. The metallographic approach is also quite time consuming, is limited by alloy etching characteristics and microscope resolution, and is complicated by the fact that it is a two-dimensional technique while ferrite pools and colonies in the alloy structure are three-dimensional.

Both the foundryman and user of stainless steel castings should recognize that the factors mentioned above place significant limits on the degree to which ferrite content (either as ferrite number or ferrite percentage) can be specified and controlled in stainless steel castings. In general, the accuracy of ferrite measurement and the precision of ferrite control diminish as the ferrite number increases. As a working rule, it is suggested that ±6 about the mean or desired ferrite number be viewed as a limit of ferrite control under ordinary circumstances, with ±3 possible under ideal circumstances.

Mechanical Properties: Corrosion-Resistant Alloys

The importance of mechanical properties in the selection of corrosion-resistant cast steels is established by the casting application. The paramount basis for alloy selection is normally the resistance of the alloy to the specific corrosive media or environment of interest. The mechanical properties of the alloy are usually, but not always, secondary considerations in these applications. The corrosion resistance of these materials is discussed in detail in the article "Corrosion of Cast Steels" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Strength and Hardness. Representative room-temperature tensile properties, hardness, and Charpy impact values for corrosion-resistant alloys are given in Table 4 and Fig. 4. These properties are representative of the alloys rather than the specification requirements. Minimum specified mechanical properties for these alloys are given in ASTM standards A 351, A 743, A 744, and A 747. A wide range of mechanical properties are attainable in high-alloy steel grades, depending on the selection of alloy composition and heat treatment. Tensile strengths ranging from 476 to 1310 MPa (69 to 190 ksi) and hardnesses from 130 to 400 HB are available among the cast corrosion-resistant alloys. Similarly, wide ranges exist in yield strength, elongation, and impact toughness.

Fig. 4 Mechanical properties of cast corrosion-resistant steels at room temperature. (a) Tensile strength. (b) 0.2% offset yield strength. (c) Charpy keyhole impact energy. (d) Brinell hardness. (e) Elongation. Also given are the heat treatments used for test materials: AC, air cool; FC, furnace cool; WQ, water quench; A, anneal; T, temper.

The straight chromium steels (CA-15, CA-40, CB-30, and CC-50) possess either martensitic or ferritic microstructures in the end-use condition (Table 1). The CA-15 and CA-40 alloys, which contain nominally 12% Cr, are hardenable through heat treatment by means of the martensite transformation and are often selected as much or more for their high strength as for their comparatively modest corrosion resistance. Castings of these alloys are heated to a temperature at which the structure is fully austenitic and then cooled at a rate (usually in air) adapted to the casting composition so that the austenite transforms to martensite. Strengths in this condition are quite high (for example, 1034 to 1379 MPa, or 150 to 200 ksi), but tensile ductility and impact toughness are limited. Consequently, martensitic castings are usually tempered at 315 to 650 °C (600 to 1200 °F) to restore ductility and toughness at some sacrifice in strength. It follows, then, that significant ranges of tensile properties, hardness, and impact toughness are possible with the martensitic CA-15 and CA-40 grades, depending on the choice of tempering temperature.

The higher-chromium CB-30 and CC-50 alloys, on the other hand, are fully ferritic alloys that are not hardenable by heat treatment. These alloys are generally used in the annealed condition and exhibit moderate tensile properties and hardness (Table 4). Like most ferritic alloys, CB-30 and CC-50 possess limited impact toughness, especially at low temperatures.

Three chromium-nickel alloys--CA-6NM, CB-7Cu, and CD-4MCu--are exceptional in their response to heat treatment and the resultant mechanical properties. Alloy CA-6NM is balanced compositionally for martensitic hardening response. This alloy was developed as an alternative to CA-15 and has improved impact toughness and weldability. The CB-7Cu and CD-4MCu alloys both contain copper and can be strengthened by age hardening. These alloys are initially solution heat treated and then cooled rapidly (usually by quenching in oil or water); thus, the phases that would normally precipitate at slow cooling rates cannot form. The casting is then heated to an intermediate aging temperature at which the precipitation reaction can occur under controlled conditions until the desired combination of strength and other properties is achieved. The CB-7Cu alloy possesses a martensitic matrix, while the CD-4MCu alloy possesses a duplex microstructure, consisting of approximately 40% austenite in a ferritic matrix. Alloy CB-7Cu is applied in the aged condition to obtain the benefit of its excellent combination of strength and corrosion resistance, but alloy CD-4MCu is seldom applied in the aged condition, because of its relatively low resistance to SCC in this condition compared to its superior corrosion resistance in the solution-annealed condition.

The CE, CF, CG, CH, CN, and CK alloys are essentially not hardenable by heat treatment. To ensure maximum corrosion resistance, however, it is necessary that castings of these grades receive a high-temperature solution anneal. This treatment consists of holding the casting at a temperature that is high enough to dissolve all chromium carbides, which are damaging to intergranular corrosion resistance, and then cooling them rapidly enough to avoid reprecipitation of the carbides by quenching in water, oil, or air. Although this can be accomplished throughout in the lower-carbon grades (<0.08% C), heavy sections of alloys with higher carbon contents may have carbides present at some distance below the surface where the cooling rate is slow. Subsurface carbides could be exposed by subsequent machining of the casting, resulting in lowered corrosion resistance in service.

By virtue of their microstructures, which are fully austenitic or duplex without significant carbide precipitation, the alloys exhibit generally excellent impact toughness at low temperatures. The tensile strength range represented by these alloys typically extends from 476 to 669 MPa (69 to 97 ksi). As indicated earlier in this article, the alloys with duplex structures can be strengthened by balancing the composition for higher ferrite levels. The tensile and yield strength of CF alloys with a ferrite number of 35 are typically 150 MPa (22 ksi) higher than those of full austenitic alloys.

Fatigue properties can become a design factor in applications in which the casting experiences cyclic loading conditions in service. The resistance of cast stainless steels to fatigue depends on a sizable number of material, design, and environmental factors. For example, design factors of importance include the stress distribution within the casting (residual and applied stresses), the location and severity of stress concentrators (surface integrity), and the environment and service temperature. Material factors of importance include strength and microstructure. It is generally found that fatigue strength increases with the tensile strength of a material. Both fatigue strength and tensile strength generally increase with decreasing temperature. Under equivalent conditions of stress, stress concentration, and strength, evidence suggests that austenitic materials are less notch sensitive than martensitic or ferritic materials.

Toughness. The fully austenitic corrosion-resistant alloys and those with duplex microstructures exhibit excellent toughness. Figure 4 indicates the magnitude of toughness attainable in various grades in Charpy keyhole impact testing.

Effects of Aging. Cast corrosion-resistant high-alloy steels are extensively used at moderately elevated temperatures (up to 650 °C, or 1200 °F). Elevated-temperature properties are important selection criteria for these applications. In addition, room-temperature properties after service at elevated temperatures are increasingly considered because of the aging effect that these exposures may have. For example, cast alloys CF-8C, CF-8M, CE-30A, and CA-15 are currently used in high-pressure service at temperatures to 540 °C (1000 °F) in sulfurous acid environments in the petrochemical industry. Other uses are in the power-generating industry at temperatures to 565 °C (1050 °F).

Room-temperature properties in the aged condition, that is, after exposure to elevated service temperatures, may differ from those in the as-heat-treated condition because of the microstructural changes that may take place at the service temperature. Microstructural changes in iron-nickel-chromium-(molybdenum) alloys may involve the formation of carbides and such phases as σ, χ, and η(Laves). The extent to which these phases form depends on the composition as well as the time at elevated temperature.

The martensitic alloys CA-15 and CA-6NM are subject to minor changes in mechanical properties and SCC resistance in NaCl and polythionic acid environments upon exposure for 3000 h at up to 565 °C (1050 °F). In CF-type chromium-nickel-(molybdenum) steels, only negligible changes in ferrite content occur during 10,000 h exposure at 400 °C (750 °F) and during 3000 h exposure at 425 °C (800 °F). Carbide precipitation, however, does occur at these temperatures, and noticeable Charpy V-notch energy losses have been reported. These effects are illustrated in Fig. 5 and 6 for CF-8 cast corrosion-resistant steel.

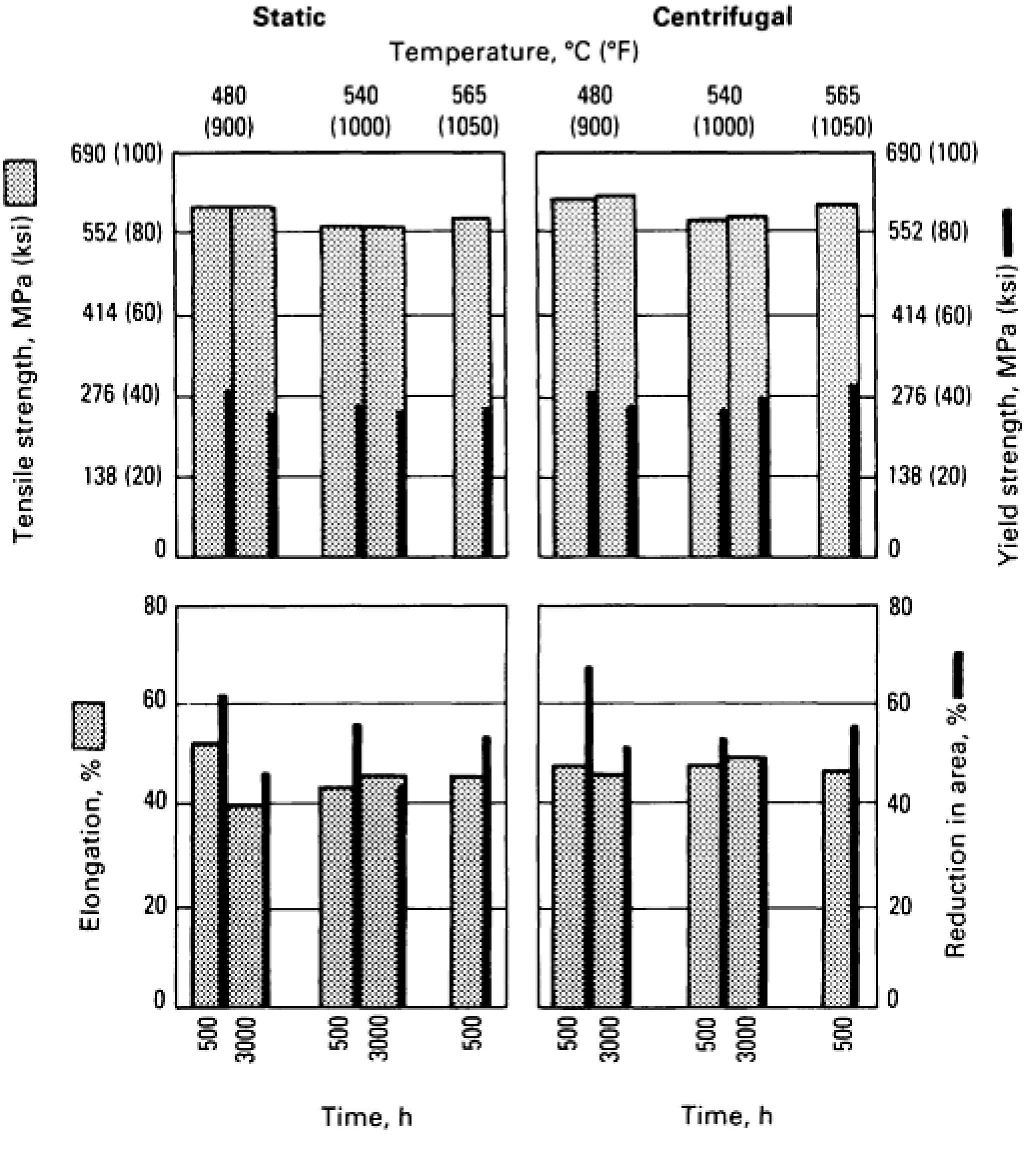

Fig. 5 Effects of time at elevated temperature on the tensile properties of static and centrifugal CF-8 alloy castings. Parts had a ferrite number of 9 to 11 and contained 0.081% N.

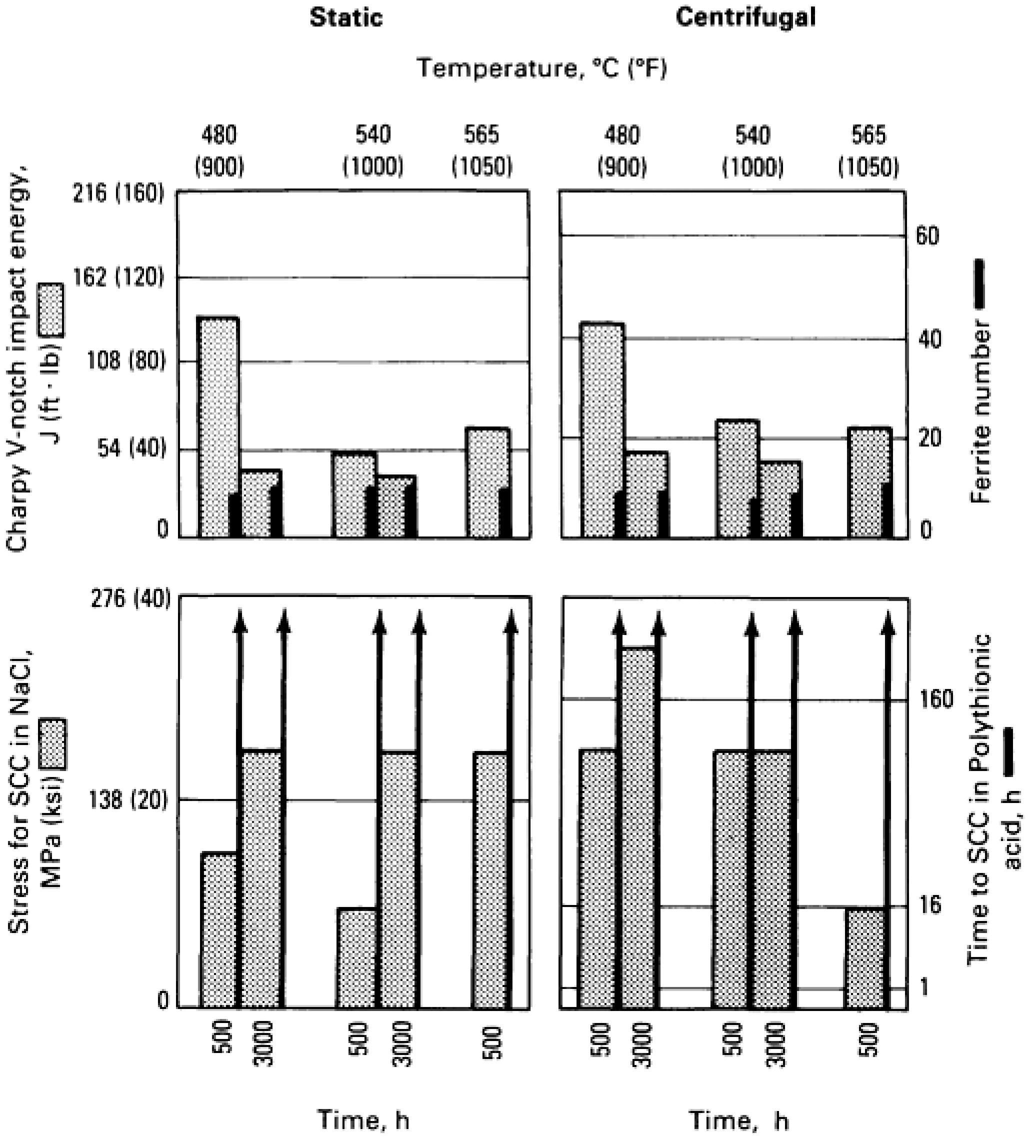

Fig. 6 Effect of time at elevated temperature on the room-temperature impact strength, ferrite number and SCC resistance of CF-8 castings with a ferrite number of 9 to 11 and nitrogen content of 0.081%. Arrows indicate no failure in SCC testing after 336 h.

Above 425 °C (800 °F), microstructural changes in chromium-nickel-(molybdenum) alloys take place at an increased rate. Carbides and σ phase form rapidly at 650 °C (1200 °F) at the expense of ferrite (Fig. 7). Tensile ductility and Charpy V-notch impact energy are prone to significant losses under these conditions. Density changes, resulting in contraction, have been reported as a result of these high-temperature exposures.

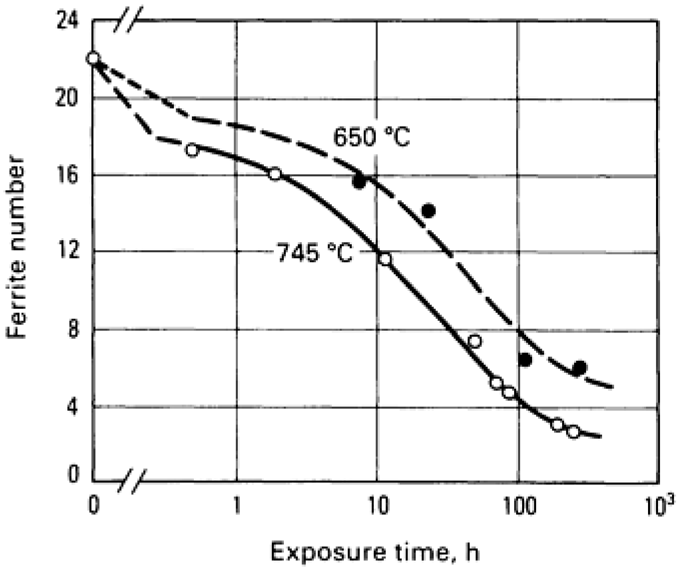

Fig. 7 Transformation of δ-ferrite to austenite and σ phase upon exposure of a solution-treated CF-8 casting to elevated temperature.

Properties of Heat-Resistant Alloys

Elevated-Temperature Tensile Properties. The short-term elevated-temperature test, in which a standard tension test bar is heated to a designated uniform temperature and then strained to fracture at a standardized rate, indentifies the stress due to a short-term overload that will cause fracture in uniaxial loading. The manner in which the values of tensile strength and ductility change with increasing temperature is shown in Fig. 8 for alloy HP-50WZ. Representative tensile properties at temperatures between 650 and 1095 °C (1200 and 2000 °F) are shown in Table 5 for several heat-resistant alloy steel grades.

Table 5 Representative short-term tensile properties of cast heat-resistant alloys at elevated temperatures

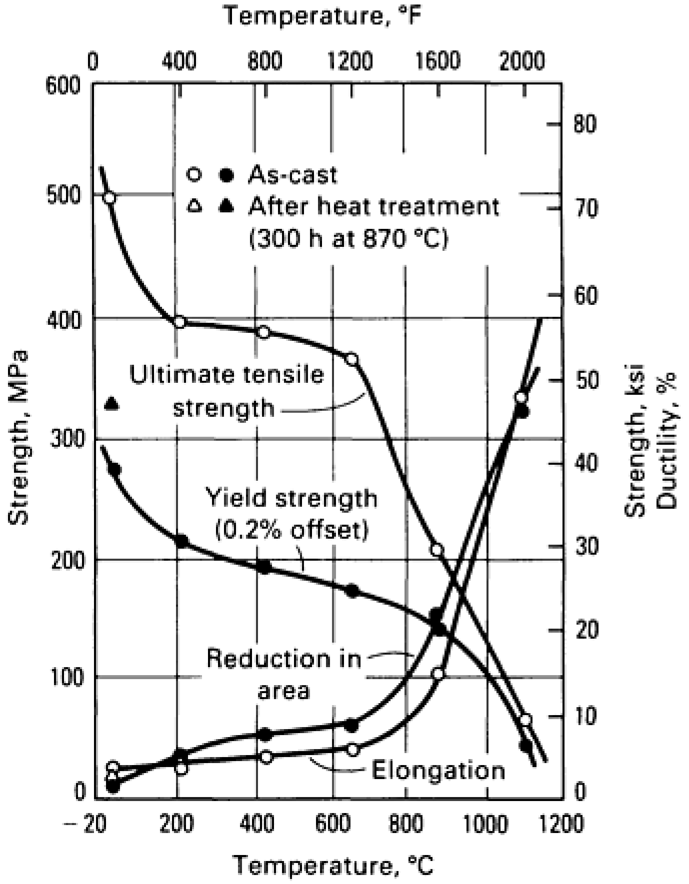

Fig. 8 Tensile properties versus temperature for heat-resistant alloy HP-50WZ.

Creep and Stress Rupture Properties. Creep is defined as the time-dependent strain that occurs under load at elevated temperature. Creep is operative in most applications of heat-resistant high-alloy castings at the normal service temperatures. In time, creep may lead to excessive deformation and even fracture at stresses considerably below those determined in room-temperature and elevated-temperature short-term tension tests. The designer must usually determine whether the serviceability of the component in question is limited by the rate or the degree of deformation. When the rate or degree of deformation is the limiting factor, the design stress is based on the minimum creep rate and design life after allowing for initial transient creep. The stress that produces a specified minimum creep rate of an alloy or a specified amount of creep deformation in a given time (for example, 1% total creep in 100,000 h) is referred to as the limiting creep strength or limiting stress. The manner in which the minimum creep rate depends on the applied stress is illustrated in Fig. 9 by data for ACI alloy HP-50WZ.

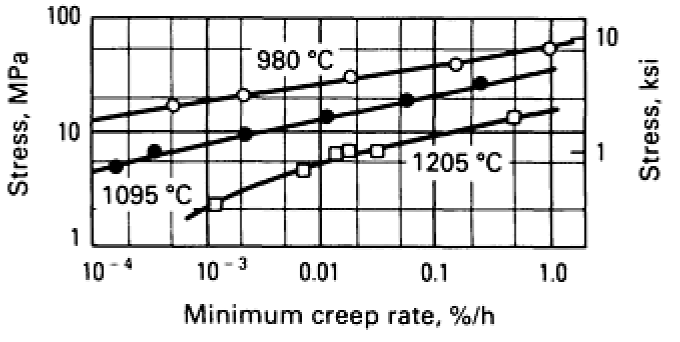

Fig. 9 Minimum creep rate versus stressed temperature for alloy HP-50WZ.

When fracture is the limiting factor, stress-to-rupture values can be used in design (Fig. 10). The stress-to-rupture values can be combined with those for minimum creep rate, as shown in Fig. 11.

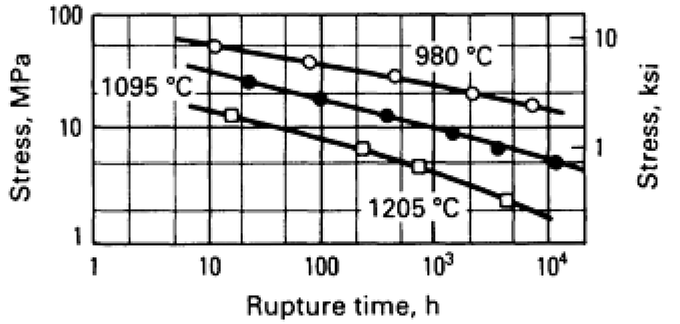

Fig. 10 Rupture time versus stress and temperature for alloy HP-50WZ.

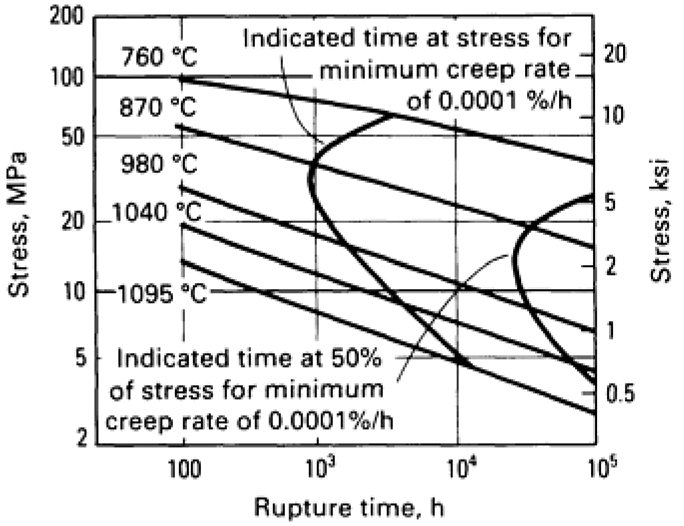

Fig. 11 Creep rupture properties of Alloy HK-40. Scatter bands are ±20% of the central tendency line. Although such a range usually encompasses data for similar alloy compositions, scatter of values may be much higher, especially at longer times and high temperatures.

It should be recognized that long-term creep and stress rupture values (for example, 100,000 h) are often extrapolated from shorter-term tests. Whether these property values are extrapolated or determined directly often has little bearing on the operating life of high-temperature parts. The actual material behavior is often difficult to predict accurately because of the complexity of the service stresses relative to the idealized, uniaxial loading conditions in the standardized tests and because of the attenuating factors such as cyclic loading, temperature fluctuations, or metal loss from corrosion. The designer should anticipate the synergistic effects of these variables.

Thermal Fatigue Resistance. The design of components that are subject to considerable temperature cycling must also include consideration of thermal fatigue. This is particularly true if the temperature changes are frequent or rapid and nonuniform within or between casting sections. Fatigue is a condition in which failure results from alternating load applications in shorter times or at lower stresses than would be expected from constant-load properties. Thermal fatigue denotes the conditions in which the stresses are primarily due to hindered thermal expansion or contraction. Good design helps minimize external restraints to expansion and contraction. Rapid heating and cooling may, however, impose temperature gradients within the part, causing the relatively cool elements of the component to restrain the hotter elements. Finite-element computer analysis has shown that, for some industrial applications, these thermally induced stresses may exceed those resulting from mechanical loads. Nevertheless, such test results have been useful in considering

alloy selection questions, identifying the superior thermal fatigue resistance of nickel-containing grades, and documenting the good performance of some HH type compositions.

Thermal Shock Resistance. Thermal shock failure may occur as a result of a single, rapid temperature change or as a result of rapid cyclic temperature changes, which induce stresses that are high enough to cause failure. Brittle ceramic materials are subject to such failure in a single temperature cycle, but only very infrequently are conditions encountered that would cause failure in a single thermal cycle of the high-alloy cast heat-resistant grades under discussion. The nickel-predominating grades are generally the most resistant to thermal shock.

Resistance to Hot Gas Corrosion. The corrosion of heat-resistant alloys, that is, their attack by the environment at elevated temperatures, varies significantly with alloy type, temperature, velocity, and the nature of the specific environment to which the part is exposed. Table 6 presents a general ranking of the standard cast heat-resistant grades in various environments.

Table 6 Corrosion resistance of heat-resistant cast steels at 980 °C (1800 °F) in 100 h tests in various atmospheres

(a) G, good (corrosion rate $r < 1.27$ mm/yr, or 50 mils/yr); S, satisfactory ($r < 2.54$ mm/yr or 100 mils/yr); U, unsatisfactory ($r > 2.54$ mm/yr, or 100 mils/yr).

(b) Contained 2 g of sulfur/m^3 (5 grains S/100 ft^3).

(c) Contained 120 g S/m^3 (300 grains S/100 ft^3).

(d) Contained 40 g S/m^3 (100 grains S/100 ft^3)

Foundry Practice

Foundry practices for cast high-alloy steels are essentially the same as those used for cast plain carbon steels. Details on melting practice, metal treatment, and foundry practices, including gating, risering, and cleaning of castings, are available in the article "Plain Carbon Steels" in this Volume.

Weldability

Corrosion-Resistant High-Alloy Steels. Most of the corrosion-resistant cast stainless steels, such as the CF-8 (the cast equivalent of wrought AISI type 304) or CF-8M (the cast equivalent of wrought AISI type 316), are readily weldable, especially if their microstructures contain small percentages of δ-ferrite. These grades of stainless can become sensitized and lose their corrosion resistance if subjected to temperatures above 425 °C (800 °F). Great care must therefore be used in welding to be certain that the casting or fabricated component is not heated excessively. For this reason, these stainless steels are almost never preheated. In many cases, the weld is cooled with a water spray between passes to reduce the interpass temperature to 150 °C (300 °F) or below.

Any welding performed on the corrosion-resistant grades will affect the corrosion resistance of the casting, but for many services the castings will perform satisfactorily in the as-welded condition. Where extremely corrosive conditions exist or where SCC may be a problem, complete reheat treatment may be required after welding. Heating the casting above 1065 °C (1950 °F) and then cooling it rapidly redissolves the carbides precipitated during the welding operation and restores corrosion resistance.

Where maximum corrosion resistance is desired and postweld heat treatment (solution annealing) cannot be performed, alloying elements can be added to form stable carbides. Although niobium and titanium both form stable carbides, titanium is readily oxidized during the casting operation and therefore is seldom used. The niobium-stabilized grade CF-8C (the cast equivalent of wrought AISI type 347) is the most commonly used cast grade. The stability of the niobium carbides prevents the formation of chromium carbides and the consequent chromium depletion of the base metal. This grade may therefore be welded without postweld heat treatment. Another approach where postweld heat treatment is undesirable or impossible is to keep the carbon content below 0.03%, as in the CF-3 and CF-3M grades. At this low carbon level, the depletion of the chromium due to carbide precipitation is so slight that the corrosion resistance of the grade is unaffected by the welding operation.

As the alloy content of the corrosion-resistant grades is increased to produce a fully austenitic structure, welding without cracking becomes more difficult. The fully austenitic low-carbon grades tend to form microfissures adjacent to the weld. This tendency toward microfissuring increases as nickel and silicon contents increase and carbon content decreases. Microfissuring is most evident in coarse-grain alloys with carbon contents of approximately 0.10 to 0.20% and nickel

contents exceeding 13%. The microfissuring is reduced by extremely low sulfur contents. In welding these grades, low interpass temperatures, low heat inputs, and peening of the weld to relieve mechanical stresses are all effective. Where strength is not a great factor, an initial weld deposit or "buttering of the weld" with AISI type 304 material is also occasionally used.

The heat-resistant grades are also subject to microfissuring in heavy sections, but to a lesser extent than the high-nickel lower-carbon corrosion grades. The same precautions used for the high-nickel corrosion grades (low heat input, low interpass temperature, and peening when required) should be exercised.

Weldability

Corrosion-Resistant High-Alloy Steels. Most of the corrosion-resistant cast stainless steels, such as the CF-8 (the cast equivalent of wrought AISI type 304) or CF-8M (the cast equivalent of wrought AISI type 316), are readily weldable, especially if their microstructures contain small percentages of δ-ferrite. These grades of stainless can become sensitized and lose their corrosion resistance if subjected to temperatures above 425 °C (800 °F). Great care must therefore be used in welding to be certain that the casting or fabricated component is not heated excessively. For this reason, these stainless steels are almost never preheated. In many cases, the weld is cooled with a water spray between passes to reduce the interpass temperature to 150 °C (300 °F) or below.

Any welding performed on the corrosion-resistant grades will affect the corrosion resistance of the casting, but for many services the castings will perform satisfactorily in the as-welded condition. Where extremely corrosive conditions exist or where SCC may be a problem, complete reheat treatment may be required after welding. Heating the casting above 1065 °C (1950 °F) and then cooling it rapidly redissolves the carbides precipitated during the welding operation and restores corrosion resistance.

Where maximum corrosion resistance is desired and postweld heat treatment (solution annealing) cannot be performed, alloying elements can be added to form stable carbides. Although niobium and titanium both form stable carbides, titanium is readily oxidized during the casting operation and therefore is seldom used. The niobium-stabilized grade CF-8C (the cast equivalent of wrought AISI type 347) is the most commonly used cast grade. The stability of the niobium carbides prevents the formation of chromium carbides and the consequent chromium depletion of the base metal. This grade may therefore be welded without postweld heat treatment. Another approach where postweld heat treatment is undesirable or impossible is to keep the carbon content below 0.03%, as in the CF-3 and CF-3M grades. At this low carbon level, the depletion of the chromium due to carbide precipitation is so slight that the corrosion resistance of the grade is unaffected by the welding operation.

As the alloy content of the corrosion-resistant grades is increased to produce a fully austenitic structure, welding without cracking becomes more difficult. The fully austenitic low-carbon grades tend to form microfissures adjacent to the weld. This tendency toward microfissuring increases as nickel and silicon contents increase and carbon content decreases. Microfissuring is most evident in coarse-grain alloys with carbon contents of approximately 0.10 to 0.20% and nickel contents exceeding 13%. The microfissuring is reduced by extremely low sulfur contents. In welding these grades, low interpass temperatures, low heat inputs, and peening of the weld to relieve mechanical stresses are all effective. Where strength is not a great factor, an initial weld deposit or "buttering of the weld" with AISI type 304 material is also occasionally used.

The heat-resistant grades are also subject to microfissuring in heavy sections, but to a lesser extent than the high-nickel lower-carbon corrosion grades. The same precautions used for the high-nickel corrosion grades (low heat input, low interpass temperature, and peening when required) should be exercised.

Heat Treatment

The heat treatment of stainless steel castings is very similar in purpose and procedure to the thermal processing of comparable wrought materials (see the article "Heat Treating of Stainless Steels" in *Heat Treating*, Volume 4 of the *ASM Handbook*). However, the differences in detail warrant separate consideration here.

Martensitic alloys CA-15 and CA-40 do not require subcritical annealing to remove the effects of cold working. However, in work-hardenable ferritic alloys, machining and grinding stresses are relieved at temperatures from about 260 to 540 °C (500 to 1000 °F). Casting stresses in the martensitic alloys noted above should be relieved by subcritical annealing prior

to further heat treatment. When these hardened martensitic castings are stress relieved, the stress-relieving temperature must be kept below the final tempering or aging temperature.

Alloy CA-6NM (UNS J91540) possesses better casting behavior and improved weldability, it equals or exceeds all of the mechanical, corrosion, and cavitation resistance properties of CA-15, and it has largely replaced the older alloy. Both CA-6NM and CA-15 castings are normally supplied in the normalized condition at 955 °C (1750 °F) minimum and tempered at 595 °C (1100 °F) minimum. However, when it is necessary or desirable to anneal CA-6NM castings, a temperature of 790 to 815 °C (1450 to 1500 °F) should be used. The alloy should be furnace cooled or otherwise slow cooled to 595 °C (1100 °F), after which it can be air cooled. When stress relieving is required, CA-6NM can be heated to 620 °C (1150 °F) maximum, followed by slow cooling to prevent martensite formation.

Homogenization. Alloy segregation and dendritic structures may occur in castings and may be particularly pronounced in heavy sections. Because castings are not subjected to the high-temperature mechanical reduction and soaking treatments involved in the mill processing of wrought alloys, it is frequently necessary to homogenize some alloys at temperatures above 1095 °C (2000 °F) to promote uniformity of chemical composition and microstructure. The full annealing of martensitic castings results in recrystallization and maximum softness, but it is less effective than homogenization in eliminating segregation. Homogenization is a common procedure in the heat treatment of precipitation-hardening castings.

Ferritic and Austenitic Alloys. The ferritic, austenitic, and mixed ferritic-austenitic alloys are not hardenable by heat treatment. They can be heat treated to improve their corrosion resistance and machining characteristics. The ferritic alloys CB-30 and CC-50 are annealed to relieve stresses and to reduce hardness by heating above 790 °C (1450 °F).

The austenitic alloys achieve maximum resistance to intergranular corrosion by solution annealing. As-cast structures, or castings exposed to temperatures from 425 to 870 °C (800 to 1600 °F), may contain complex chromium carbides precipitated preferentially along grain boundaries in wholly austenitic alloys. This microstructure is susceptible to intergranular corrosion, especially in oxidizing solutions. (In partially ferritic alloys, carbides tend to precipitate in the discontinuous ferrite pools; thus, these alloys are less susceptible to intergranular attack.) The purpose of solution annealing is to ensure the complete solution of carbides in the matrix and to retain these carbides in solid solution.

Solution-annealing procedures for all austenitic alloys are similar and consist of heating to a temperature of about 1095 °C (2000 °F), holding for a time sufficient to accomplish complete solution of carbides, and quenching at a rate fast enough to prevent reprecipitation of the carbides--particularly while cooling through the range from 870 to 540 °C (1600 to 1000 °F). The temperatures to which castings should be heated prior to quenching vary somewhat, depending on the alloy.

A two-step heat-treating procedure can be applied to the niobium-containing CF-8C alloy. The first treatment consists of solution annealing. This is followed by a stabilizing treatment at 870 to 925 °C (1600 to 1700 °F), which precipitates niobium carbides, prevents formation of the damaging chromium carbides, and provides maximum resistance to intergranular attack.

Because of their low carbon contents, CF-3 and CF-3M as-cast do not contain enough chromium carbides to cause selective intergranular attack; therefore, these alloys can be used in some environments in this condition. However, for maximum corrosion resistance, these grades require solution annealing.

Martensitic Alloys. Alloy CA-6NM should be hardened by air cooling or oil quenching from a temperature of 1010 to 1065 °C (1850 to 1950 °F). Even though the carbon content of this alloy is lower than that of CA-15, this fact in itself and the addition of molybdenum and nickel enable the alloy to harden completely without significant austenite retention when cooled as suggested.

The choice of cooling medium is primarily determined by the maximum section size. Section sizes exceeding 125 mm (5 in.) will harden completely when cooled in air. Alloy CA-6NM is not susceptible to cracking during cooling from elevated temperatures. For this reason, no problem should arise in the air cooling or oil quenching of configurations that include thick as well as thin sections.

A wide selection of mechanical properties is available through the choice of tempering temperatures. Alloy CA-6NM is normally supplied, normalized, and tempered at 595 to 620 °C (1100 to 1150 °F). Reaustenitizing occurs upon tempering above 620 °C (1150 °F); the amount of reaustenitization increases with temperature. Depending on the amount of this

transformation, cooling from such tempering temperatures may adversely affect both ductility and toughness through the transformation to untempered martensite.

Even though the alloy is characterized by a decrease in impact strength when tempered in the range of 370 to 595 °C (700 to 100 °F), the minimum reached is significantly higher than that of CA-15. This improvement in impact toughness results from the presence of molybdenum and nickel in the composition and from the lower carbon content. The best combination of strength with toughness is obtained when the alloy is tempered above 510 °C (950 °F).

The minor loss of toughness and ductility that does occur is associated with the lesser degree of tempering that takes place at the lower temperature and not with embrittlement, as might be the situation with other 12% Cr steels that contain no molybdenum. The addition of molybdenum to 12% Cr steels makes them unusually stable thermally and normally not susceptible to embrittlement in the annealed or annealed and cold-worked conditions, even when exposed for long periods of time at 370 to 480 °C (700 to 900 °F). No data are currently available on such steels in the quenched-and-tempered or normalized-and-tempered conditions.

The hardening procedures for CA-15 castings are similar to those used for the comparable wrought alloy (type 410). Austenitizing consists of heating to 955 to 1010 °C (1750 to 1850 °F) and soaking for at least 30 min; the high side of this temperature range is normally employed. Parts are then cooled in air or quenched in oil. To reduce the probability of cracking in the brittle, untempered martensitic condition, tempering should take place immediately after quenching.

Tempering is performed in two temperature ranges: up to 370 °C (700 °F) for maximum strength and corrosion resistance, and from 595 to 760 °C (1100 to 1400 °F) for improved ductility at lower strength levels. Tempering in the range of 370 to 595 °C (700 to 1100 °F) is normally avoided because of the resultant low impact strength.

In the hardened-and-tempered condition, CA-40 provides higher tensile strength and lower ductility than CA-15 tempered at the same temperature. Both alloys can be annealed by cooling slowly from the range 845 to 900 °C (1550 to 1650 °F).

Precipitation-Hardening Alloys. It is desirable to subject precipitation-hardenable castings to a high-temperature homogenization treatment to reduce alloy segregation and to obtain more uniform response to subsequent heat treatment. Even investment castings that are slowly cooled from the pouring temperature exhibit more nearly uniform properties when they have been homogenized.

Applications of C-Type Alloys

Martensitic grades include CA-15, CA-40, CA-15M, and CA-6NM. Alloy CA-15 contains the minimum amount of chromium necessary to make it essentially rustproof. It has good resistance to atmospheric corrosion as well as to many organic media in relatively mild service. Alloy CA-40 is a higher-carbon modification of CA-15 that can be heat treated to higher strength and hardness levels. A molybdenum-containing modification of CA-15, alloy CA-15M provides improved elevated-temperature strength properties. Alloy CA-6NM is an iron-chromium-nickel-molybdenum alloy of low carbon content. The presence of nickel offsets the ferritizing effect of the low carbon content so that strength and hardness properties are comparable to those of CA-15 and impact strength is substantially improved. The molybdenum addition improves the resistance of the alloy in seawater.

A wide range of mechanical properties can be obtained in the martensitic alloy group. Tensile strengths from 620 to 1520 MPa (90 to 220 ksi) and hardnesses as high as 500 HB can be obtained through heat treatment. The alloys have fair to good weldability and machinability if proper techniques are employed; CA-40 is considered the poorest and CA-6NM is the best in this regard. The martensitic alloys are used in pumps, compressors, valves, hydraulic turbines, propellers, and machinery components.

Austenitic grades include Alloys CH-20, CK-20, and CN-7M. The CH-20 and CK-20 alloys are high-chromium, high-carbon, wholly austenitic compositions in which the chromium exceeds the nickel content. They have better resistance to dilute sulfuric acid than CF-8 and have improved strength at elevated temperatures. These alloys are used for specialized applications in the chemical-processing and pulp and paper industries for handling pulp solutions and nitric acid. The high-nickel CN-7M grade containing molybdenum and copper is widely used for handling hot sulfuric acid. This alloy also offers resistance to dilute hydrochloric acid and hot chloride solutions. It is used in steel mills as containers for nitric-hydrofluoric pickling solutions and in many industries for severe-service applications for which the high-chromium CF-type alloys are inadequate.

Ferritic grades are designated CB-30 and CC-50. Alloy CB-30 is practically nonhardenable by heat treatment. As this alloy is normally made, the balance among the elements in the composition results in a wholly ferritic structure similar to that of wrought type 442 stainless steel. By balancing the composition toward the low end of the chromium and the high ends of the nickel and carbon ranges, however, some martensite can be formed through heat treatment, and the properties of the alloy approach those of the hardenable wrought type 431. Alloy CB-30 castings have greater resistance to most corrosives than the CA grades and are used for valve bodies and trim in general chemical production and food processing. Because of its low impact strength, however, CB-30 has been supplanted in many applications by the higher-nickel-containing austenitic grades of the CF type. The high-chromium CC-50 alloy has good resistance to oxidizing corrosives, mixed nitric and sulfuric acids, and alkaline liquors. It is used for castings in contact with acid mine waters and in nitrocellulose production. For best impact strength, the alloy is made with more than 2% Ni and more than 0.15% N.

Austenitic-ferritic grades include CE-30, CF-3, CF-3A, CF-8, CF-8A, CF-20, CF-3M, CF-3MA, CF-8M, CF-8C, CF-16F, and CG-8M. These alloys usually contain 5 to 40% ferrite, depending on the particular grade and the balance among the ferrite-promoting and austenite-promoting elements in the chemical composition. This ferrite content improves the weldability of the alloys and increases their mechanical strength and resistance to SCC. The amount of ferrite in a corrosion-resistant casting can be estimated from its composition by using the Schoefer diagram (Fig. 3) or from its response to magnetic measuring instruments.

Alloy CE-30 is a high-carbon high-chromium alloy that has good resistance to sulfurous acid and can be used in the as-cast condition. It has been extensively used in the pulp and paper industry for castings and welded assemblies that cannot be effectively heat treated. A controlled ferrite grade designated CE-30A, is used in the petroleum industry for its high strength and resistance to SCC in polythionic acid.

The CF alloys as a group constitute the major segment of corrosion-resistant casting production. When properly heat treated, the alloys are resistant to a great variety of corrosives and are usually considered the best general-purpose types. They have good castability, machinability, and weldability and are tough and strong at temperatures down to -255 °C (-425 °F). Alloy CF-8, the cast equivalent of AISI type 304 stainless steel, can be viewed as the base grade, and all the others as variants of this basic type. The CF-8 alloy has excellent resistance to nitric acid and all strongly oxidizing conditions. The higher-carbon CF-20 grade is satisfactorily used for less corrosive service than that requiring CF-8, and the low-carbon type CF-3 is specifically designed for use where castings are to be welded without subsequent heat treatment.

The molybdenum-containing grades CF-8M and CF-3M have improved resistance to reducing chemicals and are used to handle dilute sulfuric and acetic acids, paper mill liquors, and a wide variety of industrial corrosives. Alloy CF-8M has become the most frequently used grade for corrosion-resistant pumps and valves because of its versatility in meeting many corrosive service demands. Because CF-3M has a low carbon content, it can be used without heat treatment after welding. The niobium-stabilized CF-8C alloy is the cast equivalent of AISI type 347. Castings of this alloy, therefore, are used to resist the same corrosives as CF-8 but where field welding or service temperatures of 650 °C (1200 °F) are involved.

Higher mechanical properties are specified for grades CF-3A, CF-8A, and CF-3MA than for the CF-3, CF-8, and CF-3M alloys because the compositions are balanced to provide a controlled amount of ferrite that will ensure the required strength. These alloys are being used in nuclear power plant equipment.

The CF-16F grade has an addition of selenium to improve the machinability of castings that require extensive drilling, threading, and the like. It is used in service similar to that for which CF-20 is used. Type CG-8M has a higher molybdenum content than CF-8M and is preferred to the latter in service where improved resistance to sulfuric and sulfurous acid solutions and to the pitting action of halogen compounds is needed. Unlike CF-8M, however, it is not suitable for use in nitric acid or other strongly oxidizing environments.

The duplex alloys have higher yield strength than the austenitics. This difference gives the duplex alloys an economic edge in, for example, the chemical process industry; higher process flow rates and operating pressures are possible without a major equipment modification. Cost savings can also be realized when the higher strength allows the downgaging of the wall thickness of piping, heat exchanger tubing, tanks, columns, and pressure vessels. For rotating equipment, such as centrifuges, the mass of equipment can be reduced by using a duplex stainless steel. Further savings in motors and gearing results because of smaller loads. For some time, cast duplex valves and pumps have utilized the strength of these materials either to allow higher pressures or to lower costs by using thinner walls.

Precipitation-hardening alloys include CB-7Cu and CD-4MCu. Alloy CB-7Cu is a low-carbon martensitic alloy that may contain minor amounts of retained austenite or ferrite. The corrosion resistance of CV-7Cu lies between that of the CA types and the nonhardenable CF alloys, so it is used when both high strength and improved corrosion resistance are required. Castings of CB-7Cu are machined in the solution-treated condition and then through hardened by a low-temperature aging treatment (480 to 595 °C, or 900 to 1000 °F). Because of this capability, the CB-7Cu grade has found wide application in highly stressed, machined castings in the aircraft and food-processing industries.

Type CD-4MCu is a two-phase alloy with an austenite-ferrite structure that, because of its high chromium and low carbon contents, does not develop martensite when heat treated. Like the CB-7Cu grade, CD-4MCu can be hardened by a low-temperature aging treatment, but it is normally used in the solution-annealed condition. In this condition, its strength is double that of the CF grades, and its corrosion resistance is optimized. This alloy has corrosion resistance equal to, or better than, the CF types and has excellent resistance to SCC in chloride-containing media. It is highly resistant to sulfuric and nitric acids and is used for pumps, valves, and stressed components in the marine, chemical, textile, and pulp and paper industries, for which a combination of superior corrosion resistance and high strength is essential.

Applications of H-Type Alloys

The iron-chromium alloys include grades HA, HC, and HD. Alloy HA has limited application because of its low strength and limited resistance to gaseous corrosion at high temperature. It has been used in valves, flanges, and fittings where light stresses are encountered.

Alloys HC and HD can be used for load-bearing applications up to 650 °C (1200 °F) and where only light loads are involved up to 1040 °C (1900 °F). These grades, however, become embrittled by σphase in the 650 to 870 °C (1200 to 1600 °F) temperature range. They are similar to each other in corrosion resistance, with HD exhibiting higher strength. Both are used in ore-roasting furnaces for such parts as rabble arms and blades, for salt pots and grate bars, and in high-sulfur applications in which high strength is not required.

The iron-chromium-nickel alloys include HE, HF, HH, HI, HK, and HL. They are predominantly or completely austenitic and exhibit greater strength and ductility than the iron-chromium alloys.

Alloy HE has excellent corrosion resistance at high temperatures coupled with moderate strength. This combination of corrosion resistance and strength makes HE suitable for service to 1095 °C (2000 °F). Grade HE can be used in high-sulfur applications and is often found in ore-roasting and steel mill furnaces. The alloy is prone to σ-phase formation, however, at temperatures of 650 to 870 °C (1200 to 1600 °F).

Alloy HF is essentially immune to σ-phase formation and can be used at temperatures to 870 °C (1600 °F). It is used for tube supports and beams in oil refinery heaters and in cement kilns, ore-roasting ovens, and heat-treating furnaces.

Grade HH exhibits high strength and excellent resistance to oxidation at temperatures to 1095 °C (2000 °F). Its composition can be balanced to yield a partially ferritic or a completely austenitic structure and a wide range of properties. Because of this, the composition of the HH alloy should be tailored to the application. The partially ferritic alloy, type I, has a somewhat lower creep strength and a higher ductility at elevated temperature than the wholly austenitic alloy type II. Type I is also more prone to σ-phase formation between 650 and 870 °C (1200 and 1600 °F). Type II is preferred for application in this temperature range. Both types are widely used for furnace parts of many kinds, but are not recommended for severe-temperature cycling service, such as that experienced by quenching fixtures.

Grade HI is similar to the fully austenitic alloy HH, but its higher chromium content confers sufficient scaling resistance for use up to 1180 °C (2150 °F). Its major application has been in cast retorts for calcium and magnesium production.

Alloy HK has high creep and rupture strengths and can be used in structural applications to 1150 °C (2100 °F). Its resistance to hot gas corrosion is excellent. It is often used for furnace rolls and parts as well as for steam reformer and ethylene pyrolysis tubing.

Grade HL has properties similar to those of HK and exhibits the best resistance to corrosion in high-sulfur environments to 980 °C (1800 °F) of the alloys in this group. It is typically used in gas dissociation equipment.

The iron-nickel-chromium alloys include grades HN, HP, HT, HU, HW, and HX. These materials employ nickel as a predominant alloying (or base) element and remain austenitic throughout their temperature range of application. They

are generally suitable for use to 1150 °C (2100 °F) and resist thermal fatigue and shock induced by severe temperature cycling. However, the nickel-base grades are not considered suitable for high-sulfur environments.

Alloy HN has properties similar to those of HK. It is employed in brazing fixtures, furnace rolls, and parts.

Grade HP is extremely resistant to oxidizing and carburizing atmospheres. It has good strength in the temperature range of 900 to 1095 °C (1650 to 2000 °F) and is often specified for heat treat fixtures, radiant tubes, and coils for ethylene pyrolysis heaters.

Alloy HT can withstand oxidizing conditions to 1150 °C (2100 °F) and reducing conditions to 1095 °C (2000 °F). It is widely used to heat treat furnace parts subject to cyclic heating, such as rails, rolls, disks, chains, boxes, pots, and fixtures. It has also found application for glass rolls, enameling racks, and radiant tubes.

Alloy HU has excellent resistance to hot gas corrosion and thermal fatigue, and it has good high-temperature strength. It is often used for severe applications, such as burner tubes, lead and cyanide pots, retorts, and furnace rolls.

Grades HW and HX are extremely resistant to oxidation, thermal shock, and fatigue. Their high electrical resistivities make them suitable for the production of cast electrical heating elements. Both are highly resistant to carburization when in contact with tempering and cyaniding salts. The higher alloy content of HX confers better gas corrosion resistance, particularly in reducing gases containing sulfur, where HW is not recommended. Both grades are typically used for hearths, mufflers, retorts, trays, burner parts, enameling fixtures, quenching fixtures, and containers for molten lead.

Austenitic Manganese Steels

The compositions of the austenitic manganese steels (Table 7) can be varied to achieve differing combinations of strength, ductility, wear resistance, and machinability (see ASTM A128). Manganese steel castings are used in all sizes for a wide variety of applications.

Table 7 Compositions of austenitic manganese steels

Grade	Composition, %				
	C	**Mn**	**Cr**	**Mo**	Other
Standard	1.0-1.4	12.0-14.0	. . .	. . .	**. . .**
Chromium	1.0-1.4	12.0-14.0	1.5-2.5	. . .	**. . .**
1% Mo	0.8-1.3	12.0-15.0	. . .	0.8-1.2	**. . .**
1% Mo (lean)	1.1-1.4	5.0-7.0	. . .	0.8-1.2	**. . .**
2% Mo	1.0-1.5	12.0-15.0	. . .	1.8-2.2	**. . .**
High yield strength	0.4-0.7	12.0-15.0	. . .	1.8-2.2	**2.0-4.0Ni, 0.5-1.0V**
Machinable	**0.3-0.6**	**18.0-20.0**	**. . .**	**. . .**	**2.0-4.0Ni, 0.2-0.4Bi**

The chromium-alloyed manganese steels are the most extensively used, following the standard A128 grade. Medium-thickness (50 to 125 mm, or 2 to 5 in.) crusher castings generally exhibit increased wear life, which is attributable to the

chromium alloying. In some installations, however, it is difficult to substantiate the degree of wear improvement, and lowered ductility can lead to premature breakage in severe service. Figure 12 shows that the tensile elongation in 150 mm (6 in.) thick chromium-manganese steels is 30 to 40% lower than that of the standard grades. Impact property comparisons (Fig. 13) also show a decided impairment.

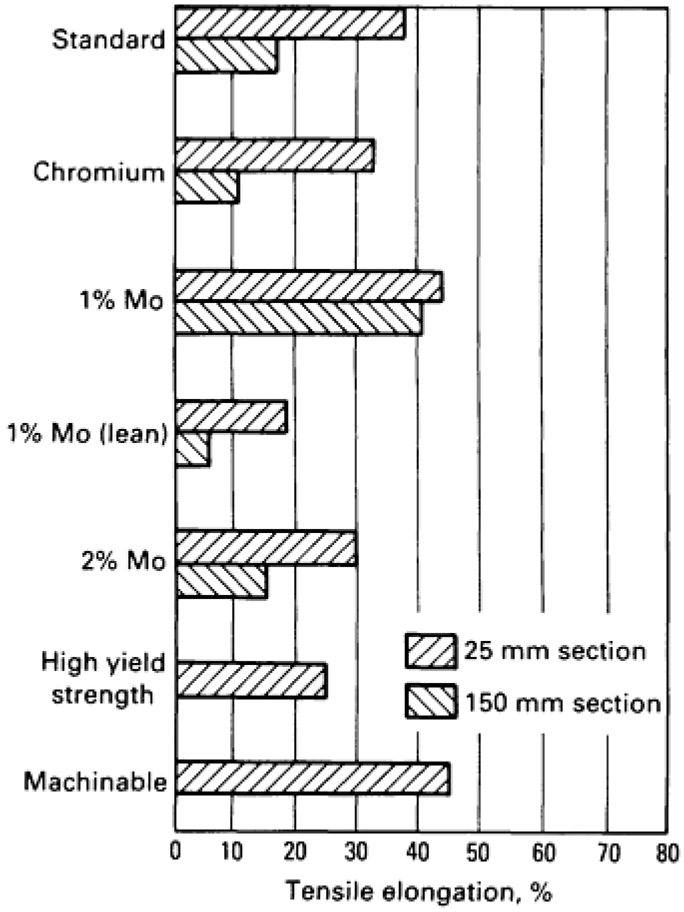

Fig. 12 Typical tensile elongations of austenitic manganese steels.

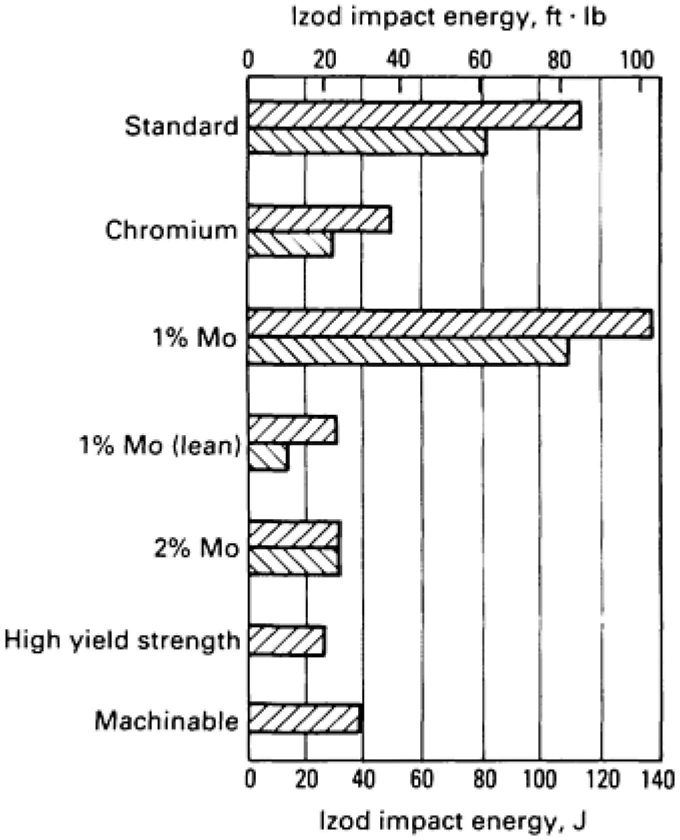

Fig. 13 Typical Izod impact energies of austenitic manganese steels. See Fig. 12 for key.

The molybdenum-alloyed manganese steels can be divided into two groups: those with 1% Mo and those with 2% Mo. The 1% Mo category is further divided into a normal alloy segment and a so-called lean alloy category. The lean alloy austenitic grade has manganese contents from 5 to 7%; this contrasts with the 12 to 14% level usually associated with austenitic manganese steels.

A normal 1% Mo alloyed grade can involve carbon levels as low as 0.80% and as high as 1.30%. Each of the extremes of the carbon range provides a distinct benefit. Heavy-section mechanical property improvement and improved resistance to mechanical property degradation as a result of elevated temperatures can lead to the use of lower-carbon materials. The higher-carbon grades can be used where improved abrasive wear resistance is needed.

The lean grade of the 1% Mo steels finds limited use in crushing applications, in which lower ductility and lower impact levels are permissible. The more rapid work-hardening tendency of the material has been claimed to account for improved wear life in certain applications, such as ball mills and rod mills.

The 2% Mo grades follow the more classical lines in that manganese contents tend to fall within the 12 to 15% range. Carbon content can vary from 1 to 1.5% in alloys that may either undergo a standard austenitizing heat treatment of a special two-step dispersion-hardening treatment. Before the availability of the multiple-alloyed, high yield strength manganese steels, the 2% Mo grades were used in the dispersion-hardened condition, in which they develop high yield strengths. The desirability of high yield strength is evident in such casting applications as large jaw plates and concave segments; this service results in a high degree of kneading of the working surface, which in turn develops extensive surface expansion. The cumulative effect of this growth can be sufficient to raise the casting from its seat or backing plate. In extreme cases, the wear castings can be physically displaced or can crack restraining structures. The 2% Mo grade can often provide a discernible improvement in overall wear life if premature failure is not encountered. However, economic considerations become involved to an extent that judgment must be exercised regarding the added cost in relation to additional wear life.

The machinable grade of manganese steel listed in Table 7 plays a somewhat parallel role, but in a different property area. Austenitic manganese steels exhibit poor machinability, certainly with regard to the drilling and tapping of small holes. The machinable grade, however, exhibits drilling and tapping advantages at a level somewhat higher than that of a wrought type 308 stainless steel.

Mechanical properties for the compositions shown in Table 7 are illustrated in Fig. 12, 13, 14, and 15. Property impairment as a result of increasing metal section and the reduced response to heat treatment is indicated. All grades, with the exception of the lean austenitic and the machinable grades, approach or exceed 827 MPa (120 ksi) in ultimate tensile strength in 25 mm (1 in.) sections. The chromium-alloyed grades and the 2% Mo grades show yield strengths of 414 MPa (60 ksi) or greater, while the high yield strength alloy develops 655 MPa (95 ksi) in 25 mm (1 in.) metal sections. Elongation and impact strength data favor the 1% Mo grades in heavy metal sections, while the 1% Mo lean alloys exhibit the poorest properties in this regard.

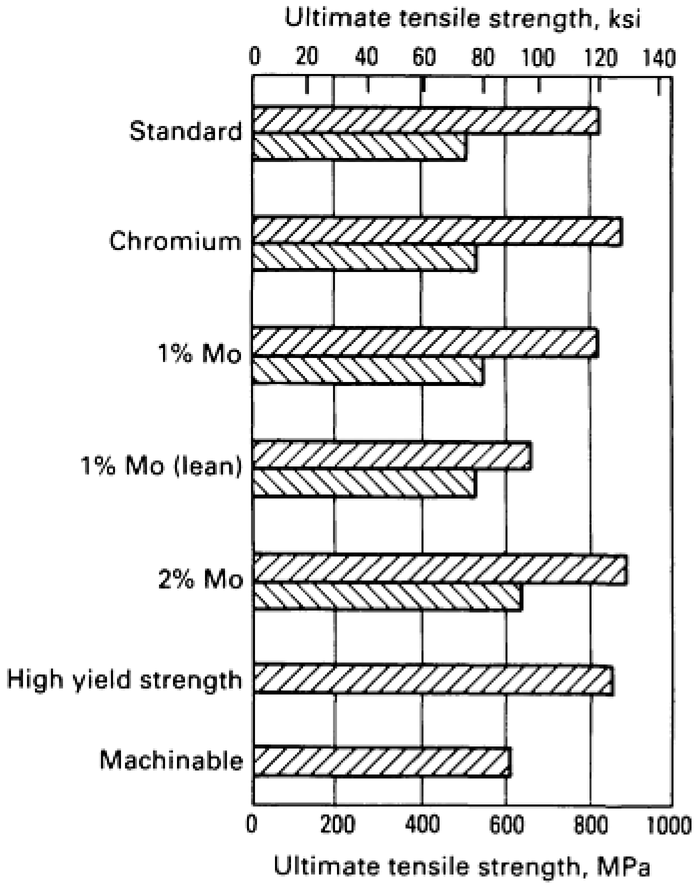

Fig. 14 Typical values of ultimate tensile strength for austenitic manganese steels. See Fig. 12 for key.

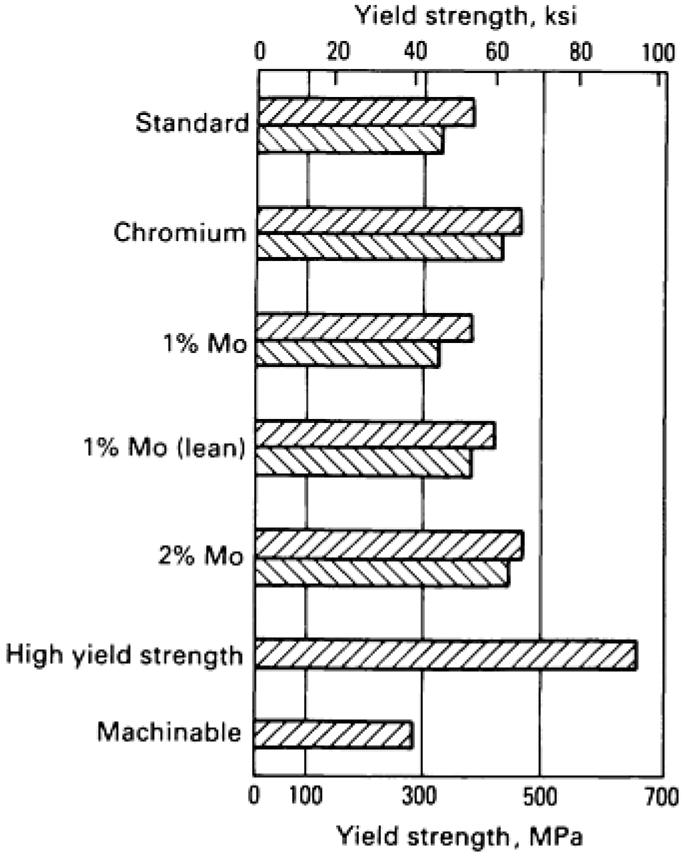

Fig. 15 Typical yield strength values for austenitic manganese steels. See Fig. 12 for key.

Low magnetic permeabilities can be attained quite readily and economically. The combination of gouging wear resistance and low magnetic permeability is used to good advantage in manganese steel magnet cover wear plates.

Machinability. Austenitic manganese steels are difficult to machine largely because they harden under and in front of the tool. Even the smallest amount of tool chatter on the casting results in high hardness at the point of contact and in the dulling and rapid wear of the tool. Machining is performed with cemented carbide tools using heavy, rigid equipment; slow, steady feed; and deep cuts.

A well-equipped machine shop, through the use of grinding techniques, can perform all basic machine tool functions. Boring, planing, keyway cutting, and similar operations are efficiently done by grinding.

Weldability. Weld repair, rebuilding, and assembly operations are routinely performed. Chromium-nickel- and molybdenum-alloyed manganese steel welding wires and electrodes are readily available. With reasonable caution, all normal welding operations can be performed. Work-hardened metal should be removed by grinding before welding. Use of the 1% Mo grades in casting affords added protection against embrittlement.

Applications. Austenitic manganese steels are widely used in crushing and grinding applications. Primary and secondary crusher mantles can vary in weight from 3.6 to 22.7 Mg (4 to 25 tons). Upper and lower sections are used to reduce overall gross weights. Smaller cone crusher castings range from 180 to 3400 kg (400 to 7500 lb). Crusher rolls, jaw crusher wear plates, hammers, impacter bars, and cage rings frequently use austenitic manganese steels as well.

Power shovel dipper buckets of 19 m^3 (25 yd^3) capacity are being manufactured using cast-weld assembly techniques. Gross weights approach 45 Mg (50 tons), while large shovel shoes approach 2720 kg (6000 lb) each. Idlers, sprockets, sheaves, and racking are also widely used.

Large pumps with 2270 to 9070 kg (5000 to 20,000 lb) cast casings are extensively used. The pumping of head-sized rock is not uncommon. Other involved wear components are impellers as well as engine and section side plates. Weld

rebuilding can be accomplished if desired. Dredge buckets, tumblers, and bushings also commonly use austenitic manganese steels.

Railroad frog and crossing castings are extensively used in trackwork assemblies. Repetitive wheel impact on points can lead to point batter and flow into flangeways, which require removal by grinding. Prehardening retards these occurrences, but does not always eliminate them. Nevertheless, austenitic manganese steels are almost exclusively used in this type of service. Other applications include steel plant crane wheels and chains, heavy-duty apron feeder pans, electric magnet cover wear plates, and coal conveyor chains.

Cast Alnico Alloys

Robert A. Schmucker, Jr., Thomas & Skinner, Inc.

Introduction

ALNICO ALLOYS (aluminum-nickel-copper-cobalt-iron) constitute a group of industrial permanent magnet materials developed in the 1940s and 1950s. The high-coercive high-titanium-bearing versions were added and perfected in the 1960s and 1970s. Although the dominant position of these materials has been challenged in the last decade by the magnetically stronger rare-earth powder metallurgy magnets, and earlier by the much less expensive ferrites, the Alnicos remain an important group.

The idea of using aluminum-nickel-iron alloys for a permanent magnet originated in Japan in the 1930s. Toward the end of that decade, greatly improved modifications were developed in England. Additional modifications were developed in Holland in 1940. The idea of increasing the magnetic strength in the most important alloy (Alnico 5) by casting to produce directional grains, that is, columnar crystals, was patented in the United States in 1951. Improvements in the heat treatment of the high-coercive high-titanium Alnico (Alnico 8) were patented in Holland in 1959 and 1960. Composition modifications to this type of alloy to permit columnar solidification (Alnico 9) were developed in Britain in 1962. Although the development of the Alnico system has been an international effort, the greatest production of the cast material has been in the United States. Alnico permanent magnets are currently used in a wide variety of applications, such as motors, tachometers, magnetos, generators, electron focusing or deflecting devices such as traveling wave and magnetron tubes, and the more familiar holding and lifting devices.

Finally, it should be emphasized that cast Alnico is a hard, brittle material that lacks ductility and can be surface finished only by grinding. It is produced primarily for its magnetic properties and should not be used as a structural component. Minor surface and internal imperfections rarely impair its magnetic strength and should not be considered detrimental.

Foundry Practice

There have been marked advances in the foundry technology of Alnico castings since the early manufacturing of the 1940s. A number of improved molding systems developed for other materials have been adapted for Alnico. Alnico magnets are cast essentially to shape in sizes that range in weight from a fraction of a pound to over 23 kg (50 lb), although most are under 4.5 kg (10 lb).

Patterns

A variety of patterns can be used to produce molds for Alnico castings (see the article "Patterns and Patternmaking" in this Volume). The molding system will determine the type of pattern. For the older baked sand cores and the current shell cores, a composite mold is used that consists of several cores and contains a common sprue and gating system (see the article "Sand Molding" in this Volume). A single core may contain impressions for several dozen magnets. The production pattern is usually made of brass or aluminum. In most cases, the full impressions of the magnet contour are in one sand core. The bottom of the upper core, upon stacking, serves to form one flat side of the magnet. When holes are required in Alnico magnets, they are produced by casting around sand or graphite inserts.

Molds for producing directional-grained Alnico, as will be explained later in this article, are entirely different from shell molds and do not consist of stacks of cores. The patterns are mounted separately on a plate, have a greater height, and are individually gated. They can be made of metal or wood.

For precision investment casting, patterns are actually wax replicas of the magnet itself; these replicas are formed by injecting wax into a metal die. The patterns are made slightly larger to compensate for volumetric shrinkage in the pattern production stage and during solidification of the metal (see the article "Basic Concepts in Crystal Growth and Solidification" in this Volume).

Molding

A wide variety of molding techniques are available for the casting of Alnico alloys, including baked sand, shell, cold-set phenolic, carbon dioxide, precision investment, and exothermic processes. No-bake processes have recently been added to both the shell sand and oil sand molding methods.

Baked sand molding was the predominant technique in the manufacture of Alnico castings until the 1970s (see the articles "Resin Binder Processes" and "Coremaking" in this Volume). This technique has been largely replaced by shell molding, but is still used for certain repetitive parts, such as pouring cups. Silica sand is mixed in a muller with a suitable cereal binder and core oil, molded in molding machines (jolt/rollover or core blower), and baked in an oven at about 205 °C (400 °F).

Shell molding (the Croning process) was developed in the United States after World War II on the basis of earlier German technology. This process was not extensively used for Alnico castings until somewhat later. It permits the manufacture of castings with a better surface finish, slightly closer tolerances, and at a lower overall cost than the baked sand method. The process involves the use of a mixture of round-grain silica sand and a thermosetting resin, usually a phenol formaldehyde. Some Alnico manufacturers mix their own sand, and others purchase commercially precoated sand. A brass or aluminum pattern with ejector pins is used for making the shell core. The sand mixture is dropped onto the preheated pattern and held for 10 to 30 s. The core is further polymerized by heating to 290 to 425 °C (550 to 800 °F) for a few minutes with the pattern attached. The core can, at this stage, be pushed away from the pattern assembly by actuation of the ejector system. A typical individual core would be 305 × 381 × 38 mm (12 × 15 × $1\frac{1}{2}$ in.). A stack of these cores about 508 mm (20 in.) high clamped together with a pouring cup would constitute the composite mold. Additional information on shell molding is available in the article "Resin Binder Processes" in this Volume.

Cold-set Phenolic Urethane Molds. A recent alternative to the shell molding system for small Alnico castings is the use of cold-set phenolic urethane molds. The cores are similar in size and shape to shell cores, and similar patterns can be used; but the process and molding equipment are entirely different. Phenolic urethane resins cure at room temperature. The process consists of combining a dry round-grain sand (AFS 60) with two liquid resin components and a liquid catalyst in a high-speed mixer. The mixture is blown onto the pattern and permeated with an amine gas to cause a chemical reaction, forming a phenol bonded core. The core can be stripped from the pattern in less than 1 min. The individual cores are stacked and clamped to form a composite mold similar to that of shell cores (see the article "Sand Molding" in this Volume).

Carbon dioxide silicate molding has a restricted usage in some Alnico foundries. It has been used to produce very large Alnico magnets. Such molds have heavy walls, and they are harder and less collapsible than shell. The process consists of combining round-grain silica sand, liquid sodium silicate, and certain additives; mixing in a muller; and then ramming the mix into molds with conventional molding machines. The molds are placed into a chamber and gassed with carbon dioxide; during this process, a silica hydrogel bond is formed (see the article "Sand Molding" in this Volume).

Precision Investment Molding. The precision investment process is used to produce only a small percentage of Alnico castings. Such castings are usually less than 0.45 kg (1 lb) in weight. The process is limited to small intricate shapes or to cases where smooth cast surfaces or restricted cast tolerances are required. The usual tolerance is ±0.005 mm/mm (±0.005 in./in.) of length. There are also certain military applications that require freedom from internal inclusions for which the investment casting process is advantageous.

In the investment molding process, the wax patterns (actually replicas of the magnet) are removed from the die, gated, and mounted on wax sprues attached to a pouring cup. The entire cluster is then dipped into a ceramic slurry, drained, and coated with a fine ceramic sand. After drying, this process is repeated again and again, using progressively coarser grades of ceramic material until a self-supporting shell is formed. The coated cluster is then placed in a steam autoclave, where the patterns melt and run out through the gates, leaving a ceramic shell. This ceramic shell mold is preheated in a furnace at 870 to 1040 °C (1600 to 1900 °F) and then removed and placed upright in a supporting container when it is ready for the casting process. Additional information is available in the article "Investment Casting" in this Volume).

Exothermic Molds. The molding processes described above are used for a wide variety of metals and alloys and are of course not restricted to Alnico castings. The resulting structure is so-called random-grain Alnico, that is, essentially equiaxed crystals. Techniques for producing fully directional-grained or columnar Alnico are unique for this material and enhance its magnetic properties. Columnar crystals are obtained by casting into hot molds placed on top of a cold chill, with a reservoir of molten metal feeding the gate (this technique has been recently applied to the production of turbine blades for jet engines). This prevents radial heat flow and ensures the growth of columnar crystals directed from the chill end to the top gated end. The method is restricted to simple shapes such as cylinders or cuboids. Mold materials must be more refractory to withstand the high preheating temperatures.

The titanium-free Alnico 5 alloy is more readily cast in columnar form, designated Alnico 5-7. Several types of proprietary mold materials can be used. One consists of an aluminum silicate refractory with a sodium silicate binder, the mold being reacted with carbon dioxide gas. Such molds are preheated in a furnace at 1260 to 1370 °C (2300 to 2500 °F), removed, and placed on a chill; the molten metal is then poured directly in.

For the high-titanium Alnico 9 alloy, columnar crystals are more difficult to obtain because of the nucleating effect of the titanium oxide particles in the melt. The usual method involves the use of exothermic molds, which produce a higher mold cavity temperature of 1425 to 1480 °C (2600 to 2700 °F). One such mixture combines an alumina-silica sand, aluminum powder, sodium nitrate, and a small amount of sodium silicofluoride. This is bonded with a sodium silicate binder, and the resulting molds are reacted with carbon dioxide gas. The molds are placed on a chill and ignited with a torch; the molten metal is poured in after the exothermic reaction is complete.

Melting and Casting Practice

Alnico alloys are melted in high-frequency induction furnaces with capacities ranging from 120 to 450 kg (250 to 1000 lb). An ideal frequency is about 960 Hz because of the resultant stirring action of the molten metal. The furnace charge usually consists of Armco iron, cobalt in the form of broken cathodes or granules, electrolytic nickel, secondary electrolytic copper, virgin aluminum, commercially pure titanium (ferrotitanium is unsatisfactory), ferrosilicon, and certain additives such as zirconium or niobium. Sulfur is sometimes added to improve fluidity of the molten metal. In the case of Alnico 9, a sulfur addition is essential to counteract the nucleating effect of the titanium oxide particles in the melt. Clean Alnico revert scrap and refined cobalt-nickel-copper-iron granules are also frequently used in the charge.

Certain impurities must be avoided in the charge, especially carbon; when carbon is present above 0.03%, it increases susceptibility to the formation of γ phase in the alloy, which degrades the magnetic properties of Alnico 5 and 6. Chromium and molybdenum above 0.25% should also be avoided.

During the melting cycle, the highly oxidizable aluminum, titanium, silicon, zirconium and niobium are added during the final stages to prevent excessive losses of these elements. Air melting is usually used, but atmospheres of nitrogen or argon are occasionally substituted.

The casting temperature must be closely controlled to ensure sound well-formed castings. Immersion thermocouples provide the best temperature measurement. The temperature is usually in the range of 1540 to 1760 °C (2800 to 3200 °F). Casting can be performed by pouring the heat directly from the furnace into the mold stacks. The alternative method consists of tapping the heat into one or several preheated ladles and pouring from these ladles into the molds. As

previously mentioned, when castings with columnar crystals are desired, the heat is poured into preheated or exothermic fired molds placed on metal chills.

Chemical Analysis and Magnetic Property Control. Control of chemical composition is essential in order to obtain optimum magnetic properties. It is important to conduct a chemical analysis of an individual heat a short time after pouring. X-ray fluorescence spectrography is the preferred method of analysis. An alternative control method consists of accelerated heat treatment and magnetic testing of a sample taken from each heat at the time of casting. All Alnico producers have used some combination of these two methods for many years. A more recent and precise method involves the extraction of a prepour sample directly from the melt, rapid analysis of this sample, and correction of the composition by additions of individual elements to the bath before the heat is poured. Regardless of the type of control, all castings from individual heats are identified in the foundry until their magnetic quality and/or chemical analysis is verified.

Processing of Castings and Preliminary Inspection. Shortly after casting, most grades of Alnico magnets are stripped from their molds and air cooled to room temperature. Because Alnico is brittle, the castings are readily broken away from the sprues manually or in a shotblast machine (see the article "Blast Cleaning of Castings" in this Volume). Castings are then subjected to 100% preliminary inspection for visible physical defects, such as shrinkage, pipe, porosity, and hot tears (see the article "Testing and Inspection of Casting Defects" in this Volume).

Gate and flash grinding operations are usually carried out before heat treatment. Gate and flash are removed by manual grinding on pedestal-type grinders. In the case of large volumes of small cylinders, gates are often removed in centerless grinding machines. At this stage, those magnets with graphite inserts are subjected to drilling operations to remove this material.

Heat Treatment

All Alnico magnets must be heat treated in order to develop their magnetic properties. This consists of three stages: a high-temperature solution treatment, a controlled cooling at a specified rate with or without a magnetic field, and a coercive aging or drawing operation that develops the necessary coercive force and energy product values. The high-temperature solution treatment can be omitted in the lower grades of Alnico if adequate cooling is applied at the initial casting stage.

Isotropic Alloys. The original Alnicos 1 through 4 have limited commercial importance today. Alnico 2 is occasionally made, and its treatment consists of a 980 °C (1800 °F) solution, cooling in about 5 min to a black color (~590 °C, or 1100 °F) without a magnetic field, and an aging draw of about 635 °C (1175 °F) for at least 2 h.

Anisotropic Alloys (Alnico 5 and 6). In these important commercial alloys, directional magnetic properties result from cooling through the Curie temperature region in a magnetic field of at least 9.5×10^4 A · m^{-1} (1200 Oe). If the alloy has been protected against γ phase formation by the addition of silicon and zirconium, it can be solution treated at about 915 °C (1680 °F), followed by the field cooling. Linear magnetic fields are provided by solenoids or electromagnets, but certain magnet configurations require the use of curved fields. The final coercive aging can be carried out at 580 °C (1075 °F) for 24 h, but variations in the form of two-step or continuous cycles can be implemented to shorten the time required.

Anisotropic Alloys (Alnico 8 and 9). For these two high-titanium alloys (Alnico 9 being essentially a directional-grained Alnico 8), a high-temperature full solution treatment in the range of 1230 to 1275 °C (2250 to 2330 °F) must be used. Also, in the field treatment stage, an isothermal holding about 45 °C (80 °F) below the Curie temperature is required, and the field strength should be at least 2.2×10^5 A · m^{-1} (2800 Oe). The isothermal furnace itself must be within this linear field. Curved field configurations have not been developed. A longer draw cycle than that used for Alnico 5 is required, typically 650 °C (1200 °F) for 5 h plus 550 °C (1020 °F) for 24 h.

Final Grinding, Inspection, and Testing

Because Alnico is a hard (45 to 58 HRC), brittle, and coarse-grained material, it can be finished to close tolerances only by grinding. These operations, which employ a variety of grinding equipment, must be carried out with great care using proper grinding wheels, coolants, and speeds to prevent cracking, heat checking, and chipping.

Final inspection and magnetic testing involve many procedures. Dimensional inspection is carried out using a variety of precision measuring devices. Physical inspection involves visual examination of parts for excessive cracks, chips, and porosity. However, minor imperfections do not impair the magnetic performance of a part and are not considered cause

for rejection unless a standard is mutually agreed upon by producer and user. Magnetic testing involves dozens of procedures and techniques that are, in general, designed to duplicate the performance of a given magnet in its final operating circuit. The general guide to all inspection criteria is provided in MMPA Standard 0100-87.

Structure and Properties

The magnetic properties of anisotropic Alnico alloys are associated with directional, submicroscopic two-phase structures. These are visible only in the electron microscope, typically at magnifications of 25,000 to 100,000×. Conventional light microscopy at magnifications below 1000× is occasionally used to diagnose such problems as the presence of spoiling γ phase or to reveal the details of grain structures. Two such structures, a normal equiaxed-grain Alnico 5 and a columnar-grained Alnico 9, are shown in Fig. 1. The lattice structure is body-centered cubic (bcc). Table 1 lists various properties of the six most important Alnico alloys.

Table 1 Magnetic, mechanical and physical properties of major cast Alnico alloys

The value $(BH)_{max}$ is the most important because it represents the maximum magnetic energy that a unit volume of the material can produce in an air gap.

Cast alloy[a]	**Nominal composition**[b]**, wt%**					Nominal magnetic properties[c]

Source: MMPA Standard 0100-87

(a) Alnico 2 is isotropic. Alnico 5, 5-7, 6, 8, and 9 are anisotropic. Alnico 5-7 and Alnico 9 are also directional grain (columnar crystals).

(b) The composition balance for all alloys is iron. Small percentages of silicon, zirconium, niobium, and sulfur may also be present in certain alloys.

(c) B_r, remanent magnetization; H_c, normal coercive force; $(BH)_{max}$, maximum magnetic energy = magnetic induction × magnetic field strength.

(d) Measurement of properties, such as hardness, plus tensile and rupture strength can be determined only under laboratory conditions and only for comparison purposes.

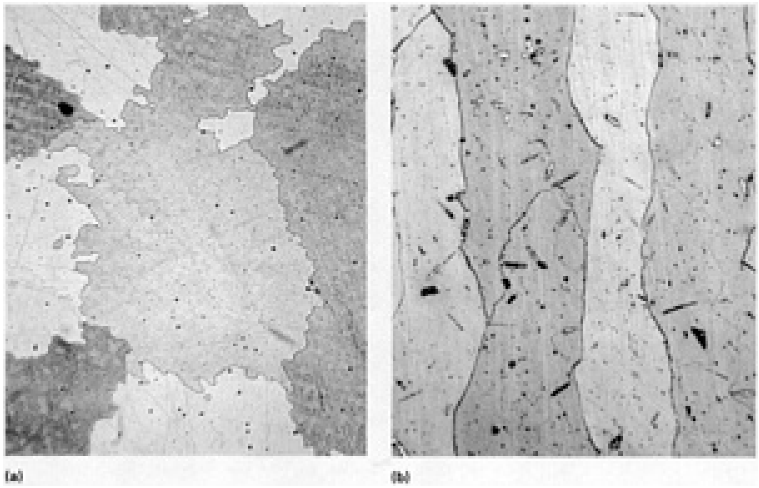

Fig. 1 Photomicrographs of cast and heat-treated anisotropic Alnico alloys showing bcc structure. (a) Equiaxed-grain Alnico 5 with random grain structure. 30×. (b) Columnar-grained Alnico 9. 100×. Both etched with Marble's reagent

Aluminum and Aluminum Alloys

Elwin L. Rooy, Aluminum Company of America

Introduction

ALUMINUM CASTINGS have played an integral role in the growth of the aluminum industry since its inception in the late 19th century. The first commercial aluminum products were castings, such as cooking utensils and decorative parts, which exploited the novelty and utility of the new metal. Those early applications rapidly expanded to address the requirements of a wide range of engineering specifications. Alloy development and characterization of physical and mechanical characteristics provided the basis for new product development through the decades that followed. Casting processes were developed to extend the capabilities of foundries in new commercial and technical applications. The technology of molten metal processing, solidification, and property development has been advanced to assist the foundryman with the means of economical and reliable production of parts that consistently meet specified requirements.

Today, aluminum alloy castings are produced in hundreds of compositions by all commercial casting processes, including green sand, dry sand, composite mold, plaster mold, investment casting, permanent mold, counter-gravity low-pressure casting, and pressure die casting.

Casting processes are normally divided into two categories: expendable mold processes and those processes in which castings are produced repetitively in tooling of extended life. Examples are green and dry sand molding for the former and die and permanent mold casting for the latter.

Alloys can also be divided into two groups: those most suitable for gravity casting by any process and those used in pressure die casting. A finer distinction is made between alloys suitable for permanent mold application and those for other gravity processes. In general, the most alloy-versatile processes (that is, those in which the largest number of alloys can be used) are those in which mold collapse accompanies pouring and solidification. The least forgiving processes, which require special consideration in alloy selection, are more rigid or permanent mold processes. The least alloy-versatile casting process based on process requirements is pressure die casting, in which more than the usual measures of castability apply. The process demands a high level of fluidity, hot strength, hot tear resistance, and die soldering resistance.

Material constraints that formerly limited the design engineer's alloy choice once a casting process had been selected are increasingly being blurred by advances in foundry technique. In the same way, process selection is also less restricted today. For example, many alloys thought to be unusable in permanent molds because of casting characteristics are in production by that process.

Aluminum and Aluminum Alloys

Elwin L. Rooy, Aluminum Company of America

Chemical Compositions

Systems used to designate casting compositions are not internationally standardized. In the United States, comprehensive listings are maintained by general procurement specifications issued through government agencies (federal, military, and so on) and by technical societies such as the American Society for Testing and Materials and the Society of Automotive Engineers. Alloy registrations by the Aluminum Association are in broadest use; its nomenclature is decimalized to define foundry alloy composition variations.

Designations in the form *xxx*.1 and *xxx*.2 include the composition of specific alloys in remelt ingot form suitable for foundry use. Designations in the form *xxx*.0 in all cases define composition limits applicable to castings. Further variations in specified compositions are denoted by prefix letters used primarily to define differences in impurity limits. Accordingly, one of the most common gravity cast alloys, 356, is shown in variations A356, B356, and C356; each of

these alloys has identical major alloy contents but has decreasing specification limits applicable to impurities, especially iron content. Aluminum Association composition limits for registered aluminum foundry alloys used to cast shapes are given in Table 1. Table 1 does not include alloys that are cast into ingots intended for subsequent working.

Table 1 Compositions of registered aluminum casting alloys used to cast shapes

Compositions of alloys used to cast primary ingots are not shown.

Although the nomenclature and designations for various casting alloys are standardized in North America, many important alloys have been developed for engineered casting production worldwide. For the most part, each nation (and in many cases the individual firm) has developed its own alloy nomenclature. Excellent references are available that correlate, cross reference, or otherwise define significant compositions in international use (Ref 2, 3).

Because differences in process capabilities exist, not all alloys can be cast by all methods. Alloys are usually separated into families in which alloy characteristics are considered as a function or process requirements. Table 1 lists common compositions and conventional use according to process type.

The Aluminum Association designation system attempts alloy family recognition by the following scheme:

- 1*xx.x*: Controlled unalloyed compositions
- 2*xx.x*: Aluminum alloys containing copper as the major alloying element
- 3*xx.x*: Aluminum-silicon alloys also containing magnesium and/or copper
- 4*xx.x*: Binary aluminum-silicon alloys
- 5*xx.x*: Aluminum alloys containing magnesium as the major alloying element
- 6*xx.x*: Currently unused
- 7*xx.x*: Aluminum alloys containing zinc as the major alloying element, usually also containing additions of either copper, magnesium, chromium, manganese, or combinations of these elements
- 8*xx.x*: Aluminum alloys containing tin as the major alloying element
- 9*xx.x*: Currently unused

Effects of Alloying Elements

Antimony. At concentration levels equal to or greater than 0.05%, antimony refines eutectic aluminum-silicon phase to lamellar form in hypoeutectic compositions. The effectiveness of antimony in altering the eutectic structure depends on an

absence of phosphorus and on an adequately rapid rate of solidification. Antimony also reacts with either sodium or strontium to form coarse intermetallics with adverse effects on castability and eutectic structure.

Antimony is classified as a heavy metal with potential toxicity and hygiene implications, especially as associated with the possibility of stibine gas formation and the effects of human exposure to other antimony compounds.

Beryllium additions of as low as a few parts per million may be effective in reducing oxidation losses and associated inclusions in magnesium-containing compositions. Studies have shown that proportionally increased beryllium concentrations are required for oxidation suppression as magnesium content increases.

At higher concentrations (>0.04%), beryllium affects the form and composition of iron-containing intermetallics, markedly improving strength and ductility. In addition to changing beneficially the morphology of the insoluble phase, beryllium changes its composition, rejecting magnesium from the Al-Fe-Si complex and thus permitting its full use for hardening purposes.

Beryllium-containing compounds are, however, numbered among the known carcinogens that require specific precautions in the melting, molten metal handling, dross handling and disposition, and welding of alloys. Standards define the maximum beryllium in welding rod and weld base metal as 0.008 and 0.010%, respectively.

Bismuth improves the machinability of cast aluminum alloys at concentrations greater than 0.1%.

Boron combines with other metals to form borides, such as Al_2 and TiB_2. Titanium boride forms stable nucleation sites for interaction with active grain-refining phases such as $TiAl_3$ in molten aluminum.

Metallic borides reduce tool life in machining operations, and in coarse particle form they consist of objectionable inclusions with detrimental effects on mechanical properties and ductility. At high boron concentrations, borides contribute to furnace sludging, particle agglomeration, and increased risk of casting inclusions. However, boron treatment of aluminum-containing peritectic elements is practiced to improve purity and electrical conductivity in rotor casting. Higher rotor alloy grades may specify boron to exceed titanium and vanadium contents to ensure either the complexing or precipitation of these elements for improved electrical performance (see the section "Rotor Castings" in this article).

Cadmium in concentrations exceeding 0.1% improves machinability. Precautions that acknowledge volatilization at 767 °C (1413 °F) are essential.

Calcium is a weak aluminum-silicon eutectic modifier. It increases hydrogen solubility and is often responsible for casting porosity at trace concentration levels. Calcium concentrations greater than approximately 0.005% also adversely affect ductility in aluminum-magnesium alloys.

Chromium additions are commonly made in low concentrations to room temperature aging and thermally unstable compositions in which germination and grain growth are known to occur. Chromium typically forms the compound $CrAl_7$, which displays extremely limited solid-state solubility and is therefore useful in suppressing grain growth tendencies. Sludge that contains iron, manganese, and chromium is sometimes encountered in die casting compositions, but it is rarely encountered in gravity casting alloys. Chromium improves corrosion resistance in certain alloys and increases quench sensitivity at higher concentrations.

Copper. The first and most widely used aluminum alloys were those containing 4 to 10% Cu. Copper substantially improves strength and hardness in the as-cast and heat-treated conditions. Alloys containing 4 to 6% Cu respond most strongly to thermal treatment. Copper generally reduces resistance to general corrosion and, in specific compositions and material conditions, stress corrosion susceptibility. Additions of copper also reduce hot tear resistance and decrease castability.

Iron improves hot tear resistance and decreases the tendency for die sticking or soldering in die casting. Increases in iron content are, however, accompanied by substantially decreased ductility. Iron reacts to form a myriad of insoluble phases in aluminum alloy melts, the most common of which are $FeAl_3$, $FeMnAl_6$, and $\alpha AlFeSi$. These essentially insoluble phases are responsible for improvements in strength, especially at elevated temperature. As the fraction of insoluble phase increases with increased iron content, casting considerations such as flowability and feeding characteristics are adversely affected. Iron participates in the formation of sludging phases with manganese, chromium, and other elements.

Lead is commonly used in aluminum casting alloys at greater than 0.1% for improved machinability.

Magnesium is the basis for strength and hardness development in heat-treated Al-Si alloys and is commonly used in more complex Al-Si alloys containing copper, nickel, and other elements for the same purpose. The hardening phase Mg_2Si displays a useful solubility limit corresponding to approximately 0.70% Mg, beyond which either no further strengthening occurs or matrix softening takes place. Common premium-strength compositions in the Al-Si family employ magnesium in the range of 0.40 to 0.070% (see the section "Premium Engineered Castings" in this article).

Binary Al-Mg alloys are widely used in applications requiring a bright surface finish and corrosion resistance, as well as attractive combinations of strength and ductility. Common compositions range from 4 to 10% Mg, and compositions containing more than 7% Mg are heat treatable. Instability and room-temperature aging characteristics at higher magnesium concentrations encourage heat treatment.

Manganese is normally considered an impurity in casting compositions and is controlled to low levels in most gravity cast compositions. Manganese is an important alloying element in wrought compositions, through which secondary foundry compositions may contain higher manganese levels. In the absence of work hardening, manganese offers no significant benefits in cast aluminum alloys. Some evidence exists, however, that a high volume fraction of $MnAl_6$ in alloys containing more than 0.5% Mn may beneficially influence internal casting soundness. Manganese can also be employed to alter response in chemical finishing and anodizing.

Mercury. Compositions containing mercury were developed as sacrificial anode materials for cathodic protection systems, especially in marine environments. The use of these optimally electronegative alloys, which did not passivate in seawater, was severely restricted for environmental reasons.

Nickel is usually employed with copper to enhance elevated-temperature properties. It also reduces the coefficient of thermal expansion.

Phosphorus. In AlP_3 form, phosphorus nucleates and refines primary silicon-phase formation in hypereutectic Al-Si alloys. At parts per million concentrations, phosphorus coarsens the eutectic structure in hypoeutectic Al-Si alloys. Phosphorus diminishes the effectiveness of the common eutectic modifiers sodium and strontium.

Silicon. The outstanding effect of silicon in aluminum alloys is the improvement of casting characteristics. Additions of silicon to pure aluminum dramatically improve fluidity, hot tear resistance, and feeding characteristics. The most prominently used compositions in all casting processes are those of the aluminum-silicon family. Commercial alloys span the hypoeutectic and hypereutectic ranges up to about 25% Si.

In general, an optimum range of silicon content can be assigned to casting processes. For slow cooling rate processes (such as plaster, investment, and sand), the range is 5 to 7%, for permanent mold 7 to 9%, and for die casting 8 to 12%. The bases for these recommendations are the relationship between cooling rate and fluidity and the effect of percentage of eutectic on feeding. Silicon additions are also accompanied by a reduction in specific gravity and coefficient of thermal expansion.

Silver is used in only a limited range of aluminum-copper premium-strength alloys at concentrations of 0.5 to 1.0%. Silver contributes to precipitation hardening and stress corrosion resistance.

Sodium modifies the aluminum-silicon eutectic. Its presence is embrittling in aluminum-magnesium alloys. Sodium interacts with phosphorus to reduce its effectiveness in modifying the eutectic and that of phosphorus in the refinement of the primary silicon phase.

Strontium is used to modify the aluminum-silicon eutectic. Effective modification can be achieved at very low addition levels, but a range of recovered strontium of 0.008 to 0.04% is commonly used. Higher addition levels are associated with casting porosity, especially in processes or in thick-section parts in which solidification occurs more slowly. Degassing efficiency may also be adversely affected at higher strontium levels.

Tin is effective in improving antifriction characteristics, and is therefore useful in bearing applications. Casting alloys may contain up to 25% Sn. Additions can also be made to improve machinability. Tin may influence precipitation-hardening response in some alloy systems.

Titanium is extensively used to refine the grain structure of aluminum casting alloys, often in combination with smaller amounts of boron. Titanium in excess of the stoichiometry of TiB_2 is necessary for effective grain refinement. Titanium is often employed at concentrations greater than those required for grain refinement to reduce cracking tendencies in hot short compositions.

Zinc. No significant benefits are obtained by the addition of zinc to aluminum. Accompanied by the addition of copper and/or magnesium, however, zinc results in attractive heat treatable or naturally aging compositions. A number of such compositions are in common use. Zinc is also commonly found in secondary gravity and die casting compositions.

Casting Processes

The wide applicability of casting processes and process variations in the production of aluminum-base compositions necessitates a comprehensive understanding of process characteristics and capabilities. The selection of casting method is based on the capabilities of each process relative to the design and the specified requirements for each part. In most cases, castings can be readily produced by more than one technique. In these cases, economics largely based on volume of production dictate the process choice. For other examples, specific quality or engineering requirements restrict the process choice.

Although the rate of new alloy development has declined in recent years, activity in new casting process development has dramatically increased. These developments are primarily variations of three broad categories: expendable mold processes, including green and dry sand casting, as well as plaster and investment molding; gravity permanent mold, including centrifugal and low-pressure casting; and pressure die casting.

Progress in pattern and mold materials and in pouring techniques in each of these processes is documented in the articles "Sand Molding," "Plaster Molding," "Ceramic Molding," "Investment Casting," "Permanent Mold Casting," "Centrifugal Casting," "Die Casting," "Replicast Process," "Counter-Gravity Low-Pressure Casting," "Directional and Monocrystal Solidification," "Squeeze Casting," and "Semisolid Metal Casting and Forging" in this Volume.

Aluminum and Aluminum Alloys

Elwin L. Rooy, Aluminum Company of America

Melting and Metal Treatment

Aluminum and aluminum alloys can be melted in a variety of ways (see the article "Nonferrous Molten Metal Processes" in this Volume). Coreless and channel induction furnaces, crucible and open-hearth reverberatory furnaces fired by natural gas or fuel oil, and electric resistance and electric radiation furnaces are all in routine use. The nature of the furnace charge is as varied and important as the choice of furnace type for metal casting operations. The furnace charge may range from prealloyed ingot of high quality to charges made up exclusively from low-grade scrap. Even under optimum melting and melt-holding conditions, molten aluminum is susceptible to three types of degradation:

- With time at temperature, adsorption of hydrogen results in increased dissolved hydrogen content up to an equilibrium value for the specific composition and temperature
- With time at temperature, oxidation of the melt occurs; in alloys containing magnesium, oxidation losses and the formation of complex oxides may not be self-limiting
- Transient elements characterized by low vapor pressure and high reactivity are reduced as a function of

time at temperature; magnesium, sodium, calcium, and strontium, upon which mechanical properties directly or indirectly rely, are examples of elements that display transient characteristics

Turbulence or agitation of the melt and increased holding temperature significantly increase the rate of hydrogen solution, oxidation, and transient element loss. The mechanical properties of aluminum alloys depend on casting soundness, which is strongly influenced by hydrogen porosity and entrained nonmetallic inclusions. Reductions in dissolved hydrogen content and in suspended included matter are normally accomplished through treatment of the melt before pouring.

Aluminum and Aluminum Alloys

Hydrogen

Hydrogen is the only gas that is appreciably soluble in aluminum and its alloys. Its solubility varies directly with temperature and the square root of pressure. As shown in Fig. 1, hydrogen solubility is considerably greater in the liquid than in the solid state. Actual liquid and solid solubilities in pure aluminum just above and below the solidus are 0.65 and 0.034 mL/100 g, respectively. These values vary slightly with alloy content. During the cooling and solidification of molten aluminum, dissolved hydrogen in excess of the extremely low solid solubility may precipitate in molecular form, resulting in the formation of primary and/or secondary voids.

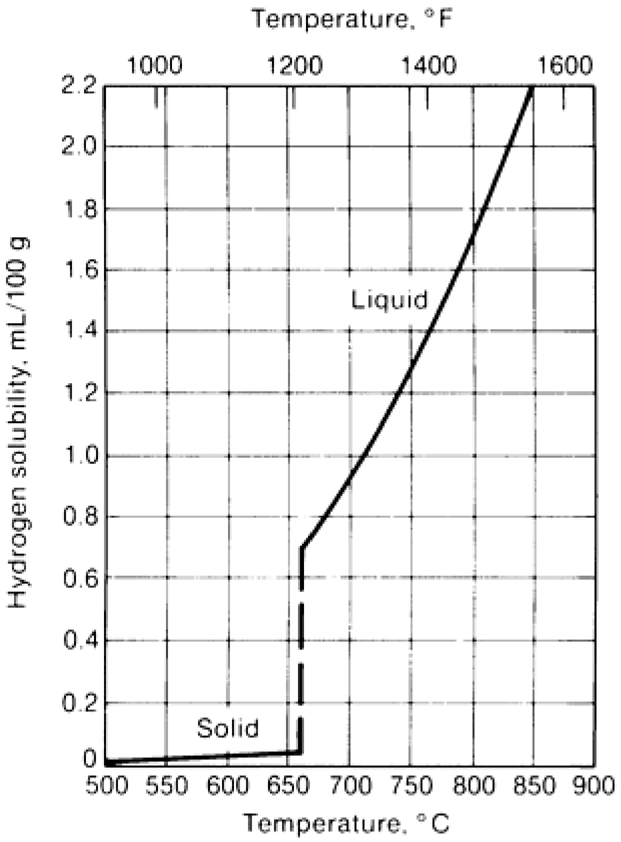

Fig. 1 Solubility of hydrogen in aluminum at 1 atm hydrogen pressure.

Hydrogen bubble formation is strongly resisted by surface tension forces, by liquid cooling and solidification rates, and by an absence of nucleation sites for hydrogen precipitation such as entrained oxides. Dissolved hydrogen concentrations

significantly in excess of solid solubility are therefore required for porosity formation. In the absence of nucleating oxides, relatively high concentrations (of the order of 0.30 mL/100 g) are required for hydrogen precipitation. No porosity was found to occur in a range of common alloys at hydrogen concentrations as high as 0.15 mL/100 g.

Hydrogen Sources. There are numerous sources of hydrogen in aluminum. Moisture in the atmosphere dissociates at the molten metal surface, offering a concentration of atomic hydrogen capable of diffusing into the melt. The barrier oxide of aluminum resists hydrogen solution by this mechanism, but disturbances of the melt surface that break the oxide barrier result in rapid hydrogen dissolution. Alloying elements, especially magnesium, may also affect hydrogen absorption by forming oxidation reaction products that offer reduced resistance to the diffusion of hydrogen into the melt and by altering liquid solubility. The introduction of moisture-contaminated tools to the melt dramatically increases dissolved hydrogen levels. Salt fluxes, which may have hydroscopically adsorbed moisture, and unprotected fluxing tubes coated by reaction product salts both increase dissolved hydrogen content. The melt charge may contain both dissolved hydrogen and, when not preheated before charging, moisture-contaminated surfaces.

An additional source of hydrogen, especially in green sand casting, is the reaction involving molten metal and water in the mold itself. In addition, the turbulence that inevitably occurs during drawing, pouring, and to some extent within the gating system increases the potential for hydrogen solution and subsequent precipitation.

Hydrogen Porosity. Two types or forms of hydrogen porosity may occur in cast aluminum. Of greater importance is interdendritic porosity, which is encountered when hydrogen contents are sufficiently high that hydrogen rejected at the solidification front results in solution pressures above atmospheric. Secondary (micronsize) porosity occurs when dissolved hydrogen contents are low, and void formation is characteristically subcritical.

Finely distributed hydrogen porosity may not always be undesirable. Hydrogen precipitation may alter the form and distribution of shrinkage porosity in poorly fed parts or part sections. Shrinkage is generally more harmful to casting properties. In isolated cases, hydrogen may actually be intentionally introduced and controlled in specific concentrations compatible with the application requirements of the casting in order to promote superficial soundness.

Nevertheless, hydrogen porosity adversely affects mechanical properties in a manner that varies with the alloy. Figure 2 shows the relationship between actual hydrogen content and observed porosity. Figure 3 defines the effect of porosity on the ultimate tensile strength of selected compositions.

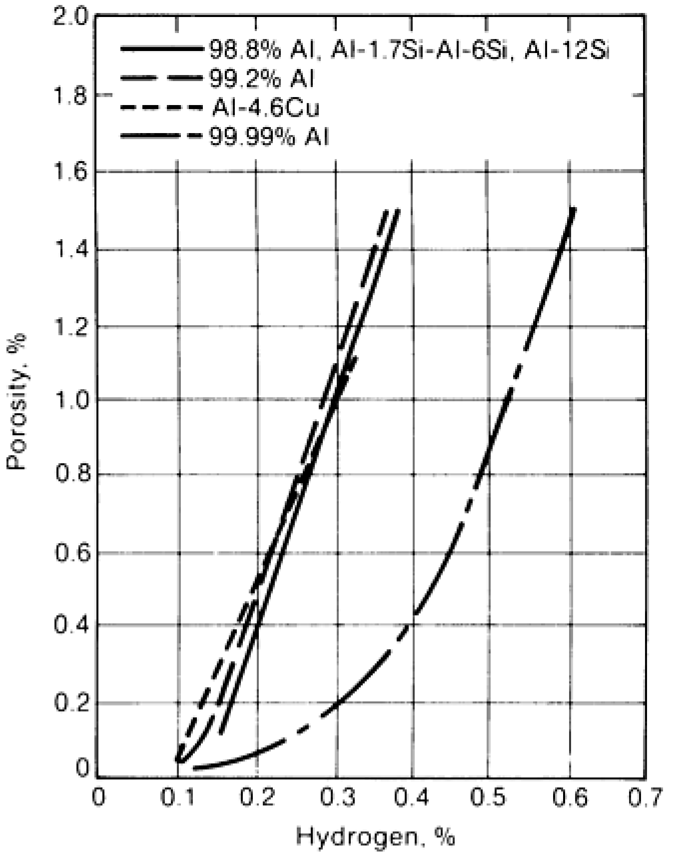

Fig. 2 Porosity as a function of hydrogen content in sand-cast aluminum and aluminum alloy bars.

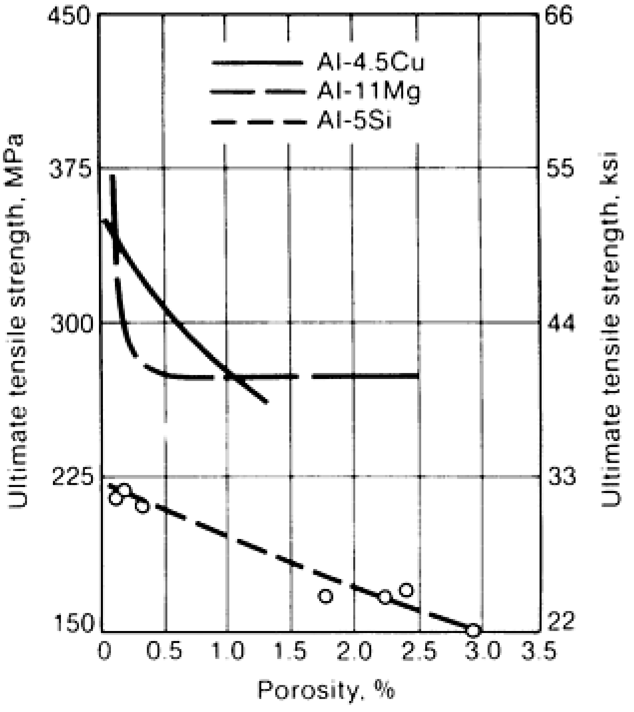

Fig. 3 Ultimate tensile strength versus hydrogen porosity for sand cast bars of three aluminum alloys.

It is often assumed that hydrogen may be desirable or tolerable in pressure-tight applications. The assumption is that hydrogen porosity is always present in the cast structure as integrally enclosed rounded voids. In fact, hydrogen porosity may occur as rounded or elongated voids and in the presence of shrinkage may decrease rather than increase resistance to pressure leakage.

Hydrogen in Solid Solution. The disposition of hydrogen in a solidified structure depends on the dissolved hydrogen level and the conditions under which solidification occurs. Because the presence of hydrogen porosity is a result of diffusion-controlled nucleation and growth, decreasing the hydrogen concentration and increasing the rate of solidification act to suppress void formation and growth. For this reason, castings made in expendable mold processes are more susceptible to hydrogen-related defects than parts produced by permanent mold or pressure die casting.

Hydrogen Removal. Dissolved hydrogen levels can be reduced by a number of methods, the most important of which is fluxing with dry, chemically pure nitrogen, argon, chlorine, and freon. Compounds such as hexachloroethane are in common use; these compounds dissociate at molten metal temperatures to provide the generation of fluxing gas.

Gas fluxing reduces the dissolved hydrogen content of molten aluminum by partial pressure diffusion. The use of reactive gases such as chlorine improves the rate of degassing by altering the gas/metal interface to improve diffusion kinetics. Holding the melt undisturbed for long periods of time at or near the liquidus also reduces hydrogen content to a level no greater than that defined for the alloy as the temperature-dependent liquid solubility.

Measurement of Hydrogen. It is possible to define quantitatively the concentration of hydrogen in an aluminum melt by liquid and solid-state extraction techniques. One instrument offers real time, accurate measurement of hydrogen in molten aluminum. A variety of solid-state extraction techniques exist for measuring hydrogen in aluminum after solidification. A number of devices have also been developed to quantify hydrogen content in molten aluminum. Commercially available systems of this type rely on the correlation of parameters governing the evolution of hydrogen from samples solidifying under vacuum (time, temperature, and pressure) or may employ other relationships to approximate or define hydrogen content. Semiquantitative tests, also based on the application of vacuum, are sometimes used.

Samples placed in a vacuum chamber should be visually observed during solidification. The rapid evolution of gas bubbles with the application of vacuum indicates a high level of oxide contamination and an unknown hydrogen level. The emergence of bubbles from the sample surface only in the last stages of solidification indicates an absence of oxides and moderately high hydrogen levels. In many foundries, vacuum solidification samples are not observed during solidification but are subsequently sectioned to obtain comparative ratings of void content. The latter technique is inferior to the analysis obtained by the visual interpretation of events that occur during sample solidification.

The selection of vacuum pressure for performing vacuum solidification tests is important. For very high quality castings, pressures of 2 to 5 mm (0.08 to 0.2 in.) of mercury are employed as the most rigorous standard. In these cases, any evolution from the visually observed sample indicates unacceptable melt quality. Different absolute test pressures are selected for lower quality acceptance limits.

For foundries relying on specific gravity determinations performed on the solidified sample, 102 mm (4 in.) of mercury is a desirable test pressure. Although not accurate for the assessment of hydrogen *per se*, the density control system has proved remarkably effective in predicting acceptance limits based on the combined influence of dissolved hydrogen and oxides on porosity formation and offers, along with more accurate measures of hydrogen content, the opportunity of statistical treatment.

Because hydrogen solubility is inversely dependent on absolute pressure during solidification, any reduction in vacuum pressure results in reduced sensitivity in whatever approach is employed in vacuum testing for hydrogen detection. It is essential that reproducible conditions be ensured regardless of the test and test pressure employed. Systems that rely on the differential from atmospheric pressure are markedly inferior to those that measure absolute and controllable test chamber pressure, preferably in millimeters of mercury.

Hydrogen porosity is normally distinguishable in casting structures by radiography, by machining tests, and by low-power or microscopic examination. Discrimination between porosity caused by shrinkage and by hydrogen is difficult and is often subject to misinterpretation. Hydrogen porosity is generally found to affect the casting cross section uniformly, with only small variations in void size and shape occurring within the cast structure.

Elwin L. Rooy, Aluminum Company of America

Oxidation

Oxide Formation. Aluminum and its alloys oxidize readily in both the solid and molten states to provide a continuous self-limiting film. The rate of oxidation increases with temperature and is substantially greater in molten than in solid aluminum. The reactive elements contained in alloys such as magnesium, strontium, sodium, calcium, beryllium, and titanium are also factors in oxide formation. In both the molten and solid states, oxide formed at the surface offers benefits in self-limitation and as a barrier to hydrogen diffusion and solution. Induced turbulence, however, results in the entrainment of oxide particles, which resist gravity separation because their density is similar to that of molten aluminum.

Oxides are formed by direct oxidation in air, by reaction with water vapor, or by aluminothermic reaction with oxides of other metals, such as iron or silicon, contained in tools and refractories. Aluminum oxide is polymorphic, but at molten metal temperature the common forms of oxide encountered are crystalline and of a variety of types depending on exposure, temperature, and time. Some crystallographic oxide forms affect the appearance and coloration of castings, without other significant effects.

Special consideration must be given to alloys containing magnesium, which oxidize more readily and more continuously as a function of environment, time, and temperature. The result can be increased melt loss and oxide generation, which increases with magnesium concentration. Magnesium oxide occurs most frequently in the form of micron-size particles. At higher holding temperatures (>745 °C, or 1375 °F), complex aluminum-magnesium oxide (spinel) is formed with a potential for rapid growth. In some forms, spinel assumes a hard, black crystalline form that contaminates furnaces, holding crucibles, and ladles. Although spinels occur only at temperatures exceeding conventional holding temperatures, it is important to consider localized rather than bulk temperatures in metal melting, holding, handling, and treatment. The impingement of gas burners, excessive temperatures at the melt surface regardless of heat source, and exothermic reactions that occur during fluxing treatments may result in the thermal conditions required for spinel formation.

Oxide Separation and Removal. It is usually necessary to treat melts of aluminum and its alloys to remove suspended nonmetallics. This is normally accomplished by using either solid or chemically active gaseous fluxes containing chlorine, fluorine, chlorides, and/or fluorides. In each case, the objective is the dewetting of the oxide/melt interface to provide effective separation of oxides and other included matter and the flotation of these nonmetallics by attachment to either solid or gaseous elements or compounds introduced or formed during flux treatment.

Fluxes can also be used to minimize oxide formation. For this reason, melts containing magnesium are often protected by the use of salts that form liquid layers, most often of magnesium chloride, on the melt surface. These fluxes, termed covering fluxes, must be periodically removed and replaced. Carbon, graphite, and boron powder also effectively retard oxidation when applied to the melt surface.

It is increasingly common to employ filtration in the treatment of molten metal to remove suspended nonmetallic particles. Such processes can be used in the transfer of metal from furnace to ladle or crucible, within crucibles and furnaces, in holding or drawing chambers, and within the mold gating system. Porous foam ceramics, bonded rigid media elements, fused permeable refractories, and depth loose medium filter systems are all in use in aluminum foundry operations. Not to be confused with ceramic strainers, metal screens, and metallic wools useful only for gross oxide separation and as gating system chokes, true molten metal filtration is capable of substantially reducing the nonmetallic content of metal introduced to the casting, measured at times in microns.

Effects of Inclusions. In addition to oxides, a number of additional compounds can be considered inclusions in cast structures. All aluminum contains aluminum carbide (Al_4C_3) formed during reduction. Borides may also be present; by agglomeration, borides can assume sufficient size to represent a significant factor in the metal structure, with especially adverse effects in machining.

Under all conditions, inclusions--whether in film or particle form--are damaging to mechanical properties. The gross effect of inclusions is to reduce the effective cross section of metal under load. The more devastating effect on properties is that of stress concentration when inclusions appear at or near the surface of parts or specimens. Fatigue performance is

reduced under the latter condition by the notch effect. Ultimate and yield strengths are typically lower, and ductility may be substantially reduced when inclusions are present.

Hard particle inclusions are frequently found in association with film-type oxides. Borides, carbides, oxides, and nonmetallic particles in the melt are scavenged and then concentrated in localized regions within the cast structure.

Inclusion content directly affects fluidity and feeding capability. The effect on shrinkage can be both general (based on feeding effectiveness) and localized (the barrier effect of some oxides on molten metal flow during solidification). The tendency for nonfills also increases with oxide content. Misruns can be minimized by ensuring a low level of oxide contamination.

Tests for Oxides. The presence of inclusions can be determined by vacuum solidification tests, radiography, metallography, and machining tests. The presence of oxide is frequently detected in mechanical test specimens because failure in standard tensile testing will occur through the weakest (inclusion-affected) plane. More sophisticated quantitative tests are available, such as specimen leaching, atomic and neutron absorption, and neutron activation. Quantitative determinations of oxide content are rarely performed because practical samples are of limited size, for which test results may not be meaningfully correlated with casting quality. Ultrasonic and electrical conductivity tests for molten aluminum are under development, but at this time are unproven in production casting operations.

Aluminum and Aluminum Alloys

Elwin L. Rooy, Aluminum Company of America

Structure Control

A number of factors define the metallurgical structure in aluminum castings. Of primary importance are dendrite cell size or dendrite arm spacing, the form and distribution of microstructural phases, and grain size. The foundryman can control the fineness of dendrite structure by controlling the rate of solidification.

Microstructural features such as the size and distribution of primary and intermetallic phases are considerably more complex. However, chemistry control (particularly control of impurity element concentrations), control of element ratios based on the stoichiometry of intermetallic phases, and control of solidification conditions to ensure uniform size and distribution of intermetallics are all means to this end. Effective grain refinement shares and strongly influences the same objectives. The use of modifiers and refiners to influence eutectic and hypereutectic structures in aluminum-silicon alloys is also an example of the manner in which microstructures and macrostructures can be optimized in foundry operations.

Dendrite Arm Spacing

In all commercial processes, solidification takes place through the formation of dendrites in the liquid solution. The cells contained within the dendrite structure correspond to the dimensions separating the arms of primary dendrites and are controlled for a given composition exclusively by solidification rate.

Through microstructural examination, it is possible to define the rate at which a given region of a casting has solidified by reference to data obtained from unidirectionally solidified samples spanning solidification rates represented by the full range of various casting processes. Figure 4 illustrates the improvement in mechanical properties achievable by the change in dendrite formation controlled by solidification rate.

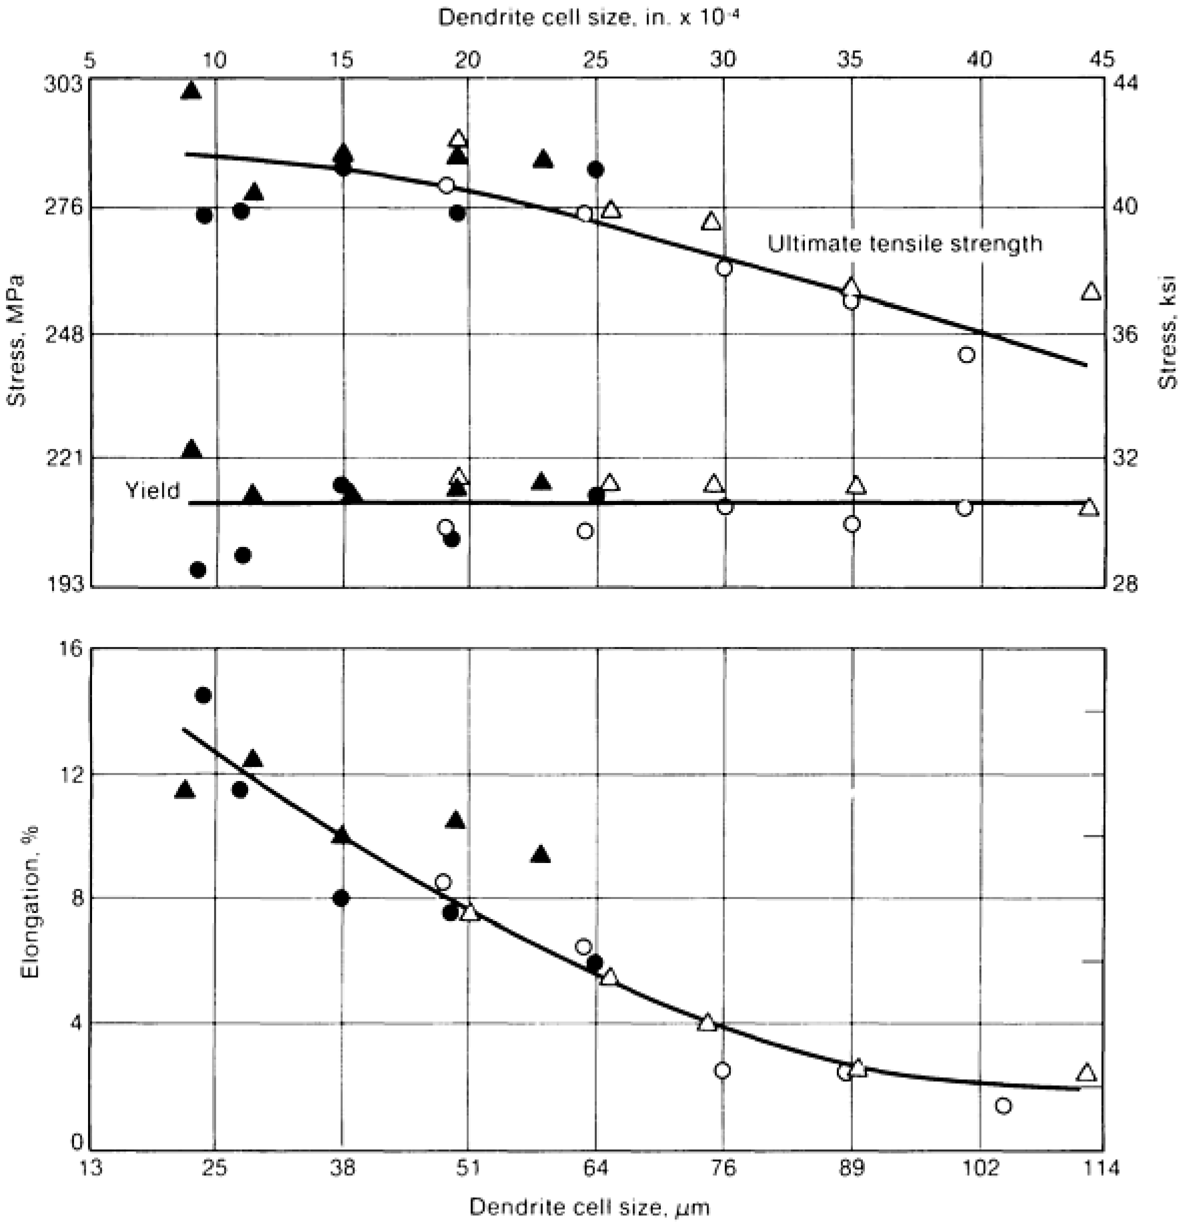

Fig. 4 Tensile properties versus dendrite cell size for four heats of aluminum alloy A356-T62 plaster cast plates.

In premium engineered castings and in many other casting applications, careful attention is given to obtaining solidification rates corresponding to optimum mechanical property development. Solidification rate affects more than dendrite cell size, but dendrite cell size measurements are becoming increasingly important.

Grain Structure

A fine, equiaxed grain structure is normally desired in aluminum castings. The type and size of grains formed are determined by alloy composition, solidification rate, and the addition of master alloys (grain refiners) containing intermetallic phase particles, which provide sites for heterogeneous grain nucleation.

Grain Refinement Effects. A finer grain size promotes improved casting soundness by minimizing shrinkage, hot cracking, and hydrogen porosity. The advantages of effective grain refinement are:

- Improved feeding characteristics
- Increased tear resistance

- Improved mechanical properties
- Increased pressure tightness
- Improved response to thermal treatment
- Improved appearance following chemical, electrochemical, and mechanical finishing

Under normal solidification conditions spanning the full range of commercial casting processes, aluminum alloys without grain refiners exhibit coarse columnar and/or coarse equiaxed structures. The coarse columnar grain structure (Fig. 5a) is less resistant to cracking during solidification and postsolidification cooling than the well-refined grain structure of the same alloy shown in Fig. 5(b). This is because reduced resistance to tension forces at elevated temperature may be expected as a result of increased sensitivity to grain-boundary formations in coarse-grain structures.

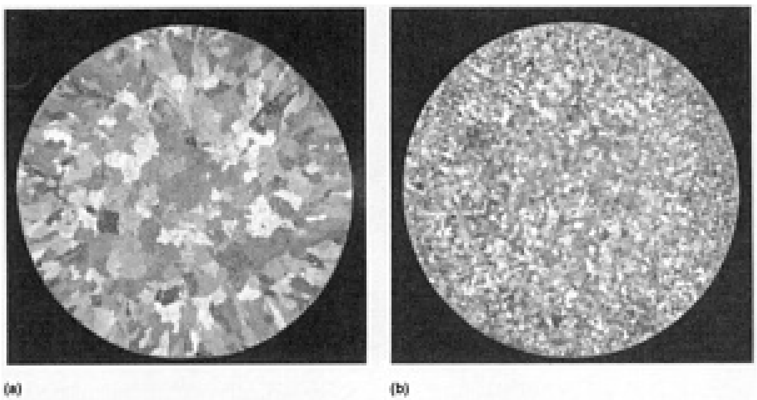

Fig. 5 As-cast Al-7Si ingots showing the effects of grain refinement. (a) No grain refiner. (b) Grain refined. Both etched using Poulton's etch; both 2×. Courtesy of W.G. Lidman, KB Alloys, Inc.

A fine grain structure also minimizes the effects on castability and properties associated with the size and distribution of normally occurring intermetallics. Large, insoluble intermetallic particles that are present or form in the temperature range between liquidus and solidus reduce feeding. A finer grain size promotes the formation of finer, more evenly distributed intermetallic particles with corresponding improvements in feeding characteristics. Because most of these more brittle phases precipitate late in the solidification process, their preferential formation at grain boundaries also profoundly affects tear resistance and mechanical properties in coarse-grain structures. By reducing the magnitude of grain-boundary effects through grain refinement, the hot cracking tendencies of some predominantly solid-solution alloys, such as those of the 2*xx* and 5*xx* families, can be substantially reduced.

Porosity, if present, is of smaller discrete void size in fine-grain parts. The size of interdendritic shrinkage voids is directly influenced by grain size. The previously mentioned effects of structural refinement on feeding characteristics minimize the potential formation of larger shrinkage cavities, and when hydrogen porosity is present, larger pore size with more damaging impact on properties will be experienced in coarse-grain rather than fine-grain castings.

The finer distribution of soluble intermetallics throughout grain-refined castings results in faster and more complete response to thermal treatment. More consistent mechanical properties can be expected following thermal treatment.

Large grains frequently emphasize different reflectances based on random crystal orientation, resulting in an orange peel or spangled appearance following chemical finishing, anodizing, or machining. Tearing also becomes more pronounced in the machining of soft coarse-grain compositions.

Grain Refinement. All aluminum alloys can be made to solidify with a fully equiaxed, fine grain structure through the use of suitable grain-refining additions. The most widely used grain refiners are master alloys of titanium, or of titanium and boron, in aluminum. Aluminum-titanium refiners generally contain from 3 to 10% Ti. The same range of titanium concentrations is used in Al-Ti-B refiners with boron contents from 0.2 to 1% and titanium-to-boron ratios ranging from about 5 to 50. Although grain refiners of these types can be considered conventional hardeners or master alloys, they differ from master alloys added to the melt for alloying purposes alone. To be effective, grain refiners must introduce

controlled, predictable, and operative quantities of aluminides (and borides) in the correct form, size, and distribution for grain nucleation. Wrought refiner in rod form, developed for the continuous treatment of aluminum in primary operations, is available in sheared lengths for foundry use. The same grain-refining compositions are furnished in waffle form. In addition to grain-refining master alloys, salts (usually in compacted form) that react with molten aluminum to form combinations of $TiAl_3$ and TiB_2 are also available.

Grain Refinement Mechanisms. Despite much progress in understanding the fundamentals of grain refinement, no universally accepted theory or mechanism exists to satisfy laboratory and industrial experience. It is known that $TiAl_3$ is an active phase in the nucleation of aluminum crystals, ostensibly because of similarities in crystallographic lattice spacing. Nucleation may occur on $TiAl_3$ substrates that are undissolved or precipitate at sufficiently high titanium concentrations by peritectic reaction. Grain refinement can be achieved at much lower titanium concentrations than those predicted by the binary Al-Ti peritectic point of 0.15%. For this reason, other theories, such as conucleation of the aluminide by TiB_2 or carbides and constitutional effects on the peritectic reaction, are presumed to be influential. Recent findings also suggest the active role of more complex borides of the Ti-Al-B type in grain nucleation.

Additions of titanium in the form of master alloys to aluminum casting compositions normally result in significantly finer and equiaxed grain structure. The period of effectiveness following grain-refiner addition and the potency of grain-refining action are enhanced by the presence of TiB_2. In the testing of some compositions, notably those of the aluminum-silicon family, aluminum borides and titanium boride in the absence of excess titanium have been found to provide effective grain refinement. However, the requirement of an excess of titanium compared to stoichiometric balance with boron in TiB_2 is commonly accepted for optimum grain-refining results, and titanium or higher-ratio titanium-boron master alloys are used almost exclusively for grain size control.

The role of boride in enhancing grain refinement effectiveness and extending its useful duration is observed in both casting and wrought alloys, forming the basis for its use. However, when the boride is present in the form of large, agglomerated particles, it assumes the character of a highly objectionable inclusion with especially damaging effects in machining. Particle agglomeration is found in master alloys of poor quality, or it may occur as a result of long, quiescent holding periods. For the latter reason, it is essential that holding furnaces be routinely and thoroughly cleaned when boron-containing master alloys are used.

The objective in every case in which master alloys or other grain refiners are added to the melt is the release of constituent particles capable of nucleating grain formation to ensure uniform, fine, equiaxed grain structure. The selection of an appropriate grain refiner, practices for grain-refiner addition, and practices covering holding and pouring of castings following grain-refiner addition are usually developed by the foundry after considering casting and product requirements and after referral to the performance characteristics of commercial grain refiners furnished by the supplier. However, grain refiners of the 5Ti-1B and 5Ti-0.6B types, which are characterized by cleanliness and fine, uniform distribution of aluminide and boride phases when added to the melt at 0.01 to 0.03% Ti, should be expected to provide acceptable grain refinement under most conditions.

Grain Size Tests. Various tests have been devised to sample molten aluminum for the purpose of determining the effectiveness of grain refinement. These tests employ principles of controlled solidification to ensure accurate, meaningful, and reproducible grain size determination following polishing and etching. For many foundries, a useful standardized test can use a dry sand mold of fixed design or routine samples, such as those poured in vacuum solidification or for mechanical property tests. The grain size of cast structures obtained by sectioning the casting itself, polishing, and etching is also determined under magnification. Determinations are usually comparative and judgmental, but quantitative grain size measurement by intercept methods is also practiced. Thermoanalytical and electrical conductivity methods are under development for the nondestructive and predictive assessment of grain structure.

Modification and Refinement of Aluminum-Silicon Alloys

Hypoeutectic aluminum-silicon alloys can be improved by inducing structural modification of the normally occurring eutectic. In general, the greatest benefits are achieved in alloys containing from 5% Si to the eutectic concentration; this range includes most common gravity cast compositions.

Chemical Modifiers

The addition of certain elements, such as calcium, sodium, strontium, and antimony, to hypoeutectic aluminum-silicon alloys results in a finer lamellar or fibrous eutectic network. It is also understood that increased solidification rates are

useful in providing similar structures. There is, however, no agreement on the mechanisms involved. The most popular explanations suggest that modifying additions suppress the growth of silicon crystals within the eutectic, providing a finer distribution of lamellae relative to the growth of the eutectic. Various degrees of eutectic modification are shown in Fig. 6.

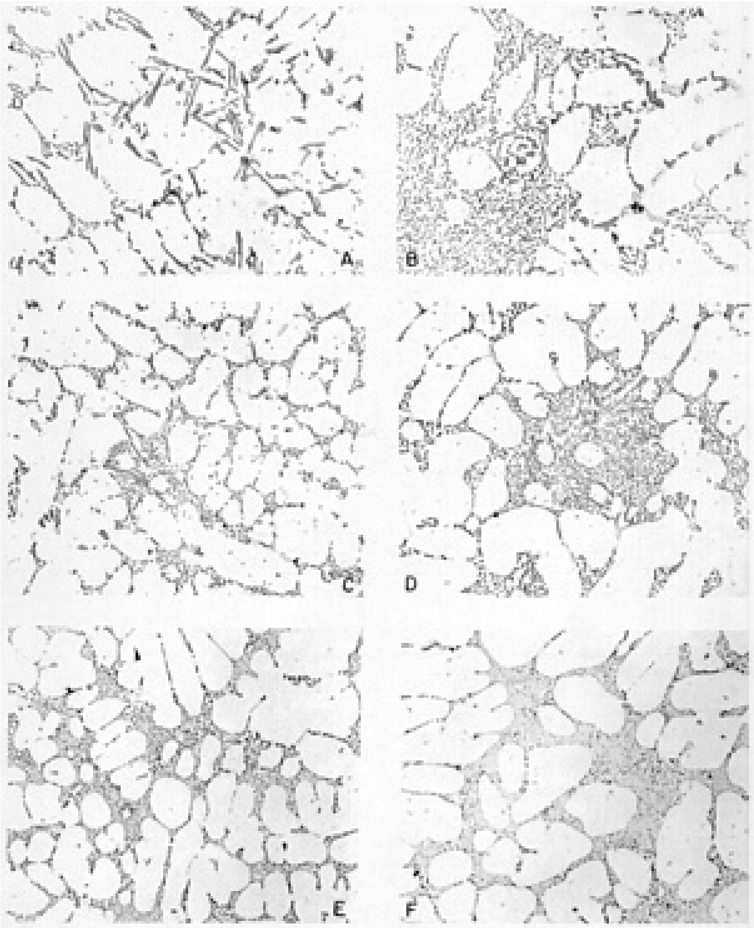

Fig. 6 Varying degrees of aluminum-silicon eutectic modification ranging from unmodified (A) to well modified (F). See Fig. 7 for the effectiveness of various modifiers.

The results of modification by strontium, sodium, and calcium are similar. Sodium has been shown to be the superior modifier, followed by strontium and calcium, respectively. Each of these elements is mutually compatible so that combinations of modification additions can be made without adverse effects. Eutectic modification is, however, transient when artificially promoted by additions of these elements. Figure 7 illustrates the relative effectiveness of various modifiers as a function of time at temperature.

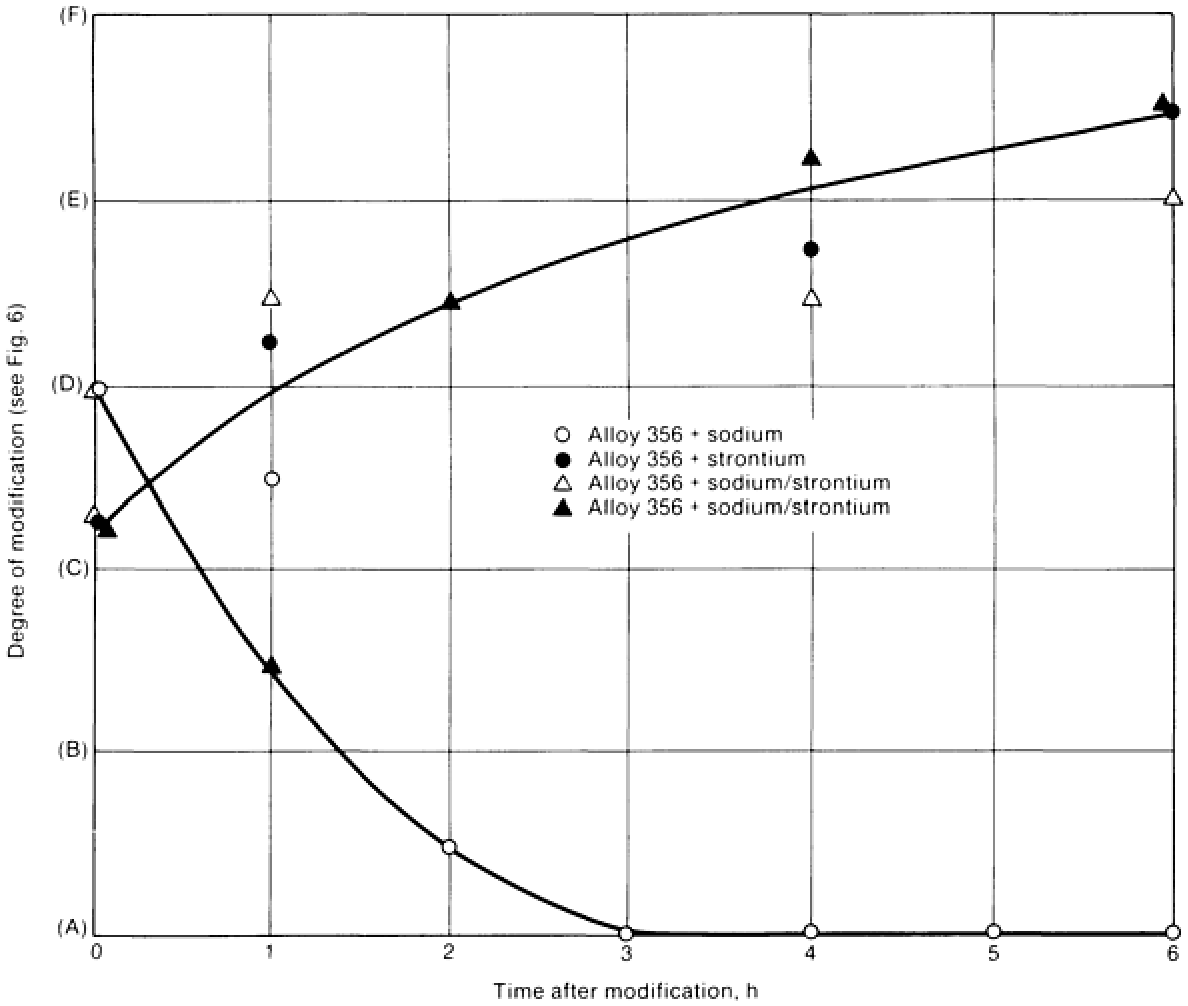

Fig. 7 Effectiveness of sodium and strontium modifiers as a function of time. See Fig. 6 for degrees of modification.

Antimony has been advocated as a permanent means of achieving structural modification. In this case, the modified structure differs; a more acicular refined eutectic is obtained compared to the uniform lacelike dispersed structures of sodium-, calcium-, or strontium-modified metal. As a result, the improvements in castability and mechanical properties offered by this group of elements are not completely achieved. Structural refinement is obtained that is time independent when two conditions are satisfied. First, the metal to be treated must be essentially phosphorus free, and second, the velocity of the solidification front must exceed a minimum value approximately equal to that obtained in conventional permanent mold casting.

Antimony is not compatible with other modifying elements. In cases in which antimony and other modifiers are present, coarse antimony-containing intermetallics are formed that preclude the attainment of an effectively modified structure and adversely affect casting results.

Modifier additions are usually accompanied by an increase in hydrogen content. In the case of sodium and calcium, the reactions involved in element solution are invariably turbulent or are accompanied by compound reactions that by their nature increase dissolved hydrogen levels. In the case of strontium, master alloys may be highly contaminated with hydrogen, and there are numerous indications that hydrogen solubility is increased after alloying.

For sodium, calcium, and strontium modifiers, the removal of hydrogen by reactive gases also results in the removal of the modifying element. Recommended practices are to obtain modification through additions of modifying elements added to well-processed melts, followed by inert gas fluxing to acceptable hydrogen levels. No such disadvantages accompany antimony use.

Calcium and sodium can be added to molten aluminum in metallic or salt form. Vacuum-prepackaged sodium metal is commonly used. Strontium is currently available in many forms, including aluminum-strontium master alloys ranging from approximately 10 to 90% Sr and Al-Si-Sr master alloys of varying strontium content.

Very low sodium concentrations (~0.001%) are required for effective modification. More typically, additions are made to obtain a sodium content in the melt of 0.005 to 0.015%. Remodification is performed as required to maintain the desired modification level.

A much wider range of strontium concentrations is in use. In general, addition rates far exceed those required for effective sodium modification. A range of 0.015 to 0.050% is standard industry practice. Normally, good modification is achievable in the range of 0.008 to 0.015% Sr. Remodification through strontium additions may be required, although retreatment is less frequent than for sodium.

To be effective in modification, antimony must be alloyed to approximately 0.06%. In practice, antimony is employed in the much higher range of 0.10 to 0.50%.

It is possible to achieve a state of overmodification, in which eutectic coarsening occurs, when sodium and/or strontium are used in excessive amounts. The corollary effects of reduced fluidity and susceptibility to hydrogen-related problems are usually encountered well before overmodification may be experienced.

The Importance of Phosphorus. It has been well established that phosphorus interferes with the modification mechanism. Phosphorus reacts with sodium and probably with strontium and calcium to form phosphides that nullify the intended modification additions. It is therefore desirable to use low-phosphorus metal when modification is a process objective and to make larger modifier additions to compensate for phosphorus-related losses.

Primary producers may control phosphorus contents in smelting and processing to provide less than 5 ppm of phosphorus in alloyed ingot. At these levels, normal additions of modification agents are effective in achieving modified structures. However, phosphorus contamination may occur in the foundry through contamination by phosphate-bonded refractories and mortars and by phosphorus contained in other melt additions, such as master alloys and alloying elements including silicon.

Effects of Modification. Typically, modified structures display somewhat higher tensile properties and appreciably improved ductility when compared to similar but unmodified structures. Figure 8 illustrates the desirable effects on mechanical properties that can be achieved by modification. Improved performance in casting is characterized by improved flow and feeding as well as by superior resistance to elevated-temperature cracking.

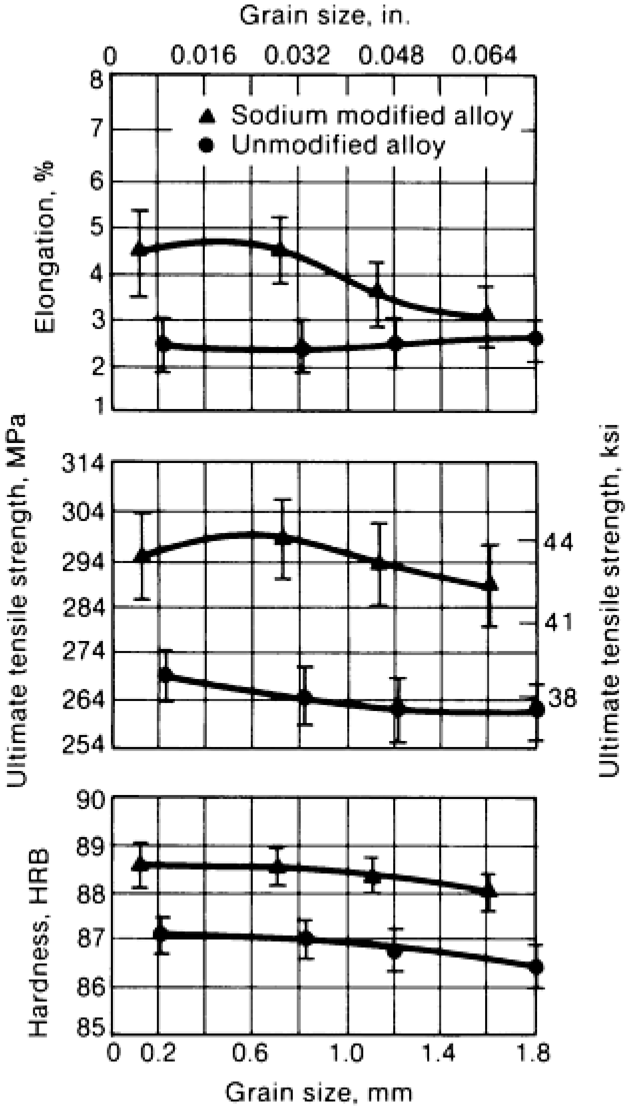

Fig. 8 Mechanical properties of as-cast A356 alloy tensile specimens as a function of modification and grain size.

Refinement of Hypereutectic Aluminum-Silicon Alloys

The elimination of large, coarse primary silicon crystals that are harmful in the casting and machining of hypereutectic silicon alloy compositions is a function of primary silicon refinement. Phosphorus added to molten alloys containing more than the eutectic concentration of silicon, made in the form of metallic phosphorus or phosphorus-containing compounds such as phosphor-copper and phosphorus pentachloride, has a marked effect on the distribution and form of the primary silicon phase. Investigations have shown that retained trace concentrations as low as 0.0015 through 0.03% P are effective in achieving the refined structure. Disagreements on recommended phosphorus ranges and addition rates have been caused by the extreme difficulty of accurately sampling and analyzing for phosphorus. More recent developments employing vacuum stage spectrographic or quantometric analysis now provide rapid and accurate phosphorus measurements.

Following melt treatment by phosphorus-containing compounds, refinement can be expected to be less transient than the effects of conventional modifiers on hypoeutectic modification. Furthermore, the solidification of phosphorus-treated melts, cooling to room temperature, reheating, remelting, and resampling in repetitive tests have shown that refinement is not lost; however, primary silicon particle size increases gradually, responding to a loss in phosphorus concentration. Common degassing methods accelerate phosphorus loss, especially when chlorine or freon is used. In fact, brief inert gas fluxing is frequently employed to reactivate aluminum phosphide nuclei, presumably by resuspension.

Practices that are recommended for melt refinement are as follows:

- Melting and holding temperature should be held to a minimum
- The alloy should be thoroughly chlorine or freon fluxed before refining to remove phosphorus-scavenging impurities such as calcium and sodium
- Brief fluxing after the addition of phosphorus is recommended to remove the hydrogen introduced during the addition and to distribute the aluminum phosphide nuclei uniformly in the melt

Figure 9 illustrates the microstructural differences between refined and unrefined structures.

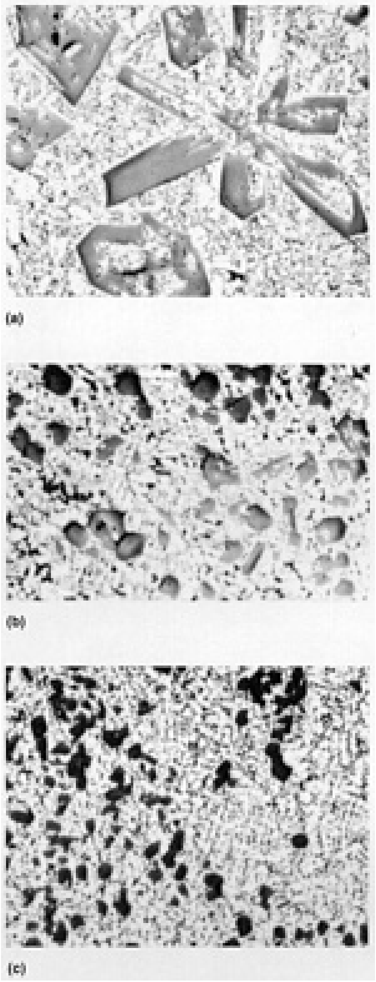

Fig. 9 Effect of phosphorus refinement on the microstructure of Al-22Si-1Ni-1Cu alloy. (a) Unrefined. (b) Phosphorus-refined. (c) Refined and fluxed. All 100×.

Effects of Refinement. Refinement substantially improves mechanical properties and castability. In some cases, especially at higher silicon concentrations, refinement forms the basis for acceptable foundry results.

Modification and Refinement. No elements are known that beneficially affect both eutectic and hypereutectic phases. The potential negative consequences of employing modifying and refining additions in the melt are characterized by the interaction of phosphorus with calcium, sodium, and strontium. Strontium has been claimed to benefit hypoeutectic and hypereutectic structures, but this claim has not been substantiated.

Metal Preparation

Gravity Casting. Regardless of the types of melting and holding furnaces and the particular gravity casting process used, there is great concern for reducing or eliminating dissolved hydrogen and entrained oxides. These procedures are less frequently employed for pressure die casting, in which concerns are focused on the dominant process-related causes of casting unsoundness, namely, entrapped gas and pouring injection-associated inclusions.

Sensitivity to melt quality varies with the casting process and part design and necessitates special consideration of relevant criteria for each application. In general, the melt is processed to achieve hydrogen reductions and the removal of oxides to meet specific casting requirements. Modification and grain-refiner additions are made as appropriate to the given alloy and end product.

Die Casting. Different melt preparation practices are employed in die casting operations because process-related conditions are more dominant in the control of product quality than those controlled by melt treatment. For this reason, degassing for the removal of hydrogen, grain refinement, and modification or silicon refinement in the case of hypereutectic silicon alloys are often intentionally neglected. The movement toward higher-integrity die castings has brought into focus the importance of the same melt quality parameters established and used in the gravity casting of aluminum alloys.

In high-production die casting operations, the consumption of internal and external scrap is of primary importance in reducing base metal costs for the predominantly secondary alloy compositions that are consumed. Scrap crushing, shredding, and pretreatment of various types precede melting, often in efficient induction systems. Oxides entrained in the melt as a result of this sequence of operations are dealt with through the use of salts and/or reactive gas fluxing. Melt treatment is typically confined to this and to rudimentary fluxing in holding furnaces to remove gross oxide and to facilitate the maintenance of minimum furnace cleanliness.

A concern in die casting is the formation of complex intermetallics that are insoluble at melt-holding temperatures and/or precipitate under holding conditions or during transfer to and injection from the hot or cold chamber. These intermetallics (sludge) affect furnaces, transfer systems, and, by inclusion, the quality of the castings produced. Die casters are familiar with composition limits that prevent sludge formation. A common rule is that iron content plus two times manganese content plus three times chromium content should not exceed the sum of 1.7%. This limit is arbitrary and inexact, it is often assigned values from 1.5 through 1.9%, and it is subject to the specific composition and actual minimum process temperature.

A concern in die casting is the formation of complex intermetallics that are insoluble at melt-holding temperatures and/or precipitate under holding conditions or during transfer to and injection from the hot or cold chamber. These intermetallics (sludge) affect furnaces, transfer systems, and, by inclusion, the quality of the castings produced. Die casters are familiar with composition limits that prevent sludge formation. A common rule is that iron content plus two times manganese content plus three times chromium content should not exceed the sum of 1.7%. This limit is arbitrary and inexact, it is often assigned values from 1.5 through 1.9%, and it is subject to the specific composition and actual minimum process temperature.

Pouring

It is critically important that the metal be drawn and poured according to the best manual or automatic procedures. These procedures avoid excessive turbulence, minimize oxide generation and entrainment, and limit regassing of hydrogen. Frequent skimming of the melt surface from which metal is drawn may be necessary to minimize oxide contamination in the ladle. Siphon ladles that fill from below the melt surface are used for these purposes, but most often, coated and preheated ladles of simple design are employed. The process of repetitive drawing and skimming inevitably degrades melt quality, and this necessitates reprocessing if required melt quality limits are exceeded.

Pouring should take place at the lowest position possible relative to the pouring basin or sprue opening. Once pouring is initiated, the sprue must be continuously filled to minimize aspiration and to maintain the integrity of flow in gates and runners.

Counter-gravity mold filling methods inherently overcome most of the disadvantages of manual pouring. Proprietary casting processes based on low pressure, displacement, or pumping mechanisms might be considered optimum for preserving the processed quality of the melt through mold filling, but some important and relevant considerations apply. Melt processing by fluxing is more difficult in some cases because the crucible or metal source may be confined. If, as in the case of low-pressure casting, the passage for introducing metal into the mold is used repetitively, its inner surface becomes oxide contaminated and a source of casting inclusions. In other counter-gravity casting, mold intrusion into the melt and devices employed to displace or pump metal to the cavity may be the source of turbulence, moisture reactions, and the possibility of hydrogen regassing.

Automated pouring systems are common in the die casting industry. Robotized ladle transfer, as well as metered pumping, may nevertheless incorporate features and reflect provisions to protect molten metal quality through sound drawing, transfer, and pouring techniques. The same techniques have application in die casting operations in which these operations are performed manually.

Hot chamber operation offers apparent metal transfer advantages over cold chamber operation. Recent developments in the use of siphons or vacuum legs to the cold chamber in pressure die casting offer new and interesting opportunities for upgrading the quality of the metal deliverable to the die cavity.

Gating and Risering

It is beyond the scope of this article to discuss comprehensively the subject of gating and risering for the processes employed in the casting of aluminum. In fact, it is in the practices, methods, and designs of gating and risering that individual foundries most differentiate their capabilities. For the most part, the evolution of these systems has been based on experience, and effective and imaginative solutions incorporating refined fluid and solidification dynamics have been developed.

More recently, technical societies and associations have fostered and developed sophisticated techniques for the design of gates, runners, and risers in gravity casting and for the design of gates, runners, injection models, and analytical control schemes for pressure die casting.

There is general agreement on the principles applicable to this highly individualistic and vital phase of metal casting. Ultimately, the challenge to the foundryman is the transfer of metal at the desired quality level to the casting cavity while retaining an acceptable level of metal quality through transfer and ensuring that solidification occurs in such a way that an acceptable level of surface, dimensional, and internal quality is attained. Transfer initiates with drawing and/or pouring, and it concludes with the final compensation of volumetric shrinkage by the riser system.

Gating and Risering Principles. The methods for introducing metal into the casting cavity, for minimizing degradation in metal quality, and for minimizing the occurrence of shrinkage porosity in the solidifying casting differ among the various casting processes, primarily as a function of process limitations. However, the objectives and principles of gating and risering are universally applicable:

- Establish nonturbulent metal flow
- Systematically fill the mold cavity with metal of minimally degraded quality
- In conjunction with the selection of an appropriate pouring temperature, provide conditions for mold filling consistent with misrun avoidance
- Establish thermal gradients within the cavity to promote directional solidification and to enhance riser effectiveness
- Design riser size and geometry, and locate risers and riser inlets to minimize the ratio of gross weight to net weight
- Minimize to the extent possible the vertical distance the metal must travel from the lowest position of metal entry to the base of the sprue
- Taper the sprue or use a sprue geometry other than cylindrical to minimize vortexing and aspiration
- Keep the sprue continuously filled during pouring
- Avoid abrupt changes in the direction of metal flow; gate and runner passages should be streamlined for minimum induced turbulence at angles or points of divergence in the system
- Provide contoured transitions in gate, runner, and infeed cross sections at points of cross-sectional area changes
- Employ multiple gates to improve thermal distribution and to reduce metal velocity at entry points
- Avoid molten metal impingement on mold surfaces or cores by appropriate gate location
- Design runners and gates, if two or more sprues are used, to prevent the turbulence associated with the collision of flow patterns
- Design risers to be of sufficient size and effectiveness to compensate for volumetric shrinkage. Riser position, shape, and filling from the gating system relative to the casting cavity are interrelated and critical considerations. In general, risers should be placed to achieve the maximum pressure differential and, when possible, should be open to the mold surface. Blind or enclosed risers must be adequately vented
- Observe the principles of directional solidification. The use of chills, riser insulation, and casting design changes may be required. The effects of inadequate gating and riser design can in some cases be corrected only by complete redesign
- Provide runner overruns, dross traps, or in-system filtration to avoid the impact of degraded metal on casting quality
- Locate the runners in the drag and locate the gates in the cope for horizontal mold orientation. This rule is subject to intelligent variation by the uniqueness of each part
- Place the riser cavities in the gate path for maximum effectiveness whenever possible
- Never place filters (if used) between riser and cavity
- Design the gates so that metal entry occurs near the lowest surface of the casting cavity
- Geometrically contour the runners to maintain uniform fluid pressure throughout. Formulas applicable to all gravity casting methods have been developed for this purpose
- Consider the ease and economics of trimming operations in gate and riser design

Somewhat different techniques in gating and risering are used for different alloys. In general, riser size and the need for stronger thermal gradients increase with more difficult-to-cast alloys.

Crack sensitivity or hot shortness forces compromises in the steps normally taken to achieve directional solidification. Extensive localized chilling may aggravate crack formation. In these cases, more uniform casting section thickness, larger fillets, more gradual section thickness changes, larger risers and in some cases riser insulation, and more graduated chilling offer the best prospects for success.

In alloys that are more difficult to feed but are relatively insensitive to cracking at elevated temperature, establishing thermal gradients by selective chilling (and heating as in permanent mold casting) usually provides good casting results.

Examples are alloys high in eutectic content, as well as purer compositions, in which the solidification range is limited. In these cases, localized areas of shrinkage are inevitable in the absence of adequate thermal gradients accompanied by effective risering.

Gating of Die Castings. Conventional pressure die casting uses gating principles that are different from those for gravity casting. Although the fundamental principles employed in gravity casting remain desirable, injection under high pressure at significant metal velocity precludes application of many of the rules that govern gravity casting processes.

In pressure die casting, gates and runners are the means by which molten metal is transferred from the shot chamber or injection system to the die impression. The gating system must be designed to permit the attainment of cavity pressurization without reducing cycle time by its own mass and solidification time. It must also be of minimum size to maximize the gross-to-net-weight ratio and to minimize trimming and finishing costs.

The objective of gating in die casting is filling of the die cavity by establishing uninterrupted frontal flow. This requires the prevention of excessive turbulence and mixing within the die cavity, and it minimizes the entrainment of air and volatiles derived from the injection system and from lubricants contained in the die cavity. Runners are usually semiellipsoidal and decrease in cross-sectional area in the direction of metal flow. Their respective cross-sectional areas should exceed corresponding gate dimensions. At no time should gate thickness exceed that of the casting. Gates are normally severely tapered at the entry point(s) to facilitate removal during trimming with minimum risk of damage to the casting.

The greatest progress has been made in research dedicated to die design and the design of metal entry conditions, including sprue, runner, gating, and parameters of injection. Based on carefully analyzed applied research as well as modeling of the die filling sequence, mathematical and instrumented programs are now available to die casters for the development, modification, and control of gating design and operation. Much less sophisticated mathematical relationships and nomographs have been employed for many years to determine the relative dimensions of plunger diameters, runners, gates, and process parameters, including fill rate and velocity, plunger velocity, gate velocity, and system pressures.

Die Casting Compositions

The most important compositions in use for pressure die casting are the highly castable and forgiving alloys of the aluminum-silicon family. Of these, Alloy 380 and its variations predominate.

Magnesium content is usually controlled at low levels to minimize oxidation and the generation of oxides in the casting process. Nevertheless, alloys containing appreciable magnesium concentrations are routinely produced.

Iron content of 0.7% or greater is preferred in most die casting operations to maximize elevated-temperature strength, to facilitate ejection, and to minimize soldering to the die face. Improved ductility through reduced iron content has been an incentive resulting in widespread efforts to develop a tolerance for iron as low as approximately 0.25%. These efforts focus on process refinements and improved die lubrication. Hypereutectic aluminum-silicon alloys are growing in importance as their valuable characteristics and excellent die casting properties are exploited in automotive and other applications.

Foundry Practices for Specialty Castings

Rotor Castings. Most squirrel cage induction-type electric motors employ an integrally cast aluminum rotor. There are many economic and manufacturing process advantages that constitute an improvement of this type of rotor construction over wire-wound assemblies. The rotors produced by the casting process range in diameter from 25 to approximately 760 mm (1 to 30 in.).

Several casting processes are used to produce cast aluminum rotors. The principal processes used are vertical and horizontal cold chamber die casting and, to a lesser extent, centrifugal and permanent mold casting.

Aluminum alloys display a wide range of electrical characteristics, and the choice of a specific alloy for a cast motor rotor depends on the specified operating characteristics of the motor. Standardized alloys of high, intermediate, and low conductivity have been developed for this industry.

Conductivity. Most cast aluminum motor rotors produced are in carefully controlled, more pure compositions 100.0, 150.0, and 170.0 (99.0, 99.5, and 99.7% Al, respectively). Impurities in these alloys are controlled to minimize variations in electrical performance based on conductivity and to minimize the occurrence of microshrinkage and cracks during casting.

Rotor alloy 100.0 contains a significantly larger amount of iron and other impurities, and this generally improves castability. With higher iron content, crack resistance is improved, and a lower tendency toward shrinkage formation will be observed. This alloy is recommended when the maximum dimension of the part is greater than 127 mm (5 in.). For the same reasons, Alloy 150.0 is preferred over 170.0 in casting performance.

Minimum and typical conductivities for each rotor alloy grade are:

Alloy	Minimum conductivity, % IACS	Typical conductivity, % IACS
100.1	54	56
150.1	57	59
170.1	59	60

IACS, International Copper Annealed Standard

For motor rotors requiring high resistivity--for example, motors with high starting torque--more highly alloyed die casting compositions are commonly used. The most popular are Alloys 443.2 and A380.2. By choosing alloys such as these, conductivities from 25 to 35% IACS can be obtained; in fact, highly experimental alloys with even higher resistivities have been developed for motor rotor applications.

Although gross casting defects may adversely influence electrical performance, the conductivity of alloys employed in rotor manufacture is more exclusively controlled by composition. Table 2 lists the effects of various elements in and out of solution on the resistivity of aluminum. Simple calculation using these values accurately predicts total resistivity and its reciprocal conductivity for any composition. A more general and easy-to-use formula for conductivity calculation that offers sufficient accuracy for most purposes is:

$$\text{Conductivity} = 63.50 - 6.9x - 83y$$

where electrical conductivity is in percent IACS, x = iron + silicon (in weight percent), and y = titanium + vanadium + manganese + chromium (in weight percent).

Table 2 Effect of elements in and out of solution on the electrical resistivity of aluminum

Element	Maximum solubility in aluminum, %	Average increase in resistivity per weight percent, μΩ· cm[(a)]	
		In solution	Out of solution[(b)]
Chromium	0.77	4.00	0.18

Copper	5.65	0.344	0.030
Iron	0.052	2.56	0.058
Lithium	4.0	3.31	0.68
Magnesium	14.9	0.54[(c)]	0.22[(c)]
Manganese	1.82	2.94	0.34
Nickel	0.05	0.81	0.061
Silicon	1.65	0.65	0.059
Titanium	1.0	2.88	0.12
Vanadium	0.5	3.58	0.28
Zinc	82.8	0.094[(d)]	0.023[(d)]
Zirconium	0.28	1.74	0.044

Source: Ref 4

(a) Add indicated increase to the base resistivity for high-purity aluminum (2.65 μΩ· cm at 20 °C, or 68 °F, or 2.71 μΩ· cm at 25 °C, or 77 °F).

(b) Limited to about twice the concentration given for the maximum solid solubility, except as noted.

(c) Limited to approximately 10%.

(d) Limited to approximately 20%.

Reference to specified composition limits for rotor alloys shows the use of composition controls that reflect electrical considerations. The peritectic elements are limited because their presence is harmful to electrical conductivity. Prealloyed ingot produced to these specifications is produced by boron addition, which complexes and precipitates these elements before casting. In addition, iron and silicon contents are subject to control by ratio with the objective of promoting the α Al-Fe-Si phase intermetallics least harmful to castability. Ignoring these important relationships results in variable electrical performance and, of equal importance, variable casting results.

As in all casting operations, but especially in die casting, establishment of reproducible casting conditions depends heavily on the rhythm of the process itself. Variable chemical composition--for example, when unfurnaced and untreated primary aluminum grades are used for cost advantage over rotor alloys--will always introduce a degree of unpredictable casting results that will adversely effect both process and product performance. In contrast, the use of rotor alloys ensures optimum casting and controlled product results.

Casting Processes. The horizontal cold chamber die casting method is recommended and is the most widely used for the high-volume production of fractional-horse-power motor rotors. Multiple-cavity dies are usually employed to cast several rotors of the same or different design simultaneously.

The vertical pressure die casting method has been successfully used for many years to cast both fractional and integral horse-power units. In this process, the lower press platen contains a sump or depression into which molten metal is automatically or manually poured. The sump is typically lined with a refractory material, such as fiberfrax paper, mica, or other insulating paper. Sprayed refractory coatings can also be used to insulate and to protect the basin from attack. The mold and indexed mounting for the laminate stack are located in the upper platen. Molten metal is forced into the die through a network of small gates separating the lower and upper platens. These gates are normally tapered in the direction of metal flow through the base plate and into the collector ring of the part.

For either horizontal or vertical casting processes, preheating of the laminate pack is recommended, but in practice preheating is rarely performed. The preheat temperature for the laminate assembly is from 205 to 540 °C (400 to 1000 °F). When preheating is not performed, individual ferrous laminations must be free of surface contamination, especially oil and moisture. Preheating also oxidizes the laminate and its sheared outer surface to inhibit metallurgical bonding during the casting process. A post-casting thermal treatment of heating to a temperature in excess of 260 °C (500 °F) will effectively shear the brittle intermetallics formed when bonding does occur. Advantages are attributed to more severe postcasting thermal treatment to ensure bond separation and to oxidize the interface surfaces. Annealing at 425 to 510 °C (800 to 950 °F) followed by still air cooling is conventional, with cooling practices dictated by the electrical advantages of rejecting solute phases from solid solution.

The foundryman should be certain that the laminations are clean and free of excessive burrs that might result in current leakage. The preheating of poorly sheared laminate disks at higher temperature is recommended.

Good die venting is essential in rotor casting. Failure to provide and to maintain vents will always result in excessive end ring porosity and unsoundness in the conductor bars. Another defect encountered in rotor casting that is related to venting is backfilled conductor bars. This condition is induced by preferential flow in one region of the cavity and simultaneous molten metal entry to a single bar from both end rings. Accurate laminate assembly and placement in the mold cavity, clean laminates, minimum die lubrication, effective gate design, and adequate die venting are essential in the production of quality rotors.

Gating scrap is often directly recharged to the furnace in rotor casting. This results in the potentially heavy oxide contamination in the metal source that is a major cause of casting defects.

The most common defects, apart from misruns or nonfills, are broken bars resulting from different rates of thermal contraction between the core and the conductor bars and from massive oxide inclusions, which significantly influence flowability and casting recovery and obstruct current flow in the conductor bars. The direct recharging of scrap may include the inadvertent or intentional addition of iron, particularly in the form of steel laminates readily available to operators for the purposes of improving casting results at the expense of electrical characteristics.

The direct recharging of scrap also influences temperature control with obvious harmful effects on process variability. For best results, a temperature control range of ±10 °C (±18 °F) is recommended.

Premium engineered castings provide higher levels of quality and reliability than are found in conventionally produced parts. These castings may display optimum performance in one or more of the following characteristics: mechanical properties (determined by test coupons machined from representative parts), soundness (determined radiographically), dimensional accuracy, and finish. However, castings of this classification are notable primarily for mechanical property attainment that reflects extreme soundness, fine dendrite arm spacing, and well-refined grain structure. These technical objectives require the use of chemical compositions competent to display premium engineering properties. Alloys considered to be premium engineered compositions appear in separately negotiated specifications or in specifications such as military specification MIL-A-21180, which is extensively used in the United States for premium engineered casting procurement.

Alloys commonly considered premium by definition and specification are 201.0, C355.0, A206.0, A356.0, 224.0, A357.0, 249.0, 358.0, and 354.0. All alloys employed in premium engineered casting work are characterized by optimum concentrations of hardening elements, and restrictively controlled impurities. Although any alloy can be produced in cast form with properties and soundness conforming to a general description of premium values relative to corresponding

commercial limits, only those alloys demonstrating yield strength, tensile strength, and especially elongation in a premium range belong in this discussion. They fall into two categories: high-strength aluminum-silicon compositions and those alloys of the 2*xx* series, which, by restricting impurity element concentrations, provide outstanding ductility, toughness, and tensile properties with notably poorer castability.

In all premium casting alloys, impurities are strictly limited for the purposes of improving ductility. In aluminum-silicon alloys, this translates to control of iron at or below ~0.010% with measurable advantages in further reductions to the range of 0.03 to 0.05%, the practical limit of commercial smelting capability.

Beryllium is present in A357.0 and 358.0 alloys not to inhibit oxidation (although that is a corollary benefit) but to alter the form of the insoluble phase to a more nodular form least detrimental to ductility. Beryllium also alters the chemistry of the insoluble phase to exclude magnesium, which then becomes fully available for hardening purposes. Magnesium is normally controlled in the upper specification range to maximize Mg_2Si formation for strength development at some loss in ductility.

The presence of iron and silicon in alloys such as 295.0 contributes to reasonably good castability. For the development of premium properties in the 2*xx* family of alloys, these impurities are severely restricted. As a result of these composition restrictions, all premium engineered casting alloys of the 2*xx* type can be characterized as extremely sensitive to crack formation. They are also highly susceptible to shrinkage, requiring unusual foundry expertise in gating and risering. Design engineers and the producing foundry usually must collaborate to develop configurations offering maximum compatibility with casting requirements. The development of hot isostatic pressing for aluminum alloys is pertinent to the broad range of premium castings, but is especially relevant for the more difficult-to-cast aluminum-copper series (see the article "Hot Isostatic Pressing of Castings" in this Volume).

Table 3 defines mechanical property limits normally applied to premium engineered castings. It must be emphasized that the negotiation of limits for specific parts is usual practice, with higher as well as lower specific limits based on part design criteria and foundry capabilities.

(a) Values from specification MIL-A-21180.

(b) This class is obtainable in favorable casting configurations and must be negotiated with the foundry for the particular configuration desired.

Melt Preparation. Metal treatment is performed for this class of casting to achieve the highest possible quality. Reactive gas fluxing to hydrogen levels lower than 0.10 mL/100 g and effective removal of oxides and other nonmetallics by active gas fluxing and/or filtration are essential in meeting specified soundness levels and mechanical property limits.

Extreme care is also exercised in all phases of metal handling and pouring to preserve metal quality. Proprietary pouring methods have been developed for this purpose, including mechanical pumping, displacement, and nonturbulent transfer from metal source to the casting cavity.

Casting Processes. Molds are usually dry sand and other materials comprising composite mold construction, such as plaster and metallic sections. Elaborate planning and control of solidification through mold design and controlled chilling are normal.

Many premium engineered castings are produced by other gravity casting processes, notably, permanent mold and plaster molding. In every case, however, the same exacting approach is necessary for control of solidification to achieve the structures and soundness needed to furnish castings within specification.

Dimensional Control. Dimensional variations depend on part size, complexity, and alloy, but the use of highly accurate mold and core patterns and the dimensional control of molding media provide for extreme dimensional accuracy. Tolerances applicable to typical casting dimensions can be specified at ±0.254 mm (±0.010 in.), and in special cases, tolerances as small as ±0.127 mm (±0.005 in.) may apply. Even the inspection methods used in these cases represent an unusual capability on the part of premium engineered casting foundries. Datum plane measuring concepts are required that are agreed upon by both customer and vendor. The datum plane system is a cost-effective means of establishing dimensions, and it is highly adaptable to automated coordinate measurement.

Another advantage of premium engineered castings is the attainment of structural integrity in thin walls. This ranges from 1.52 to 2.03 mm (0.060 to 0.080 in.) for large plane areas and is as low as 0.51 to 0.76 mm (0.020 to 0.030 in.) for more limited casting sections.

Casting surface finish is always a function of mold surface and characteristics. The selection of mold materials and the accuracy of mold finish maintained in premium casting operations ensure that specified requirements are met.

Heat Treatment

The metallurgy of aluminum and its alloys fortunately offers a wide range of opportunities for employing thermal treatment practices to obtain desirable combinations of mechanical and physical properties. Through alloying and temper selection, it is possible to achieve an impressive array of features that are largely responsible for the current use of aluminum alloy castings in virtually every field of application. Although the term heat treatment is often used to describe the procedures required to achieve maximum strength in any suitable composition through the sequence of solution heat treatment, quenching, and precipitation hardening, in its broadest meaning, heat treatment comprises all thermal practices intended to modify the metallurgical structure of products in such a way that physical and mechanical characteristics are controllably altered to meet specific engineering criteria. In all cases, one or more of the following objectives form the basis for temper selection:

- Increase hardness for improved machinability
- Increase strength and/or produce the mechanical properties associated with a particular material condition
- Stabilize mechanical and physical properties
- Ensure dimensional stability as a function of time under service conditions
- Relieve residual stresses induced by casting, quenching, machining, welding, or other operations

To achieve any of these objectives, parts can be annealed, solution heat treated, quenched, precipitation hardened, overaged, or treated with combinations of these practices. In some simple shapes (for example, bearings), thermal treatment can also include plastic deformation in the form of cold work.

Temper Designations and Practices

The Aluminum Association has standardized the definitions and nomenclature applicable to thermal practice and maintains a registry of standard heat treatment practices and designations for industry use. Standardized temper designations applicable to castings are:

- O (formerly T2, T2*x*): annealed (thermally stress relieved)
- T4: solution heat treated and quenched
- T5: artificially aged
- T6: solution heat treated, quenched, and artificially aged
- T7: solution heat treated, quenched, and overaged
- T8: cold reduced before aging to improve compressive yield strength (bearings only)

Variations in thermal treatment practice are shown as the second and third digits in the standard designations; for example, T61, T62, T572, and so on. There is no consistent convention for the assignment of temper designation variations except that for solution heat treated alloys general practice has been to assign tempers T6, T61, and T62 to an ascending order in strength development up to full hardness. Recommended thermal treatment practices for aluminum casting alloys are listed in Table 4.

(a) S, sand; P, permanent mold.

(b) Unless otherwise indicated, solution treating is followed by quenching in water at 65-100 °C (150-212 °F).

(c) Except where ranges are given, listed temperatures are ±6 °C or ±10 °F.

(d) Stress relieve for dimensional stability as follows: hold 5 h at 413 ± 14 °C (775 ± 25 °F); furnace cool to 345 °C (650 °F) over a period of 2 h or more; furnace cool to 230 °C (450 °F) over a period of not more than $\frac{1}{2}$ h; furnace cool to 120 °C (250 °F) over a period of approximately 2 h; cool to room temperature in still air outside the furnace.

(e) No quench required; cool in still air outside furnace.

(f) Air-blast quench from solution-treating temperature.

(g) Casting process varies (sand, permanent mold, or composite) depending on desired mechanical properties.

(h) Solution heat treat as indicated, then artificially age by heating uniformly at the temperature and for the time necessary to develop the desired mechanical properties.

(i) Quench in water at 65-100 °C (150-212 °F) for 10-20 s only.

(j) Cool to room temperature in still air outside furnace.

Principles of Heat Treatment

The heat treatment of aluminum alloys is based on the varying solubilities of metallurgical phases in a crystallographically isotropic system. Because the solubility of the eutectic increases with increasing temperature to the solidus, as in the binary eutectic system shown in Fig. 10, the variations in degree of solution and the formation and distribution of precipitated phases can be used to influence material properties.

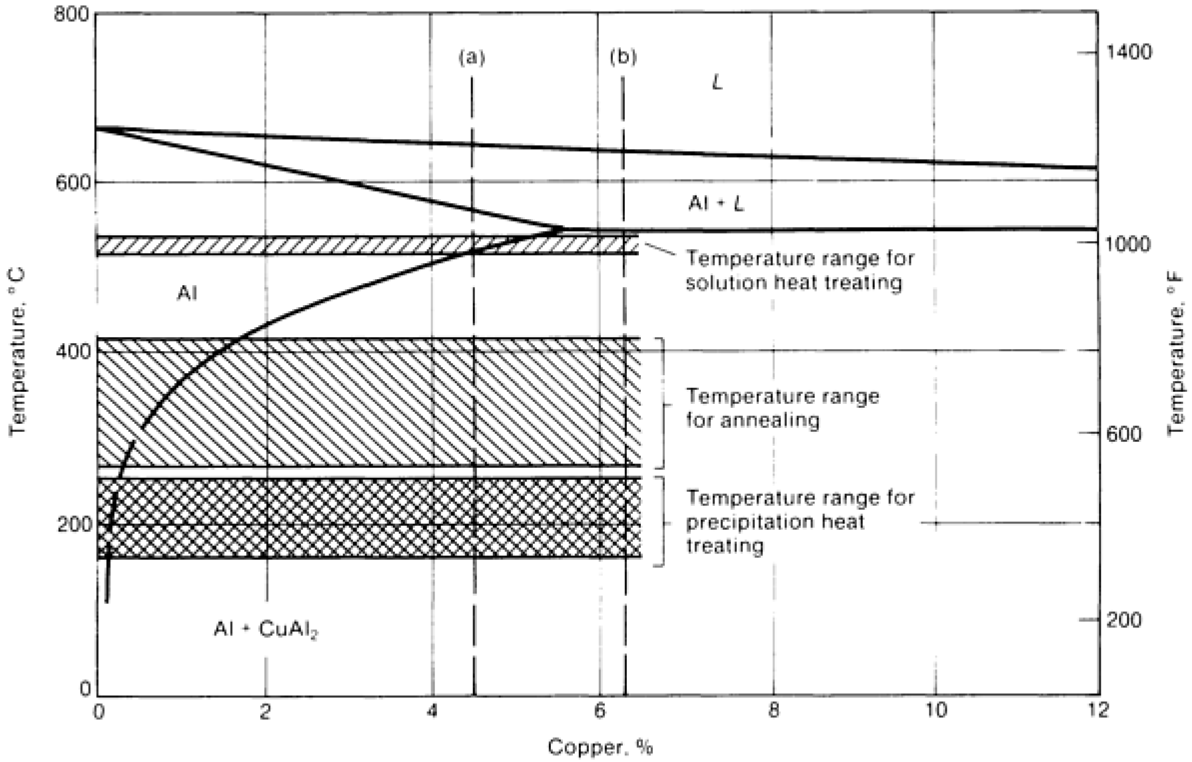

Fig. 10 Portion of aluminum-copper binary phase diagram. Temperature ranges for annealing, precipitation heat treating, and solution heat treating are indicated.

In addition to the phase and morphology changes associated with soluble elements and compounds, other (sometimes desirable) effects accompany elevated-temperature treatment. The microsegregation characteristic of all cast structures is minimized or eliminated. The residual stresses caused by solidification or by prior quenching are reduced, insoluble phases may be physically altered, and susceptibility to corrosion, especially in certain compositions, may be affected.

Solution Heat Treatment. Exposure to temperatures corresponding to maximum safe limits relative to the lowest melting temperature for a specific composition results in the dissolution of soluble phases formed during and after casting solidification. The rate of heating to solution temperature is technically unimportant in casting compositions except when more than one soluble phase is present, as in the Al-Si-Cu-Mg and Al-Zn-Cu-Mg systems. In these cases, stepped heat treatment is sometimes essential to avoid the melting of lower-melting phases. Very rapid heating can result in nonequilibrium melting in highly segregated structures, but the conditions required for such occurrences are most unlikely in engineered castings.

In all cases, the most complete degree of solution is desirable for subsequent hardening, and a number of factors are involved. Different casting processes and foundry practices result in microstructural differences with relevance to heat treatment practice. The coarser microstructures associated with slow solidification rate processes require a longer solution heat treatment exposure. The time required at temperature to achieve solution is progressively shorter for investment, sand, and permanent mold castings, but thin-wall sand castings produced with extensive use of chills can often display finer microstructures than heavy-section permanent mold parts produced in such a way that process advantages are not exploited. For these reasons, solution heat treatment practices can be optimized for any specific part to achieve solution with the shortest reasonable cycle once production practice is finalized, even though most foundries and heat treaters will standardize a practice with a large margin of safety.

Because the slope of the characteristic solvus illustrated in Fig. 10 changes as temperature approaches the eutectic melting point, it is apparent that temperature is critical in determining the degree of solution that can be attained. In addition, temperature affects diffusion rates, and this directly influences the degree of solution as a function of time at temperature. Within the temperature ranges defined for solution heat treatment by applicable specifications lies a significant corresponding range of solution values.

The knowledgeable heat treater/foundry seeking to obtain superior properties based on solution heat treatment will bias temperature selection within specification limits to obtain the highest degree of solution. Superior furnaces, thermocouples, and furnace controls, representing the state-of-the-art, along with recognition of the normal resistance of cast structures to melting based on diffusion considerations, offer the potential of superior property development compared to historically more conservative temperature selection. However, although temperatures just below the eutectic melting point are desirable for optimum property development, it is critical that eutectic melting resulting in brittle intergranular eutectic networks be avoided.

Insoluble phases, including those containing impurity elements, are normally thought to be unaffected by solution heat treatment, but limited changes do occur. The surfaces of primary and eutectic silicon particles are characteristically rounded during solution heat treatment. The solution heat treatment of Alloy A444, which contains no soluble phase, is justified solely by this phenomenon and its effect on ductility. Limited solubility also results in similar boundary physical changes in other insoluble intermetallics.

Quenching. This discussion separates quenching as a distinct step in thermal practice leading to the metastable solution heat treated (T4) condition. Specific parameters can be associated with the heating of parts to achieve solution, and separate parameters apply to the steps required to achieve the highest postquench degree of retained solution. Rapid cooling from solution temperature to room temperature is essential, and it is possible to describe quenching as the most difficult and often least controlled step in thermal treatment.

For optimum results, quench delay must be minimized. Although specifications often define quench delay limits, in practice, the shortest possible delay is observed. This may require specialized equipment, such as bottom-drop or continuous furnaces. Excessive delays result in temperature drop and the rapid formation of coarse precipitate in a temperature range in which the effects of precipitation are lost for hardening purposes. Even though castings are characteristically more tolerant of quench delay than wrought products based on structure and diffusion, excessive quench delays result in less than optimum strengthening potential.

Water is the quench medium of choice for aluminum alloys, and its temperature has a major effect on results. Most commercial quenching is accomplished in water near the boiling point, but room temperature, 65 °C (150 °F), and 80 °C (180 °F) have also become common standardized alternatives. Because higher potential strength is generally thought to be associated with the most rapid quenching and because corrosion and stress corrosion performance are usually enhanced by rapid quenching, it would appear that room-temperature water should routinely be employed. However, the selection of quench temperature becomes less obvious when the objective of quenching is to retain the highest possible degree of solution with the least warpage or distortion and the lowest level of induced residual stresses consistent with commercial or specified requirements.

The key to the compromise between goals involving property development and the physical consequences of quenching is uniformity of heat extraction, which is in turn a complex function of the operable heat extraction mechanism. Nucleate, vapor film, and convective boiling occur with dramatically different heat extraction rates at different intervals. Differences in section thickness, load density, positioning, and casting geometry also influence the results. As section thicknesses increase, the metallurgical advantages of quench rates obtained with water temperatures less than 65 °C (150 °F) diminish, but the cooling rate advantage of the 65 versus the 100 °C (150 versus 212 °F) quench temperature is retained independently of section thickness. In addition to developing racking and loading methods that space and orient parts for the most uniform quenching, quenchant additions can be made for the following purposes:

- To promote stable vapor film boiling by the deposition of compounds on the surface of parts as they are submerged in the quench solution
- To suppress variations in heat flux by increasing vapor film boiling stability through chemically decreased quench solution surface tension
- To moderate quench rate for a given water temperature

Quenching rates are also affected by the surface condition of the parts. More rapid quenching occurs with oxidized, stained, and rough surfaces, while bright, freshly machined, and etched surfaces quench more slowly.

The common use of water as a quenching medium is largely based on its superiority in terms of quenching characteristics relative to other materials. Nevertheless, quenching has been accomplished in oil, salt baths, and organic solutions. For

many compositions, fan or mist quenching is feasible as a means of obtaining dramatic reductions in residual stress levels with considerable sacrifices in hardening potential.

Precipitation Heat Treating/Aging. In general, parts that have been solution heat treated and quenched display tensile properties and elongation superior to those of the as-cast (F) condition. However, the T4 condition is rarely employed. Instead, the advantages of aging or precipitation hardening are obtained by thermal treatment following quenching. Among these advantages are increased strength and hardness with a corresponding loss in ductility, improved machinability, the development of more stable mechanical properties, and reduced residual stresses. It is through precipitation treatment that cast aluminum products may be most powerfully differentiated.

Most aluminum alloys age harden naturally to some extent after quenching; that is, properties change as a function of time at room temperature solely as a result of zone formation within the solid solution. The extent of change is highly alloy dependent. For example, room-temperature aging in alloys such as A356 and C355 occurs within 48 h, with insignificant changes taking place thereafter. Alloy 520, normally used in the T4 condition, age hardens over a period of years, and a number of aluminum-zinc-magnesium alloys that are used without heat treatment exhibit rapid changes in properties over 3 or 4 weeks and harden at progressively reduced rates thereafter.

The process of hardening is accelerated by artificial aging at temperatures ranging from approximately 95 to 260 °C (200 to 500 °F), depending on the alloy and the properties desired. In artificial aging, supersaturation, which characterized the room-temperature solution condition, is relieved by the precipitation of solute, which proceeds in stages with specific structural effects.

At low aging temperatures or during transition at higher temperatures, the principal change is the diffusion of solute atoms to high-energy sites within the lattice, producing distortion of the lattice planes and forming concentrations of subcritical crystal nuclei. With continued exposure to aging temperature, these sites reach or fail to reach critical nucleation size, a stage leading to the formation of discrete particles displaying the identifiable crystallographic character of the precipitated phase. These transitional phase particles grow with an increase in coherency strains until, with sufficient time and temperature, interfacial bond strength is exceeded.

Coherence is lost and with it the strengthening effects associated with precipitate formation and growth. Continued growth of the now equilibrium phase occurs without strength benefit, corresponding to the overaged condition.

The practice to be employed in artificial aging depends entirely on the desired level of property development. Aging curves have been developed to facilitate process selection. The results of a large number of aging curve studies are reflected in specification recommendations and industry references. The heat treater can reasonably predict the results of aging by reference to these curves. It should be noted that longer times at lower aging temperatures generally result in higher peak strength values. The behavior of aging response or rate of property change as a function of time at peak strength points is also of interest. The flatter curves associated with lower aging temperatures allow greater tolerance in the effects of time-temperature variations. Unlike solution heat treatment, the time required to reach the aging temperature may be significant, but is seldom included in age cycle control. The energy imparted during heating to the precipitation-hardening temperature can be integrated into the control sequence to control results more accurately with minimum cycle time.

The overaged T7 condition is less common than the T6 temper, but there are good reasons for its use. Precipitation hardening as practiced for the T6 condition results in reductions in residual stress levels imposed by quenching of 10 to 35%. By definition, overaging consists of carrying the aging cycle to a point beyond peak hardness, but it is most often conducted at higher temperatures than those used for the fully hardened condition. A substantial further decrease in residual stresses is associated with the higher-temperature aging treatment. Furthermore, parts become more dimensionally stable as a result of more complete degrowthing, and increased stability in properties and performance is ensured when service involves exposure at elevated temperatures.

Annealing was originally assigned the designation T2, but is now known as the O temper. It is rarely employed, but is useful in providing parts with extreme dimensional and physical stability and the lowest practical level of residual stresses. The annealed condition is also characterized by extremely low strength and a correspondingly poor level of machinability. Typical annealing practices are for relatively short (2 to 4 h) exposures at a minimum temperature of 345 °C (650 °F). Higher-temperature practices are employed for more complete relaxation of residual stresses. The cooling rate from annealing temperatures must be controlled such that residual stresses are not reinduced and resolution effects are avoided.

Heat Treating Problems. Under optimum conditions, the measurable results of thermal practices may be other than those anticipated. When specification limits are not met, analytical procedures and judgments are applied to establish a corrective course of action based on evidence or assumptions concerning the cause of failure.

Mechanical property limits statistically define normalcy for a given composition heat treated by specific practices. Chemical composition is a major variable in mechanical property development, and when mechanical properties have failed specification limits, chemistry is the logical starting point for investigation.

The role of trace elements in mechanical property development is important because these elements are often not separately specified in alloy specifications except as others each and others total. Sodium and calcium are embrittling in 5*xx* alloys. Low-melting elements such as lead, tin, and bismuth may under some conditions form embrittling intergranular networks with similar effects. Insoluble impurity elements are generally responsible for decreases in elongation.

Low concentrations of soluble elements in heat-treatable compositions naturally result in the more frequent distribution of mechanical property values in the lower specification range. Element relationships such as copper-magnesium, silicon-magnesium, iron-silicon, iron-manganese, and zinc-copper-magnesium are also important considerations in defining the causes of abnormal mechanical property response to thermal treatment.

A second important consideration is that of casting soundness. Unsound castings will not consistently meet specified mechanical property or other limits sensitive to structural integrity. All defects adversely affect strength and elongation. Shrinkage, hydrogen porosity, cracks, inclusions, and other casting-related defects influence mechanical properties adversely, and their effects should be considered before addressing the possibility of heat treatment problems.

The quality of solution heat treatment can be assessed in several ways. There is, of course, the rounding effect on insoluble phases, which serves as evidence of elevated-temperature exposure. The elimination of coring in many alloys is another indication of elevated-temperature treatment. The effective solution of soluble phases can be determined microscopically. Undissolved solute can be distinguished from the appearance of precipitate that forms at high temperatures and results from quench delay or an inadequate or incomplete quench. There is also a tendency for the precipitates formed as a result of quench delay or inadequate quench to concentrate at grain boundaries as opposed to more normal distribution through the microstructure for properly solution heat treated and aged material.

Although the overaged condition is microscopically apparent, underaging is difficult to assess because of the submicroscopic nature of transitional precipitation. Evidence of acceptable aging practice is best obtained from aging furnace records, which might indicate errors in the age cycle. Underaging can be corrected by additional aging, but for all other heat treatment aberrations except those associated with objectionable conditions such as high-temperature oxidation or eutectic melting, re-solution heat treatment is an acceptable corrective action despite many myths to the contrary. Eutectic melting occurs when the eutectic melting temperature is exceeded, resulting in the characteristic rosettes of resolidified eutectic and/or intergranular eutectic.

High-temperature oxidation is a misnamed condition of hydrogen diffusion that affects surface layers during elevated-temperature treatment. This condition can result from moisture contamination in the furnace atmosphere and is sometimes aggravated by sulfur (as in heat treatment furnaces also used for magnesium alloy castings) or other furnace refractory contamination.

There are no technical reasons for discouraging even repeated heat treatments to obtain acceptable mechanical properties. In the case of aluminum-copper alloys, it is essential that re-solution heat treatment be conducted at a temperature equivalent to or higher than the original practice to ensure effective re-solution. However, when the results of repeated heat treatment prove unsatisfactory, it should be apparent that other conditions are responsible for mechanical property failure.

Metallurgical structure also plays a role in property development. Modification of the eutectic is effective in improving elongation in hypoeutectic aluminum-silicon alloys and has little effect on tensile and yield strengths. Refinement of the primary phase in hypoeutectic silicon alloys is even more important in reducing brittle behavior.

Fine grain size promotes improved mechanical properties, while coarse grain size, by emphasizing grain-boundary effects, results in lower mechanical property performance. Cell size has been recognized as highly significant in improving ductility for given strength levels.

Quality Control

The most effective method of determining the combined consequences of chemistry, material condition, and heat treatment is the determination of tensile strength, yield strength, and elongation. This is often done by testing separate cast tensile specimens. These values most conclusively indicate the acceptability of a product relative to specification requirements. Hardness can be established as an acceptance criterion through negotiation, but it is less adequate in aluminum alloys than in other metal systems for control purposes. Hardness in aluminum corresponds only approximately to yield strength, and although hardness can be viewed as an easily measurable indicator of material condition, it is not normally accurate enough to serve as a guaranteed limit. Electrical conductivity only approximates material condition in cast or cast and heat treated structures, and it remains excessively variable for most control purposes.

Stability

Because thermal treatment affects the stability of mechanical properties and directly influences residual stress levels, additional discussion of these two considerations is warranted.

Stability is defined as the condition of unchanging structural and physical characteristics as a function of time under specific conditions of application. As previously mentioned, the metastable T4 condition is subject to hardening (extensive in some alloys and limited in others) at room and higher temperatures. Under service conditions involving temperatures greater than room temperature, significant physical and mechanical changes are to be expected.

Although these changes may be acceptable for a given application, changes in susceptibility to corrosion and stress corrosion, which can be associated with transitional states in some alloy systems, must be carefully considered.

The most stable conditions obtainable are associated with the (in order of decreasing stability) annealed, overaged, and as-cast conditions. Underaged and solution heat treated parts are least stable.

Residual stresses are caused by differing rates of cooling, especially postsolidification cooling, quenching from solution heat treatment temperature, and drastic changes in temperature at any intermediate step. Residual stress development depends on the differential rate of cooling, section thickness, and material strength. Stresses imposed by quenching from the solution heat treatment temperature are much more important than casting stresses or stresses normally obtained in conventional processing. Decreasing the severity of the quench from solution heat treatment results in a lower level of residual stresses but with correspondingly decreased material strength. Air quenching may provide a useful compromise in applications requiring unusual dimensional stability.

Residual stresses can also be relaxed by exposure to elevated temperature followed by slow cooling, or by plastic deformation. Plastic deformation that is routinely practiced for stress relief in wrought products has little application in the complex designs of engineered products such as castings; therefore, stress relief becomes more exclusively a function of postquench thermal treatment. Overaging results in significant reductions in residual stresses, and annealing provides a practical minimum in residual stress levels.

Natural Versus Artificial Property Development

When foundrymen work closely with design engineers, alloys and tempers can be selected that are capable of meeting both the manufacturing objectives of the foundry and the engineering criteria at the lowest possible cost. A frequent point of discussion is whether a superior selection might be a naturally hardening alloy (a composition that hardens naturally at room temperature after casting) or an alloy requiring heat treatment for mechanical property development. Unfortunately, room temperature hardening alloys, which offer a wide range of attractive properties, are also characterized by relatively inferior casting characteristics so that final material selection may become an issue of foundry versus application considerations. The selection of a heat-treatable composition with good casting characteristics in combination with effective heat treatment often offers significant advantages in cost, performance, uniformity, and reliability.

Cleaning

Alkaline and acid solutions are used to clean aluminum. Alkaline solutions are formulated in various degrees of etching activity ranging from nonetching silicates and borates to trisodium phosphate and highly aggressive sodium hydroxide. Acid cleaners are frequently based on phosphoric and sulfuric acids, often with appropriate detergents to emulsify contaminants.

Oxides are removed prior to other operations by using so-called deoxidizers. These are usually acid solutions containing phosphates, sulfates, and fluorides, often in conjunction with an oxidizing agent.

Chemical Finishing. Chemical treatments are applied to aluminum to remove surface contamination, staining, and oxides; to develop specular and matte appearances; to remove metal selectively as in chemical milling; and to develop various types of decorative or protective conversion coatings. Although sometimes used as the final finish, chemical treatments are widely used to prepare aluminum for other finishing operations, such as anodizing, electroplating, painting, and adhesive bonding.

Specular and Matte Appearances. Concentrated phosphoric-nitric acid solutions at 90 °C (195 °F) or, occasionally, nitric-fluoride solutions at lower temperatures are used on relatively pure metal to develop specularity. A matte surface is obtained by etching the aluminum with sodium hydroxide and then removing the etching smut with an oxidizing acid solution. High-silicon alloys are treated most effectively in a concentrated nitric-hydrofluoric acid solution.

Chemical milling and selective etching are conducted with both alkaline and acid solutions. Hot 15% sodium hydroxide solutions are generally used for chemical milling, with a removal rate of about 0.025 mm (0.001 in.) per minute. Pattern etching and engraving are often performed in ferric chloride or in acid fluoride solutions.

Chemical conversion coatings are formed when a portion of the aluminum surface is dissolved and a reaction film is formed. Examples of such films are aluminum oxide, chromic phosphate, and chromium aluminum chromate. Although there are various applications, the most important use for conversion coatings has been as a preparation for organic finishes. The clean, uniform, and inert coating provides good adhesion for the organic film and protects against undermining corrosion.

Welding

Foundry welding is employed to salvage scrap castings primarily by correcting surface and dimensional defects or irregularities. The inert gas shielded arc welding processes are normally utilized, rather than the processes using flux mixtures or flux-coated filler rods. The welding techniques used for castings are similar to those for wrought products. However, special consideration must be given to the thicker-surface aluminum oxide film and the void content of castings. The quality of weldments is closely related to the soundness of the casting in the weld area. The quality of conventional welds is generally very poor in castings displaying hydrogen porosity and in most die castings.

Welding Method. Casting flaws or areas requiring correction are usually small; therefore, the gas tungsten arc welding (GTAW) process is normally used. The gas metal arc welding process can be used if economics and operating conditions indicate that satisfactory results can be achieved.

Equipment for the GTAW Process. Alternating current welding transformers that deliver a balanced wave and incorporate high-frequency stabilization minimize the production of tungsten inclusions and produce the highest-quality welds. In general, the ac-dc and unbalanced wave types of power supply tend to spit tungsten. Tungsten inclusions in a weld are considered as detrimental as other casting defects of similar dimension.

Pure tungsten is preferred for facilitating a stable arc and minimizing tungsten spitting. The second choice is zirconiated tungsten.

Shielding Gas. Argon and mixtures of argon and helium gases are used to gas tungsten arc weld aluminum castings. When a gas mixture is used, helium usually constitutes 25 to 50% of the total mixture. The helium helps produce a hotter arc at a particular current setting, clean up the weld puddle if casting quality is a problem, and reduce the size of gas porosity voids in the weld. A y-tube connector can be used to blend the appropriate volumes of gases directly from the individual gas bottles and flowraters rather than maintaining a supply of a variety of premixed gas ratios.

Preparation for Welding. Flaws should be removed by pneumatic chipping or hand tool milling. This operation should be performed without the use of a lubricant, if possible. The leading edge of the chipping tool should be u-shaped rather than v-shaped to facilitate welding. The milling or deburring tool should have a coarse cutting bit to prevent it from becoming loaded with aluminum.

Cavity Preparation. The cavity that is to be repaired should be smooth, that is, without exaggerated ridges, and the sides of the cavity should be chamfered rather than being a steep-sided hole. Chamfering promotes good fusion in the

casting repair. It also provides a means for any gas in the casting that is released during welding to become uniformly distributed throughout the weld rather than becoming concentrated as linear porosity around the edge of the weld.

Cleaning. Oil and grease, if present, should be removed with a locally applied solvent or by a vapor degreasing operation. The type of solvent used--toluene, for example--should not leave a residue that may gasify the weld or produce harmful fumes during the welding operation. Etchants should not be used to clean the casting before welding unless absolutely necessary. Etchants are usually corrosive and tend to be retained in the surface pores of the casting. They can also contribute to gas porosity in the weld if the casting surface containing these trapped liquids becomes involved in the welding operation.

Impregnated Castings. Castings should not be impregnated for pressure tightness before welding. If an impregnated casting must be welded, the impregnant can be partially removed by prolonged heating at a temperature of 150 to 205 °C (300 to 400 °F).

Surface Preparation. After cleaning with a solvent and just before welding, the area to be welded and the immediately adjacent area (a 13 mm, or $\frac{1}{2}$ in., band around the weld area) should be hand brushed with a stainless steel bristle brush to reduce the thickness of the aluminum oxide on the casting surface and to remove any sand or foreign material. In cases in which the as-cast surface is to be welded, the surface should be scraped or scarfed to a depth of 1.5 mm (0.06 in.) or more to overcome the effects of the oxidized, rough casting surface.

The filler metal is often the same alloy as the casting being welded. Filler material can be cast in rod-shaped molds when production castings are being poured. If the castings are to be heat treated after welding, the filler material selected may be different from that used if ease of welding is the only consideration.

The size of the filler rod used for welding is usually the largest one that will not freeze the weld puddle. To minimize hot short weld cracking, weld composition should be maintained as closely as possible to a ratio of 70% filler alloy to 30% base alloy.

Preheating. Although it can be beneficial in reducing the size of gas porosity in the weld, preheating of the casting is not necessary before making a weld repair. The ability to maintain a puddle is the primary consideration. In some cases, however, preheating may be necessary to overcome cracking, distortion, or welding speed problems. Each case is different, and the need for preheating depends on the alloy, section thickness, casting size and geometry, residual stress, and potential thermal gradients between hot and cool areas. When it is required, preheating can be accomplished by placing the entire casting in a furnace, or if the size of the casting does not permit this method, the casting can be preheated with a gas torch. The casting is usually heated to 150 to 205 °C (300 to 400 °F).

Welding Technique. Weld quality is directly related to casting quality. The general problems encountered in making good welds with castings are the same as those encountered with wrought alloys except that the aluminum oxide on casting surfaces is thicker than on wrought alloys and must be reduced to diminish welding problems.

A good general rule of welding technique is to "get in and then get out quickly." To accomplish fast melting and weld puddle cleanup, helium shielding gas in a mixture with argon gas should be used. Cracks cannot be melted out, however, because the melting point of the aluminum oxide that lines the cracks is prohibitively high. The cracks must be chipped out and the cavity filled with weld metal.

Postweld Heat Treatment. Castings that require heat treatment should be heat treated after welding. Castings that have been heat treated and then welded will suffer localized loss of tensile properties. However, postweld heat treatment will restore their properties if the proper filler alloy has been used in welding.

Aluminum and Aluminum Alloys

Elwin L. Rooy, Aluminum Company of America

Properties of Aluminum Casting Alloys

The physical and mechanical properties of aluminum casting alloys are well documented and are listed in Tables 5, 6, and 7 in this article (see also the Selected References). The discussion in this article is not intended as a comprehensive discussion of all the commonly tested properties of aluminum casting alloys (for example, tensile strength). Rather, certain properties, such as fatigue resistance and corrosion resistance, will be discussed in terms of testing, problems in testing, and how the properties of cast aluminum may differ from those of wrought alloys. Melt fluidity, shrinkage during cooling, and hot cracking will also be discussed.

(a) S, and cast; P, permanent mold; D, die cast.

(b) The specific gravity and weight data in this table assume solid (void-free) metal. Because some porosity cannot be avoided in commercial castings, their specific gravity or weight is slightly less than the theoretical value.

Table 6 Ratings of castability, corrosion resistance, machinability, and weldability for aluminum casting alloys

1, best; 5, worst. Individual alloys may have different ratings for other casting processes.

Alloy	Resistance to hot cracking[a]	Pressure tightness	Fluidity[b]	Shrinkage tendency	Corrosion resistance[c]	Machinability[d]	Weldability[e]

(a) Ability of alloy to withstand stresses from contraction while cooling through hot short or brittle temperature range.

(b) Ability of liquid alloy to flow readily in mold and to fill thin sections.

(c) Based on resistance of alloy in standard salt spray test.

(d) Composite rating based on ease of cutting, chip characteristics, quality of finish, and tool life.

(e) Based on ability of material to be fusion welded with filler rod of same alloy

(a) 500 kg (1100 lb) load on 10 mm (0.4 in.) ball

It must be noted here that the data given in Tables 5, 6, and 7 are useful for comparing alloys, but they should not be used for design purposes. Properties for design must be obtained from pertinent specifications or design standards or by negotiation with the producer.

Fatigue

When a part is subjected to repeated loads, cracks may develop in highly stressed areas and grow as cyclic or repetitive loading occurs. Such cracks may occur at stress levels below the characteristic ultimate strength of the material. Failure by such a mechanism is termed fatigue failure. Fatigue cracks frequently initiate at stress raisers such as abrupt changes in section, holes, notches, machining gouges, stamped emblems, the edges of a weld bead, porosity, surface oxide concentrations, dross inclusions, or other surface discontinuities.

Fatigue Testing. Separately cast test bars are often employed to avoid the destruction of production parts. Unfortunately, the fatigue resistance of such specimens is usually higher than that of most cast products due to factors such as relatively low porosity and the presence of beneficial residual surface compressive stresses. It may therefore be appropriate to machine specimens from critical casting areas when fatigue properties are important.

The fatigue strength of castings is normally lower than that of wrought materials. However, discontinuities that considerably reduce the fatigue strength of a wrought material (for example, holes) have much less effect on the fatigue performance of a cast part (that is, castings are less notch-sensitive than wrought materials).

Premium engineered castings combine a number of conventional casting procedures in a selective manner to provide premium strength, soundness, dimensional tolerances, surface finish, or a combination of these characteristics. As a result, premium engineered castings typically have somewhat higher fatigue resistance than conventional castings. Improved surface finish, better soundness at the surface, finer grain size, and adjustments in heat treated condition may all contribute to this enhanced resistance.

Avoiding Fatigue Cracking. Because castings are less notch-sensitive than wrought materials, it is not so critical to avoid discontinuities with castings as it is with wrought products. The following general considerations, however, should be kept in mind for castings that are to be subject to repeated loading:

- Use gradual changes in section and symmetry of design where practical
- Minimize scratches and the presence and magnitude of surface defects or discontinuities of any kind in highly stressed areas
- Alleviate possible fretting between contacting surfaces
- Provide proper maintenance and suitable protection against corrosion

Corrosion

The corrosion resistance of aluminum casting alloys in service depends on such factors as alloy composition and the environment to which the alloy is exposed. The mechanical and physical conditions under which the alloy is exposed are also important. Detailed information on the corrosion resistance of wrought aluminum alloys is available in the article "Corrosion of Aluminum and Aluminum Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Minimizing Corrosion Problems. Corrosion can be minimized by designing the application to include protective measures and by selecting the alloy that will economically meet all design requirements, including those pertaining to corrosion. In many applications, the corrosion resistance of various casting alloys is similar enough that alloy selection can be based on other factors. Only in severe environments, such as marine atmospheres or heavily polluted urban industrial atmospheres, do differences in the general corrosion resistances of various aluminum casting alloys become apparent.

Mechanical Properties

Mechanical Properties and Casting Design. Any casting design is based on two expectations:

- The casting will meet certain minimum requirements for mechanical properties that are characteristic of the alloy and temper selected
- The combination of design and properties will provide reliable service performance

The mechanical properties of castings produced by a particular process in a specific alloy and temper are critical considerations in alloy and temper selection.

Mechanical Properties and Quality Assurance. Some type of quality assurance program is required to ascertain that metal composition, molten metal quality, foundry practices, and heat treatment are consistently under control, and that parts with the expected properties are being consistently produced. Specimens for mechanical property testing may be cast separately, integrally cast, or cut from representative castings.

Minimum Values for Mechanical Tests. Minimum mechanical property limits are usually defined by the terms of general procurement specifications, such as those developed by government agencies and technical societies. These documents often specify testing frequency, tensile bar type and design, lot definitions, testing procedures, and the limits applicable to test results. By references to general process specifications, these documents also invoke standards and limits for many additional supplier obligations, such as specific practices and controls in melt preparation, heat treatment, radiographic and liquid penetrant inspection, and test procedures and interpretation.

Some specifications for sand, permanent mold, plaster, and investment castings have defined the correlation between test results from specimens cut from the casting and separately cast specimens. A frequent error is the assumption that test values determined from these sources should agree. Rather, the properties of separately cast specimens should be expected to be superior to those of specimens machined from the casting. In the absence of more specific guidelines, one rule of thumb defines the average tensile and yield strengths of machined specimens as not less than 75% of the minimum requirements for separately cast specimens, and elongation as not less than 25% of the minimum requirement. These relations may be useful in establishing the commercial acceptability of parts in dispute.

Premium Engineered Castings. Quality assurance for premium engineered castings frequently involves tensile testing of specimens machined from castings or cast integrally with the casting. Property requirements are established by negotiation and agreement between customer and supplier, and may include guarantees only for critical areas of the casting or for the entire part.

Molten Metal Fluidity

The Nature of Fluidity. Fluidity is the characteristic of a molten alloy that enables mold filling. Different alloys have different fluidities, and therefore different abilities to provide definition of detail and integrity in thin sections.

Factors Affecting Fluidity. Fluidity depends on two major factors: the intrinsic fluid properties of the molten metal, and casting conditions. The properties usually thought to influence fluidity are viscosity, surface tension, the character of the surface oxide film, inclusion content, and manner in which the particular alloy solidifies.

Casting conditions that influence fluidity include part configuration; physical measures of the fluid dynamics of the system, such as liquidstatic pressure drops, casting head, and velocities; mold material; mold surface characteristics; heat flux; rate of pouring; and degree of superheat.

Viscosity. The measured viscosities of molten aluminum alloys are quite low and fall within a relatively narrow range. Kinematic viscosity (viscosity/specific gravity) is less than that of water. It is evident on this basis that viscosity is not strongly influential in determining casting behavior and therefore is an unlikely source of variability in casting results.

Surface Tension and Oxide Film. A high surface tension has the effect of increasing the pressure required for liquid metal flow. A number of elements influence surface tension, primarily through their effects on the surface tension of the oxide. Figure 11 illustrates the effect of selected elements on surface tension. In aluminum alloys, the true effect of surface tension is overpowered by the influence of surface oxide film characteristics. The oxide film on pure aluminum, for example, triples apparent surface tension.

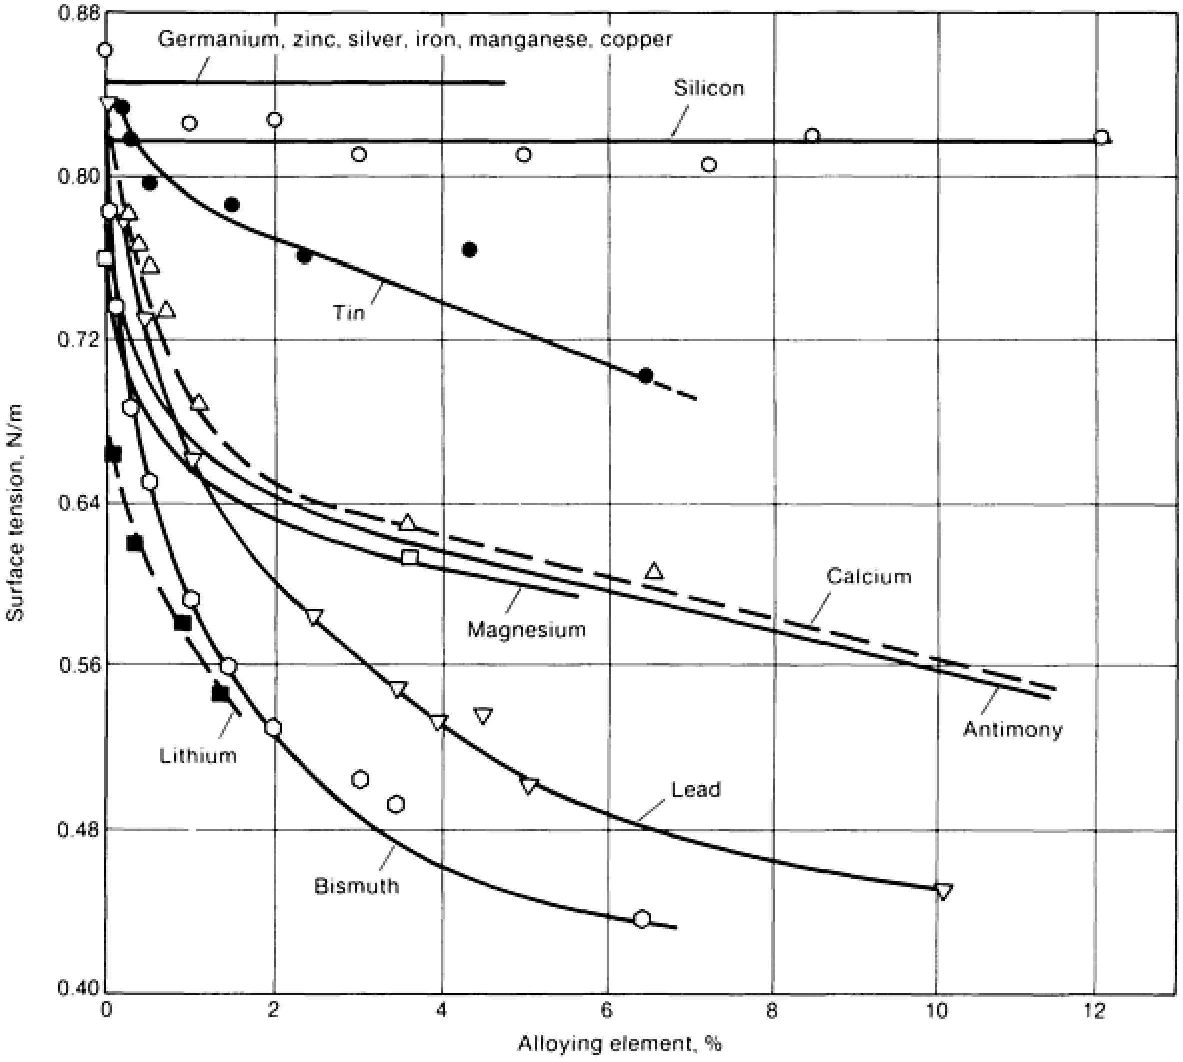

Fig. 11 Effect of various elements on surface tension of 99.99% Al in argon at 700 to 740 °C (1290 to 1365 °F).

Inclusions in the form of suspended insoluble nonmetallic particles dramatically reduce the fluidity of molten aluminum.

Solidification. It has been shown that fluidity is inversely proportional to freezing range (that is, fluidity is highest for pure metals and eutectics, and lowest for solid solution alloys). The manner in which solidification occurs may also influence fluidity.

Fluidity Testing. Correlation between fluidity test results (usually of the spiral or variable-dimension type) and foundry experience has been poor. No accepted method for the determination or prediction of fluidity, with relevance to the casting process, has been developed.

Shrinkage

For most metals, the transformation from the liquid to the solid state is accompanied by a decrease in volume. In aluminum alloys, volumetric solidification shrinkage can range from 3.5 to 8.5%. The tendency for formation of shrinkage porosity is related to both the liquid/solid volume fraction and the solidification temperature range of the alloy. Riser requirements relative to the casting weight can be expected to increase with increasing solidification temperature range. Requirements for the establishment of more severe thermal gradients, such as by the use of chills or antichills, also increase.

Hot Cracking

The Source of Hot Cracking. As previously mentioned, aluminum alloys shrink from 3.5 to 8.5% during solidification. A further, much smaller contraction occurs in post-solidification cooling to room temperature. Tearing or hot cracking occurs during solidification, when the greatest amount of shrinkage occurs and when the casting is least resistant to stresses imposed by the geometrical constraints of the mold. This type of cracking, sometimes termed hot shortness, is always intergranular and is a feature to some extent of all casting alloys. Hot strength (resistance to cracking at solidification temperature), however, is alloy-dependent.

Minimizing Hot Cracking. Hot cracking problems can be minimized by proper selection of casting process, alloy selection, part and mold design, solidification control, and grain refinement. Aluminum casting alloys demonstrate varying degrees of resistance to cracking; therefore, the crack sensitivity of alloys capable of meeting part requirements should be an important criterion in final alloy selection.

Mold Design. Improper mold design is a frequent cause of hot cracking. It is important to avoid abrupt changes in cross sectional area and inadequately radiused or filleted angles or corners. These are design features that can sharply increase and concentrate stresses resulting from restrained contraction during and following solidification. The intelligent use of chills and/or antichills can also be beneficial in preventing hot cracks.

Effective grain refinement to ensure a fine, equiaxed grain structure is especially important in hot-short alloys or in casting designs with features that aggravate cracking tendencies. Fine grain size reduces local stress concentrations by minimizing grain boundary effects.

Applications

Aluminum alloy castings are economical in many applications. They are used in the automotive industry, in construction of machines, appliances, and structures, as cooking utensils, as covers and housings for electronic equipment, and in innumerable other areas. Table 8 lists typical applications of some aluminum casting alloys, and Fig. 12 illustrates some common applications.

Table 8 Representative applications for aluminum casting alloys

Alloy	Representative applications
100.0	Electrical rotors larger than 152 mm (6 in.) in diameter
201.0	Structural members; cylinder heads and pistons; gear, pump, and aerospace housings
208.0	General-purpose castings; valve bodies, manifolds, and other pressure-tight parts
222.0	Bushings; meter parts; bearings; bearing caps; automotive pistons; cylinder heads
238.0	Sole plates for electric hand irons
242.0	Heavy-duty pistons; air-cooled cylinder heads; aircraft generator housings
A242.0	Diesel and aircraft pistons; air-cooled cylinder heads; aircraft generator housings
B295.0	Gear housings; aircraft fittings; compressor connecting rods; railway car seat frames

308.0	General-purpose permanent mold castings; ornamental grilles and reflectors
319.0	Engine crankcases; gasoline and oil tanks; oil pans; typewriter frames; engine parts
332.0	Automotive and heavy-duty pistons; pulleys, sheaves
333.0	Gas meter and regulator parts; gear blocks; pistons; general automotive castings
354.0	Premium-strength castings for the aerospace industry
355.0	Sand: air compressor pistons; printing press bedplates; water jackets; crankcases. Permanent: impellers; aircraft fittings; timing gears; jet engine compressor cases
356.0	Sand: flywheel castings; automotive transmission cases; oil pans; pump bodies. Permanent: machine tool parts; aircraft wheels; airframe castings; bridge railings
A356.0	Structural parts requiring high strength; machine parts; truck chassis parts
357.0	Corrosion-resistant and pressure-tight applications
359.0	High-strength castings for the aerospace industry
360.0	Outboard motor parts; instrument cases; cover plates; marine and aircraft castings
A360.0	Cover plates; instrument cases; irrigation system parts; outboard motor parts; hinges
380.0	Housings for lawn mowers and radio transmitters; air brake castings; gear cases
A380.0	Applications requiring strength at elevated temperature
384.0	Pistons and other severe service applications; automatic transmissions
390.0	Internal combustion engine pistons, blocks, manifolds, and cylinder heads
413.0	Architectural, ornamental, marine, and food and dairy equipment applications
A413.0	Outboard motor pistons; dental equipment; typewriter frames; street lamp housings
443.0	Cookware; pipe fittings; marine fittings; tire molds; carburetor bodies
514.0	Fittings for chemical and sewage use; dairy and food handling equipment; tire molds

A514.0	Permanent mold casting of architectural fittings and ornamental hardware
518.0	Architectural and ornamental castings; conveyor parts; aircraft and marine castings
520.0	Aircraft fittings; railway passenger car frames; truck and bus frame sections
535.0	Instrument parts and other applications where dimensional stability is important
A712.0	General-purpose castings that require subsequent brazing
713.0	Automotive parts; pumps; trailer parts; mining equipment
850.0	Bushings and journal bearings for railroads
A850.0	Rolling mill bearings and similar applications

---

Introduction

COPPER IS ALLOYED with other elements because pure copper is extremely difficult to cast as well as being prone to surface cracking, porosity problems, and to the formation of internal cavities. The casting characteristics of copper can be improved by the addition of small amounts of elements including beryllium, silicon, nickel, tin, zinc, chromium, and silver. Alloy coppers, for example, constituted to have improved strength properties over those of high-purity copper, while maintaining a minimum of 85% conductivity, are widely used for cast electrical conducting members.

When casting copper and its alloys, the lowest possible pouring temperature needed to suit the size and form of the solid metal should be adopted to encourage as small a grain size as possible as well as to create a minimum of turbulence of the metal during pouring.

Copper alloys in cast form (designated in UNS numbering system as C80000 to C99999) are specified when factors such as tensile and compressive strength, wear qualities when subjected to metal-to-metal contact, machinability, thermal and electrical conductivity, appearance, and corrosion resistance are considerations for maximizing product performance. Such is the case when using cast copper alloys in applications such as bearings, bushings, gears, fittings, valve bodies, and miscellaneous components for the chemical processing industry.

Types of Copper Alloys

Copper alloys are poured into many types of castings such as sand, shell, investment, permanent mold, chemical sand, centrifugal, and die. Additional information on these casting processes can be found in the articles "Sand Molding," "Permanent Mold Casting," "Centrifugal Casting," and "Die Casting" in this Volume.

The copper-base casting alloy family can be subdivided into three groups according to solidification (freezing range). Unlike pure metals, alloys solidify over a range of temperatures. Solidification begins when the temperature drops below the liquidus; it is completed when the temperature reaches the solidus. The liquidus is the temperature at which the metal begins to freeze, and the solidus is the temperature at which the metal is completely frozen. The three groups are as follows:

Group I alloys are alloys that have a narrow freezing range, that is, a range of 50 °C (90 °F) between the liquidus and solidus.

Group II alloys are those that have an intermediate freezing range, that is, a freezing range of 50 to 110 °C (90 to 200 °F) between the liquidus and the solidus.

Group III alloys have a wide freezing range. These alloys have a freezing range of well over 110 °C (200 °F), even up to 170 °C (300 °F).

Concern is felt about the freezing ranges given. Factually, the freezing range of cupro-nickel is probably less than 50 °C (90 °F); this would place this alloy in group I rather than in group II. It might be better to simply have three groups--short, medium, and long--without specifying exact freezing ranges.

The Major Copper-Base Alloy Ranges

The alloys in group I (with narrow solidification temperature range of 50 °C, or 90 °F, or less) have the nominal chemical composition and typical mechanical properties shown in Table 1. These are the yellow brasses, manganese and aluminum bronzes, nickel bronze, manganese bronze alloys, chromium copper, and copper.

Table 1 Nominal chemical composition and typical mechanical properties for group I alloys

Melting Practice

Fuel-Fired Furnaces. Copper-base alloys are melted in oil- and gas-fired crucible and open-flame furnaces. Crucible furnaces, either tilting or stationary, incorporate a removable cover or lid for removal of the crucible, which is transported to the pouring area where the molds are poured. The contents of the tilting furnace are poured into a ladle, which is then used to pour the molds (Fig. 1 and 2).

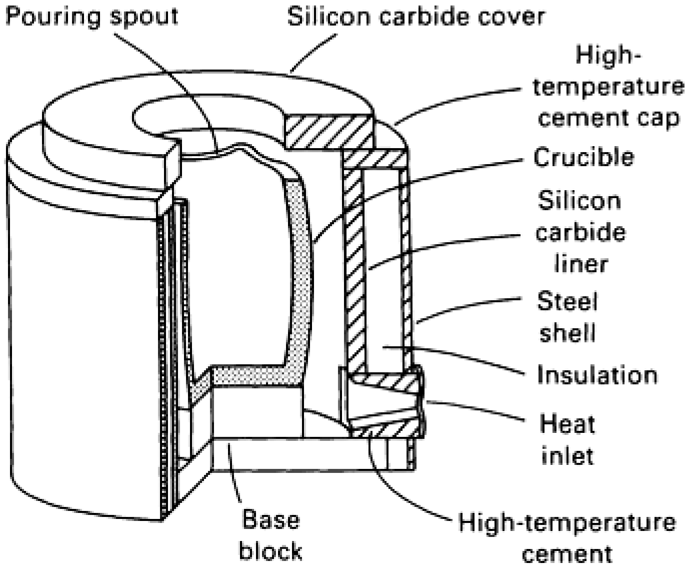

Fig. 1 Typical lift-out type of fuel-fired crucible furnace, especially well adapted to foundry melting of smaller quantities of copper alloys (usually less than 140 kg, or 300 lb).

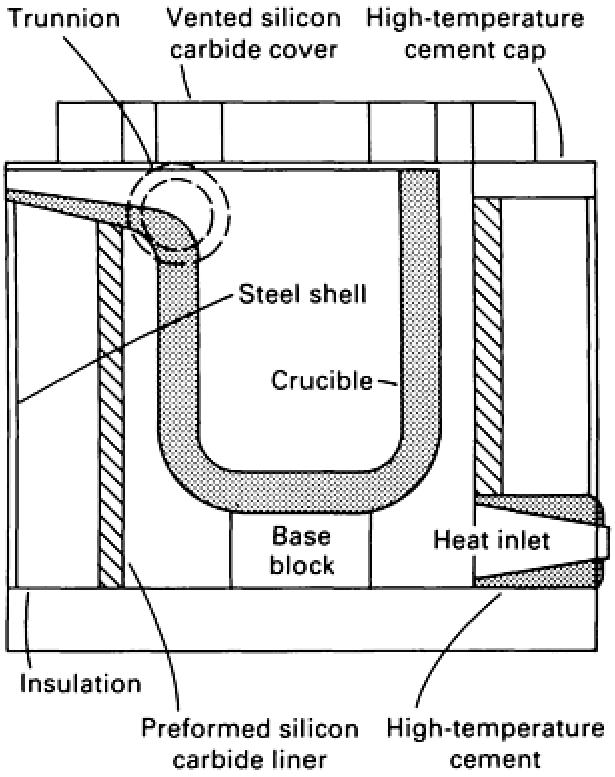

Fig. 2 Typical lip-axis tilting crucible furnace used for fuel-fired furnace melting of copper alloys. Similar furnaces are available that tilt on a central axis.

These furnaces melt the raw materials by burning oil or gas with sufficient air to achieve complete combustion. The heat from the burner heats the crucible by conduction and convection; the charge melts and then is superheated to a particular temperature at which either the crucible is removed or the furnace is tilted to pour into a ladle. While the molten metal is in the crucible or ladle, it is skimmed, fluxed, and transferred to the pouring area, where the molds are poured.

The other type of fuel-fired furnace is the open-flame furnace, which is usually a large rotary-type furnace with a refractory lined steel shell containing a burner at one end and a flue at the other. The furnace is rotated slowly around the horizontal axis, and the rotary movement helps to heat and melt the furnace charge. Melting is accomplished both by the action of the flame directly on the metal and by heat transfer from the hot lining as this shell rotates. These furnaces usually tilt so that they can be charged and poured from the flue opening. At the present time, these furnaces are not used often because of the requirement that a baghouse be installed to capture all the flue dust emitted during melting and superheating. While these furnaces are able to melt large amounts of metal quickly, there is a need for operator skill to control the melting atmosphere within the furnace. Also, the refractory walls become impregnated with the melting metal, causing a contamination problem when switching from one alloy family to another.

Electric Induction Furnaces. In the past 20 years, there has been a marked changeover from fuel-fired melting to electric induction melting in the copper-base foundry industry. While this type of melting equipment has been available for more than 50 years, very few were actually used due to the large investment required for the capital equipment. Because of higher prices and the question of availability of fossil fuels and because of new regulations on health and safety imposed by the Occupational Safety and Health Administration (OSHA), many foundries have made the changeover to electric induction furnaces.

When melting alloys in group III, fumes of lead and zinc are given off during melting and superheating. The emission of these harmful oxides is much lower when the charge is melted in an induction furnace because the duration of the melting cycle is only about 25% as long when melting the same amount of metal in a fuel-fired furnace. By the use of electric induction melting, compliance with OSHA regulations can be met in many foundries without the need for expensive air pollution control equipment. Additional information on electric induction furnaces is available in the article "Induction Furnaces" in this Volume.

The two types of electric induction furnaces are the core type, better known as the channel furnace, and the coreless type.

Core Type. This furnace (shown in Fig. 3) is a large furnace used in foundries for pouring large quantities of one alloy when a constant source of molten metal is required. This furnace has a primary coil, interfaced with a laminated iron core, surrounded by a secondary channel, which is imbedded in a V- or U-shape refractory lining located at the bottom of a cylindrical hearth. Here the channel forms the secondary of a transformer circuit. This furnace stirs and circulates molten metal through the channel at all times, except when the furnace is emptied and shut down. When starting up, molten metal must be poured into the furnace to fill up the "heel" on the bottom of the bath. Because these furnaces are very efficient and simple to operate with lining life in the millions of pounds poured, they are best suited for continuous production runs in foundries making plumbing alloys of group III. They are not recommended for the dross-forming alloys of group I. The channel furnace is at its best when an inert, floating, cover flux is used and charges of ingot, clean remelt, and clean and dry turnings are added periodically.

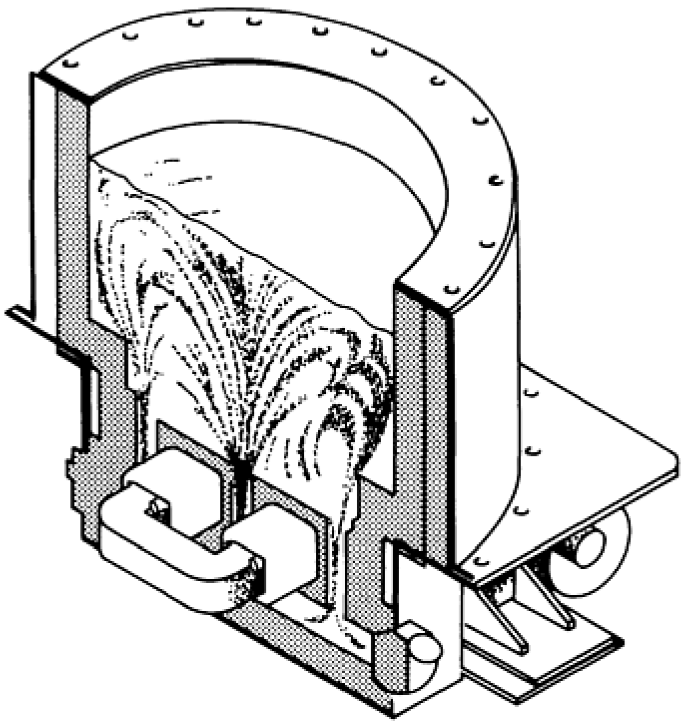

Fig. 3 Cutaway drawing of a twin-channel induction melting furnace.

Coreless Type. This furnace has become the most popular melting unit in the copper alloy foundry industry. In earlier years, the coreless furnace was powered by a motor generator unit, usually at 980 Hz. The present coreless induction furnaces draw 440 volt, 60 cycle power and, by means of solid state electronic devices, convert the power to 440 volts and 1000 or 3000 Hz. These furnaces are either tilting furnaces (Fig. 4) or crucible lift-out units (Fig. 5 and Fig. 6).

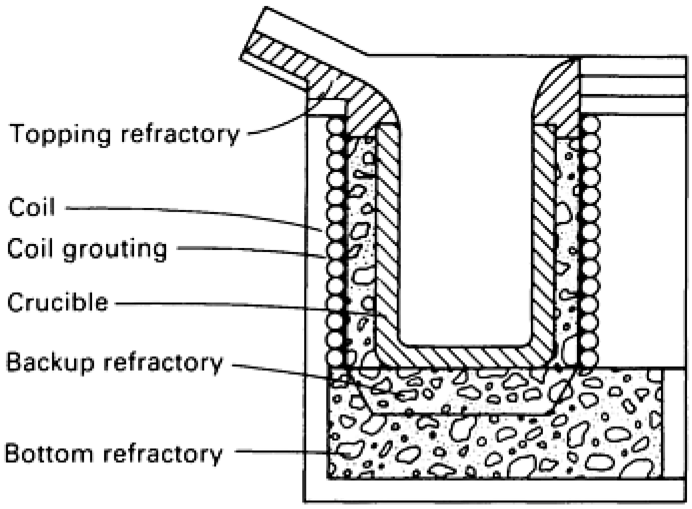

Fig. 4 Cross section of a tilt furnace for high-frequency induction melting of brass and bronze alloys. Crucible is of clay graphite composition.

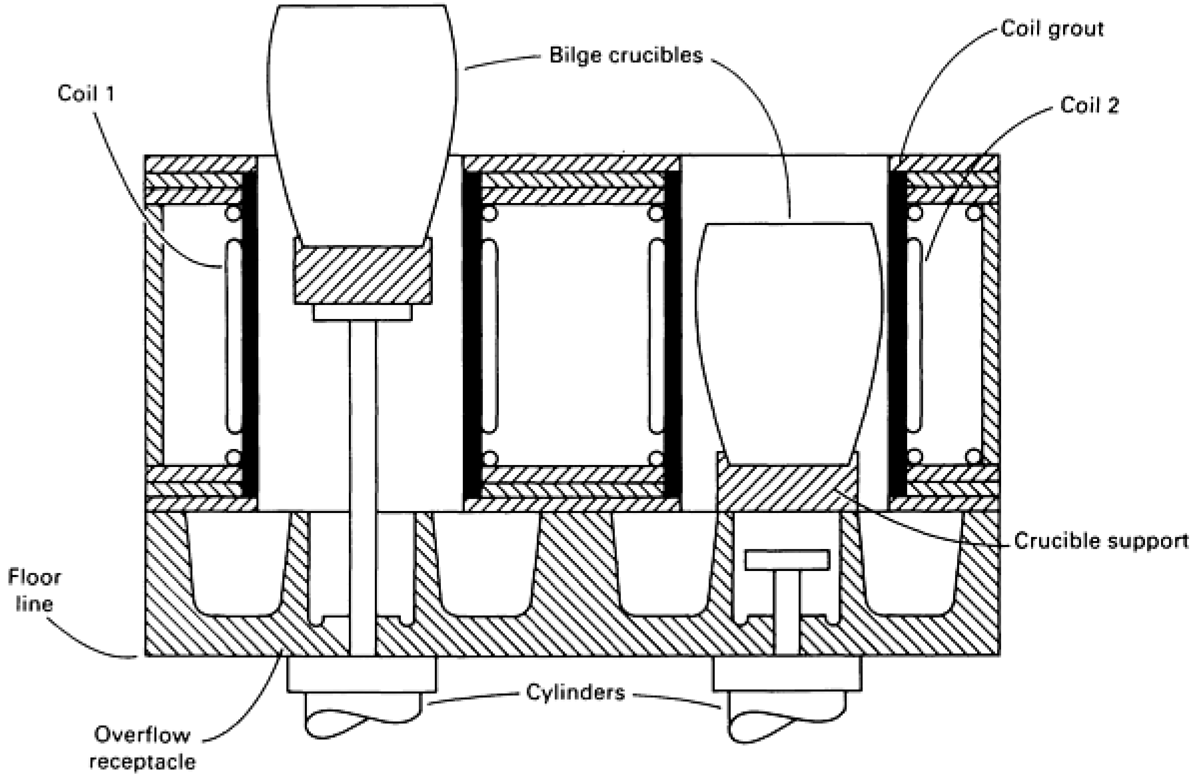

Fig. 5 Cross section of a double push-out furnace. Bilge crucibles are placed on refractory pedestals and raised and lowered into position within the coils by hydraulic cylinders.

Fig. 6 Foundry installation of high-frequency induction lift swing furnaces.

A coreless induction furnace is comprised of a water-cooled copper coil in a furnace box made of steel or Transite. The metal is contained in a crucible or in a refractory lining rammed up to the coil. Crucibles used in these furnaces are made of clay graphite; silicon carbide crucibles cannot be used because they become overheated when inserted in a magnetic field. Clay graphite crucibles do a good job of conducting the electromagnetic currents from the coil into the metal being melted.

Induction furnaces are characterized by electromagnetic stirring of the metal bath. Because the amount of stirring is affected by both power input and power frequency, the power unit size and frequency should be coordinated with the furnace size in order to obtain the optimum-size equipment for the specific operation. In general, the smaller the unit, the higher the frequency and the lower the power input.

Large tilting units are used in foundries requiring large amounts of metal at one time. These furnaces, if over 4.5 Mg (10,000 lb) capacity, operate at line frequency (60 Hz). They are very efficient and will melt large quantities of metal in a very short time if powered with the proper-size power unit.

Stationary lift-out furnaces are often designed as shown in Fig. 5. Here the crucible sits on a refractory pedestal, which can be raised or lowered by a hydraulic cylinder. This unit, also called a push-out furnace, operates by lowering the crucible into the coil for melting and then raising the crucible out of the coil for pickup and pouring. While one crucible is melting, the other crucible can be charged and ready to melt when the knife switch is pulled as the completed heat is being pushed up for skimming and pouring.

The other common type of coreless induction melting is the lift swing furnace (Fig. 6). Here the coil (and box) is cantilevered from a center post to move up or down vertically and swing horizontally about the post in a 90° arc. Because there are two crucible positions, one crucible can be poured, recharged, and placed into position to melt, while the other is melting. When the metal is ready to pour, the furnace box is lifted (by hydraulic or air cylinder), pivoted to the side, and lowered over the second crucible. The ready crucible is then standing free and can be picked up and poured, while melting is taking place in the second furnace.

Copper and Copper Alloys

Group I Alloys

Pure Copper and Chromium Copper. Commercially pure copper and high copper alloys are very difficult to melt and are very susceptible to gassing. In the case of chromium copper, oxidation loss of chromium during melting is a problem. Copper and chromium copper should be melted under a floating flux cover to prevent both oxidation and the pickup of hydrogen from moisture in the atmosphere. In the case of copper, crushed graphite should cover the melt. With chromium copper, the cover should be a proprietary flux made for this alloy. When the molten metal reaches 1260 °C (2300 °F), either calcium boride or lithium should be plunged into the molten bath to deoxidize the melt. The metal should then be poured without removing the floating cover.

Yellow Brasses. These alloys flare, or lose zinc, due to vaporization at temperatures relatively close to the melting point. For this reason, aluminum is added to increase fluidity and keep zinc vaporization to a minimum. The proper amount of aluminum to be retained in the brass is 0.15 to 0.35%. Above this amount, shrinkage takes place during freezing, and the use of risers becomes necessary. Other than the addition of aluminum, the melting of yellow brass is very simple, and no fluxing is necessary. Zinc should be added before pouring to compensate for the zinc lost in melting.

Manganese Bronzes. These alloys are carefully compounded yellow brasses with measured quantities of iron, manganese, and aluminum. The metal should be melted and heated to the flare temperature or to the point at which zinc oxide vapor can be detected. At this point, the metal should be removed from the furnace and poured. No fluxing is required with these alloys. The only addition required with these alloys is zinc. The amount required is that which is needed to bring the zinc content back to the original analysis. This varies from very little, if any, when an all-ingot heat is being poured, to several percent if the heat contains a high percentage of remelt.

Aluminum Bronzes. These alloys must be melted carefully under an oxidizing atmosphere and heated to the proper furnace temperature. If needed, degasifiers can be stirred into the melt as the furnace is being tapped. By pouring a blind sprue before tapping and examining the metal after freezing, it is possible to tell whether it shrank or exuded gas. If the sample purged or overflowed the blind sprue during solidification, degassing is necessary. Degasifiers remove hydrogen and oxygen. Also available are fluxes that convert the molten bath. These are in powder form and are usually fluorides. They aid in the elimination of oxides, which normally form on top of the melt during melting and superheating.

Nickel Bronzes. These alloys, also known as nickel silver, are difficult alloys to melt. They gas readily if not melted properly because the presence of nickel increases the hydrogen solubility. Then, too, the higher pouring temperatures shown in Table 4 aggravate hydrogen pickup. These alloys must be melted under an oxidizing atmosphere and quickly

superheated to the proper furnace temperature to allow for temperature losses during fluxing and handling. Proprietary fluxes are available and should be stirred into the melt after tapping the furnace. These fluxes contain manganese, calcium, silicon, magnesium, and phosphorus and do an excellent job in removing hydrogen and oxygen.

White Manganese Bronze. There are two alloys in this family, both of which are copper-zinc alloys containing a large amount of manganese and, in one case, nickel. They are manganese bronze type alloys, are simple to melt, and can be poured at low temperatures because they are very fluid (Table 4). They should not be overheated, as this serves no purpose. If the alloys are unduly superheated, zinc is vaporized and the chemistry of the alloy is changed. Normally, no fluxes are used with these alloys.

Group II Alloys

Information on melting and fluxing of group II alloys is found below. Again, pouring temperatures for these alloys are found in Table 4.

Beryllium Coppers. These alloys are very toxic and dangerous if beryllium fumes are not captured and exhausted by proper ventilating equipment. They should be melted quickly under a slightly oxidizing atmosphere to minimize beryllium losses. They can be melted and poured successfully at relatively low temperatures (Table 4). They are very fluid and pour well.

Silicon Bronzes and Brasses. The alloys known as silicon bronzes, UNS alloys C87300, C87600, and 87610, are relatively easy to melt and should be poured at the proper pouring temperatures (Table 4). If overheated, they can pick up hydrogen. While degassing is seldom required, if necessary, one of the proprietary degasifiers used with aluminum bronze can be successfully used. Normally no cover fluxes are used here. The silicon brasses (UNS alloys C87500 and C87800) have excellent fluidity and can be poured slightly above their freezing range. Nothing is gained by excessive heating, and in some cases, heats can be gassed if this occurs. Here again, no cover fluxes are required.

Copper-Nickel Alloys. These alloys (90Cu-10Ni, UNS C96200 and 70Cu-30Ni, UNS C96400) must be melted carefully because the presence of nickel in high percentages raises not only the melting point but also the susceptibility to hydrogen pickup. In virtually all foundries, these alloys are melted in coreless electric induction furnaces, because the melting rate is much faster than it is with a fuel-fired furnace. When ingot is melted in this manner, the metal should be quickly heated to a temperature slightly above the pouring temperature (Table 4) and deoxidized either by the use of one of the proprietary degasifiers used with nickel bronzes or, better yet, by plunging 0.1% Mg stick to the bottom of the ladle. The purpose of this is to remove all the oxygen to prevent any possibility of steam-reaction porosity from occurring. Normally there is little need to use cover fluxes if the gates and risers are cleaned by shotblasting prior to melting.

Group III Alloys

The following discussion covers melting and fluxing of group III alloys. Again, pouring temperatures are found in Table 4.

These alloys, namely leaded red and semired brasses, tin and leaded tin bronzes, and high-leaded tin bronzes, are treated the same in regard to melting and fluxing and thus can be discussed together. Because of the long freezing ranges involved, it has been found that chilling, or the creation of a steep thermal gradient, is far better than using only feeders or risers. Chills and risers should be used in conjunction with each other for these alloys. For this reason, the best pouring temperature is the lowest one that will pour the molds without having misruns or cold shuts. In a well-operated foundry, each pattern should have a pouring temperature which is maintained by use of an immersion pyrometer.

Fluxing. In regard to fluxing, these alloys should be melted from charges comprised of ingot and clean, sandfree gates and risers. The melting should be done quickly in a slightly oxidizing atmosphere. When at the proper furnace temperature to allow for handling and cooling to the proper pouring temperature, the crucible is removed or the metal is tapped into a ladle. At this point, a deoxidizer (15% phosphor copper) is added. The phosphorus is a reducing agent (deoxidizer). This product must be carefully measured so that enough oxygen is removed, yet a small amount remains to improve fluidity. This residual level of phosphorus must be closely controlled by chemical analysis to a range between 0.010 and 0.020% P. If more is present, internal porosity may occur and cause leakage if castings are machined and pressure tested.

In addition to phosphor copper, pure zinc should be added at the point at which skimming and temperature testing take place prior to pouring. This replaces the zinc lost by vaporization during melting and superheating. With these alloys, cover fluxes are seldom used. In some foundries in which combustion cannot be properly controlled, oxidizing fluxes are added during melting, followed by final deoxidation by phosphor copper.

Pouring and Gating (Ref 1)

The major function of a gating system is to deliver clean metal from the ladle into the mold cavity without adversely affecting the quality of the metal. Secondary considerations are the ease of molding, removal of gates, and high casting yield. However, these factors should not dictate a design that contributes to the production of castings of unacceptable quality.

The Pouring Basin. The production of high-quality castings requires not only proper melting and molding operations and properly designed pattern equipment but also an understanding of the principles of gating so that clean metal can be delivered to the mold cavity with a minimum amount of turbulence. A pouring basin allows a sprue to be filled quickly and maintains a constant head throughout the pour (Fig. 7).

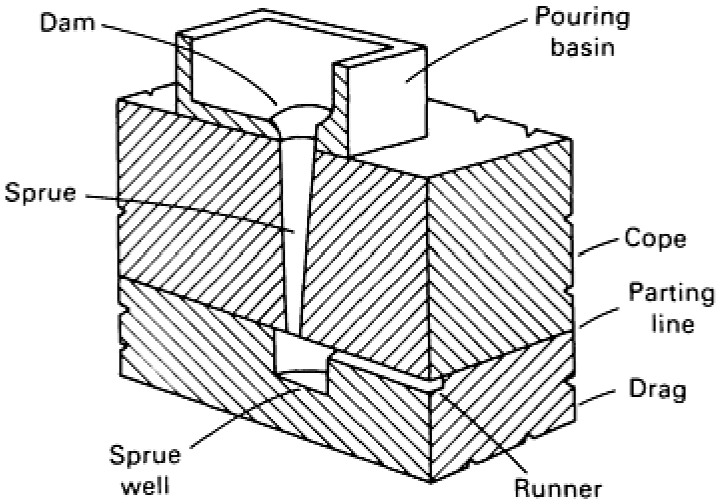

Fig. 7 Section of a typical sand mold with pouring basin.

When the weight of poured metal in a mold exceeds 14 kg (30 lb), use of a pouring basin offers many advantages. The pourer can better direct the flow of metal from the ladle into the basin, with less chance of spillages; also, the sprue need not be located near the edge of the mold. The pouring ladle can be brought within 25 to 50 mm (1 to 2 in.) of the basin, and a continued flow rate may be more easily maintained through a larger pouring head. If there are any brief interruptions in pouring the metal into the basin, the surplus metal will take up the slack until pouring has resumed. The major disadvantage of the pouring basin is that the yield is lowered, thereby requiring more metal to be recycled.

Sprue. The correct sprue size is the single most important part of the gating system. If a wrong size is selected, or an improper taper is used, the damage done to the metal in the mold cavity is extensive and cannot be corrected regardless of the quality of the runner and gating systems.

Because most molds under about 14 kg (30 lb) of poured weight are made on a high production scale in flasks of 102 to 152 mm (4 to 6 in.) in cope height, a fairly standard sprue size may be used for all copper-base alloys. The top third of the sprue should be the pouring part, with about a 50 mm (2 in.) diam opening. The remaining portion of the sprue should taper down to 13 to 22 mm ($\frac{1}{2}$ to $\frac{7}{8}$ in.) in final diameter depending on the pouring rate to be used.

Figure 8 shows a sketch of a sprue that will do an excellent job of conveying brass or bronze into the gating system. There are many charts and formulas available to determine the entry diameter of a tapered sprue, but for the most part this diameter should be just sufficient to provide about a 10 to 20° slope on the side of the sprue. When the sprue height is over 305 mm (12 in.), the top diameter of the sprue is much more important and should be about 50% larger than the diameter at the base of the sprue. When designing a pouring system for sprues of 102 to 152 mm (4 to 6 in.) in height, it is best to select the desired pouring rate first in order to determine the proper sprue base to be used.

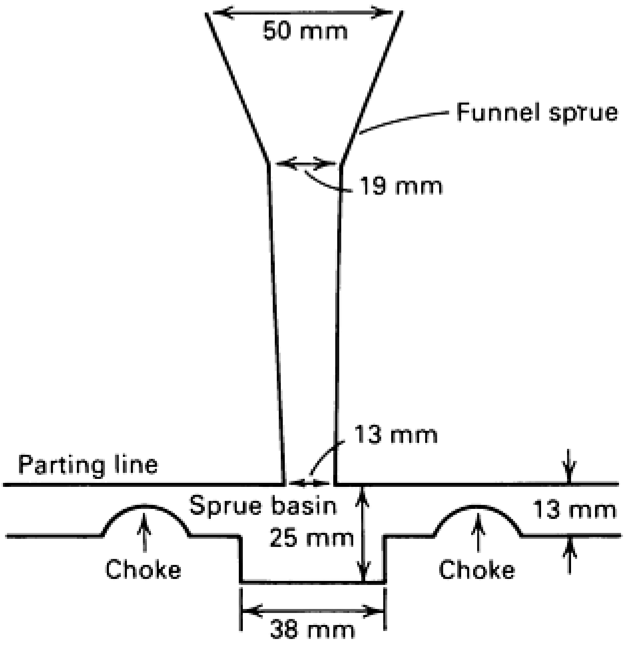

Fig. 8 Funnel sprue, sprue basin, and chokes for reducing turbulence.

The Sprue Base. Because the velocity of the stream is at its maximum at the bottom of the sprue and is proportional to the square root of the height of the fall of the metal, it is mandatory that a sprue base or well be used as a cushion for the stream flowing down the sprue. The base also helps change the vertical flow of metal into a horizontal flow with the least amount of turbulence. Recommended sprue basin sizes are about twice as deep as the drag runner and two to three times as wide as the base of the sprue. In most cases a well 25 to 38 mm (1 to $1\frac{1}{2}$ in.) deep with a width of 38 to 50 mm ($1\frac{1}{2}$ to 2 in.) on each side is usually adequate for the majority of sprues being used for most normal pouring rates. Little damage is done if the sprue base is larger than necessary except that the overall casting yield will be lowered slightly.

Chokes should be used only when the proper pouring rate cannot be controlled by the correct sprue size. If clean metal is delivered into the sprue, a strainer core serves the sole function of retarding the metal flow rate. Conventional strainer cores, whether of tinned steel, mica, glass fiber, or ceramic, usually reduce the flow of metal by about 70%, depending on the size and number of holes that are open to the sprue area. The best strainer is one that has only one hole with a diameter of the correct sprue size. This avoids the turbulence caused by the metal being divided into many streams as it enters the runner. In no instance should a strainer be placed into the top of the sprue; if one must be used, the only suitable place is just above the sprue base at the parting line. Tinned steel strainers are the least acceptable because the remelted runners can introduce iron and hard spots to the copper-base alloys if they are not properly skimmed during melting. The mica and glass fiber strainers are popular because they can be laid on the parting line just above the sprue base before the mold is closed, thereby requiring no "prints" or recesses, as do the thicker ceramic or sand strainer cores, which are usually about 3.2 mm ($\frac{1}{8}$ in.) thick.

A choke in the runner pattern is often the only consistent way to achieve a proper pouring rate. In no instance should the choke be put in the gate area. When necessary, it should be placed in the drag runner as close to the sprue as possible (Fig. 8). The chokes should have a smooth radiused contour and be located at the bottom of the drag runner. Choke depth may vary from $\frac{1}{4}$ to $\frac{3}{4}$ of the total runner depth with a cross-sectional area not exceeding $\frac{3}{4}$ of the area of the sprue base. The chokes should be located within an inch of the sprue base to ensure rapid filling of the sprue and maintenance of full capacity throughout the pour. This also permits dissipation of the turbulence before the stream reaches the gates.

Pouring rate depends on many factors, such as weight of the casting, section size, height of the sprue, and alloy system. Most alloys in group III for small work weighing 14 kg (30 lb) or less are poured with a hand ladle at about 1.8 kg/s (4 lb/s). Light memorial plaque castings are being successfully poured at 4.5 kg/s (10 lb/s), while many automatic pouring units operate at mold pouring rates of 3.6 to 4.5 kg/s (8 to 10 lb/s). Alloys in group I, if the poured weight is under 14 kg (30 lb), should be poured at 0.9 to 1.8 kg/s (2 to 4 lb/s) in order to obtain a clean, nonturbulent metal flow in the mold. Sprue exit diameters required for specific flow rates and various sprue heights are shown in Fig. 9. Table 5 shows flow rates from the bottom of the sprue for a number of commonly used sprue heights and diameters. As an example, for a gross casting weight of 14 kg (30 lb) or less and a sprue height of 102 to 152 mm (4 to 6 in.), a sprue diameter of 13 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$ in.) is adequate to obtain a flow rate of 0.9 to 1.8 kg/s (2 to 4 lb/s). It should not be necessary to use a 22 to 29 mm ($\frac{7}{8}$ to $1\frac{1}{8}$ in.) diam sprue base unless pouring plaque work or using automatic pouring. A quite popular sprue for most production work is the 16 to 19 mm ($\frac{5}{8}$ or $\frac{3}{4}$ in.) diam size, which will deliver enough hot metal to fill most molds up to 14 kg (30 lb) weight in 8 to 10 s. The total pouring time in seconds may be calculated by dividing the total weight of the mold poured (castings plus gates and risers) by the flow rate at the base of the sprue, or:

$$\frac{\textit{Total}\ \text{weight of casting including gates and rises(lb)}}{\text{Flow rate at base of sprue(lb/s)}} = \text{Calculated pouring time in seconds}$$

Table 5 Flow rates of copper-base alloys through tapered sprues of varying diameter and height

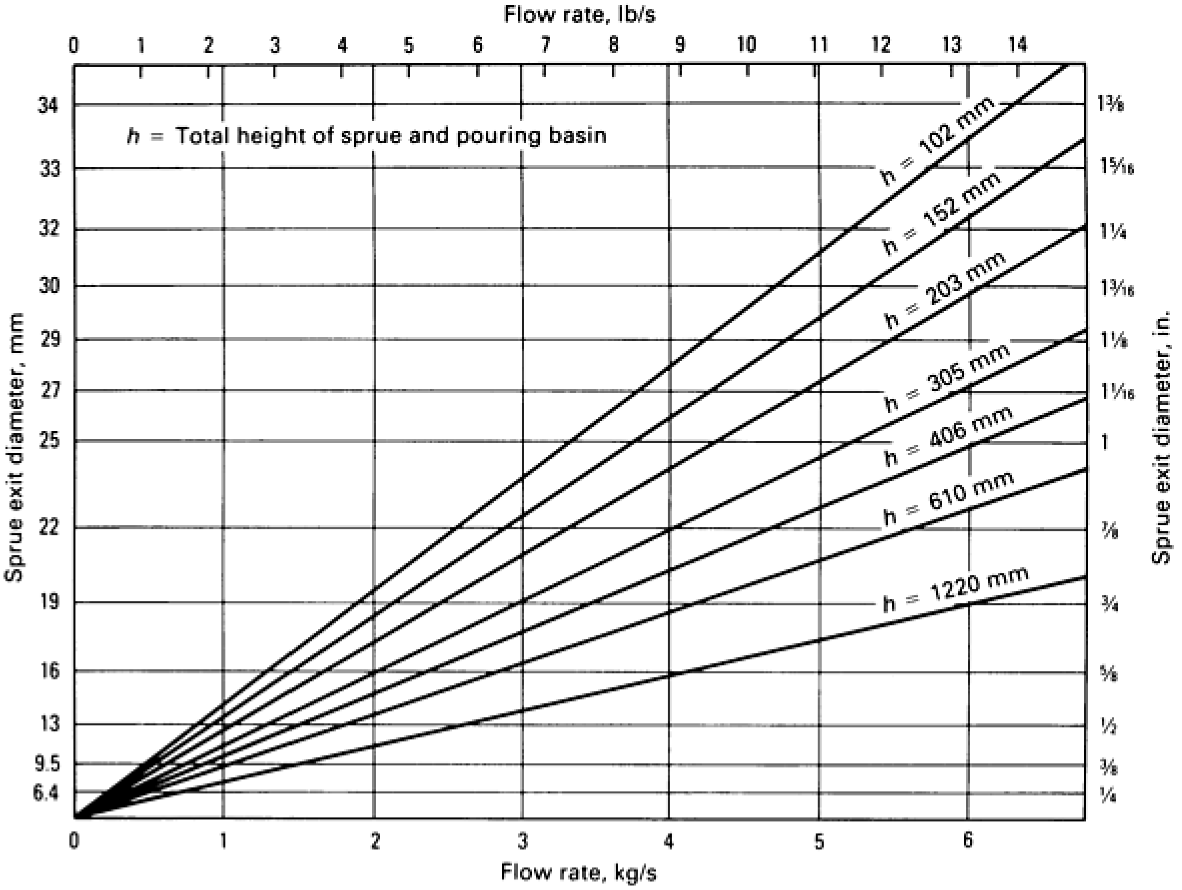

Fig. 9 Flow rates of copper-base alloys through tapered sprues of varying diameter and height.

Runners and Gates. For alloys in groups I and II, it is mandatory that all runners be placed in the drag and as much of the casting as possible be placed in the cope. In this way, all runners will be completely filled before any metal enters the gates, and the metal will drop the least amount or will rise to enter the mold cavity from the gates. Although this practice is also excellent for alloys in group III, experience has shown that quality castings may be obtained by using more traditional casting techniques because the alloys in group III are less sensitive to drossing and have a tendency to self heal when dross is formed in the gating system. Runners should be as rectangular in shape as possible, and their total maximum cross-sectional area should be two to four times that of the tapered sprue or the choke, if chokes are used in the runner system. Care must be taken to ensure that the cross section of the runners is adequate in order to prevent premature chilling. Experience has shown that a rectangular runner with the wide side laying horizontal works best. The next best is a square runner, and the least desirable is a rectangular runner with the wide side being vertical, although sometimes space limitations necessitate use of this type of runner in order to obtain the proper ratios. The rectangular runner should be about twice as wide as it is deep.

The cross-sectional area of the runner must be reduced by that of each gate as it is passed, so that metal enters the mold cavity simultaneously from each gate (Fig. 10). Because back filling is seldom desired from the runner system, a well at the end of the runner can be used (Fig. 11), particularly if the runner does not have any taper. A good example of multiple-cavity gating may be seen in Fig. 11. X-ray movies of metal flow in sand molds show that relatively uniform gate discharge rates are achieved only when stepped or tapered runners are used.

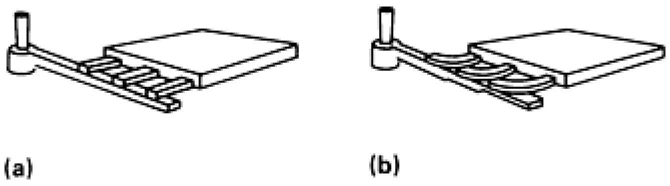

Fig. 10 Typical single-cavity gating systems. (a) Tapered runner. (b) Stepped runner.

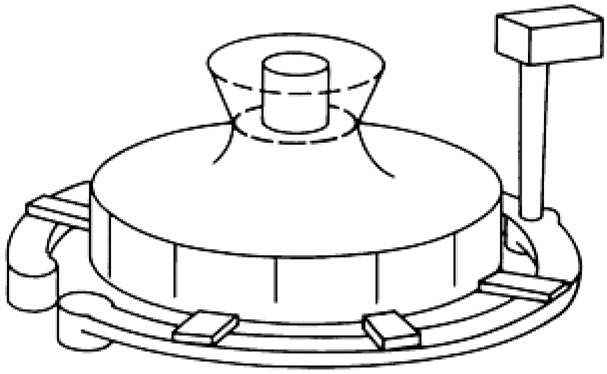

Fig. 11 Method of running a pump impeller with a well at the end of the runner.

Multiple gates are shown in Fig. 10, 11, and 12. The preferred location is in the cope just above the runner at the parting line. A rectangular flat gate is more desirable than a square gate, and a gate that has its wide dimension in the vertical plane is the least desirable, just as is the case for runners. In order to avoid a pressurized gating system, it is important that the total gate area be at least as large as the total runner area. If a pattern has an excessive amount of small castings, it might be necessary to have the total gate area many times the runner area in order to obtain a sufficient gate to each casting. This deviation is acceptable because the gating system remains unpressurized. Figure 10(a) and 10(b) shows good gating systems with streamlined gates and right-angle gates, with Fig. 10(a) producing the minimum amount of turbulence. Gates should enter the casting cavity at the lowest possible level in order to avoid the erosion and turbulence associated with a falling stream of molten metal. To ensure nonturbulent filling of the casting nearest to the sprue, its gate should be at least 50 mm (2 in.) away from the base of the sprue.

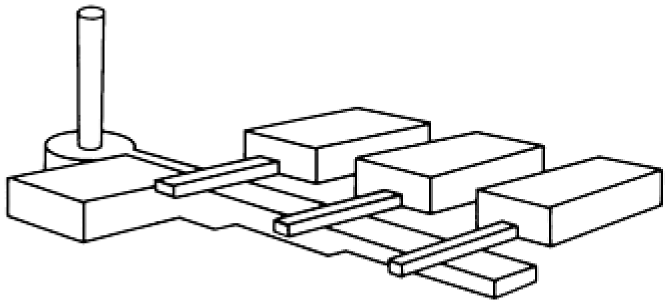

Fig. 12 Recommended multiple-cavity gating system with stepped runner.

Regardless of the excellence of a gating system design, castings of acceptable quality will not be produced if the ladle is not positioned as close as is practical to the pouring basin or sprue, and if the sprue is not filled quickly and kept at full capacity throughout the pour.

Knife and Kiss Gating Systems. Special applications of gating systems work in many cases for specific castings. Knife and kiss gating are popular when group III alloys are used but not recommended for groups I and II because these alloys form too much dross with this system and cannot be fed adequately to eliminate surface shrinkage. Advantages are a high casting yield, easy removal of runner systems, and minimum grinding of gates. The major disadvantage is that many small castings become detached during shakeout, necessitating their manual retrieval from mechanized systems. Figure 13 shows a graphic representation of the arrangement of knife and kiss gating. In kiss gating, the casting must be completely in the cope or the drag with the runner over-lapping the casting by 0.8 to 2.4 mm ($\frac{1}{32}$ to $\frac{3}{32}$ in.). Actually there is no gate in this system because the metal goes directly from the runner into the casting.

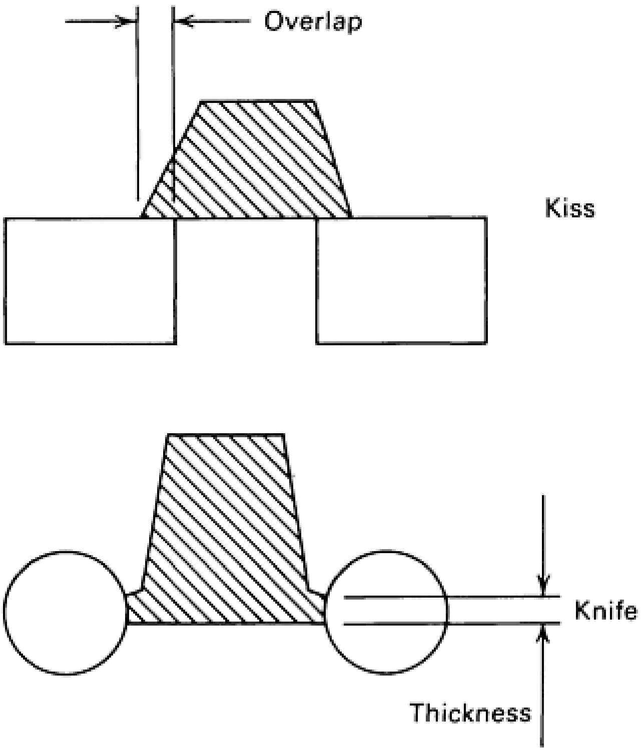

Fig. 13 Basic kiss and knife gates.

Knife gating is used when the casting is in both the cope and the drag and there is a contact at the parting line of 0.8 to 2.4 mm ($\frac{1}{32}$ to $\frac{3}{32}$ in.) thickness just at the casting surface. Knife gating systems work well when the runner is in just the cope or just the drag or in both the cope and the drag.

Maximizing Casting Quality. Excellent, clean, high quality castings may be obtained for the copper-base alloy groups of narrow, intermediate, and wide freezing range alloys if the basic principles discussed for the pouring basin, sprue, sprue base, chokes, pouring rates, runners, and gates are applied. By following these recommendations, the maximum ease in molding, casting yield, and ease of removal of gates and runners may be obtained.

Feeding

The objectives of feeding or risering are to eliminate surface sinks or draws and to reduce internal shrinkage porosity to acceptable levels (less than 1%).

To minimize porosity, the feeding system must establish:

- Directional solidification, as shown in Fig. 14, in which the solidification front is substantially V-shaped in a longitudinal cross section with the large end of the V directed toward the riser
- Steep temperature gradients along the casting toward the riser

The feeding techniques for group I (short freezing range) alloys and group II (medium freezing range) alloys can be discussed together. The basic principles of risering of group III (long freezing range) alloys will be described separately.

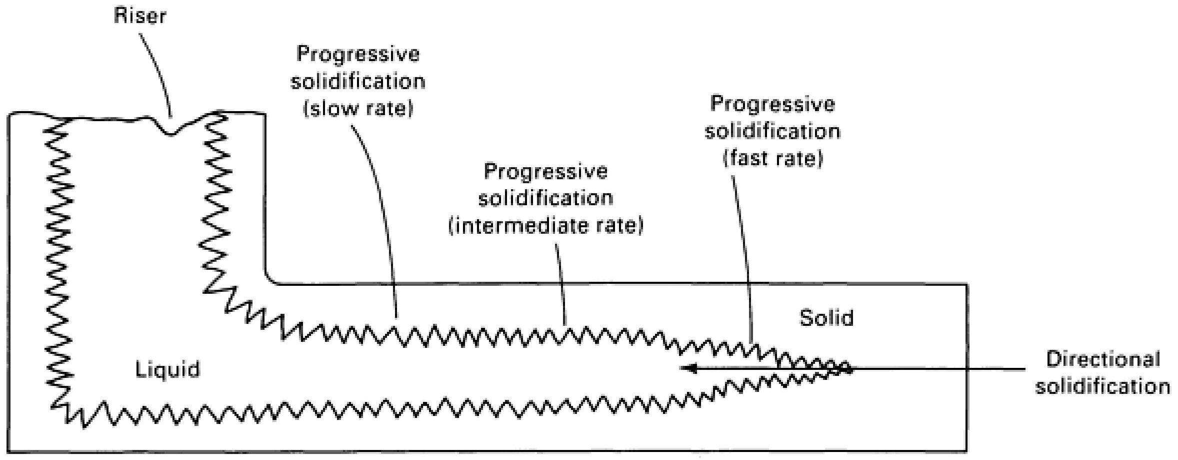

Fig. 14 Features of progressive and directional solidification. Source: Ref 2.

Group I and II Alloys

The feeding technique for these alloys is similar to that used in the manufacture of steel castings. Gates and risers are positioned such that directional solidification is ensured, with due consideration being given to the feeding range of the alloy in question. To avoid hot spots, local chills may be applied to bosses, ribs, and to other sections having sudden changes in thickness.

Solidification Contours. The first step in determining riser placement is to draw the solidification contours. This is illustrated by the hypothetical casting shown in Fig. 15, which consists essentially of a plate to which is attached a thinner section, C, and a boss, B. The thin end of the casting, C, would normally undergo rapid cooling after pouring as the result of edge-cooling effects. Thus, it is possible to place the riser at the heavy section, A, and gate through the riser to provide favorable temperature gradients. The dotted lines in Fig. 16 show successive positions of the solidification front. As shown, porosity will develop in the boss unless a chill is placed on the boss or the riser is relocated there. A chill is a block of metal or other material with a higher heat conductivity and heat capacity than sand.

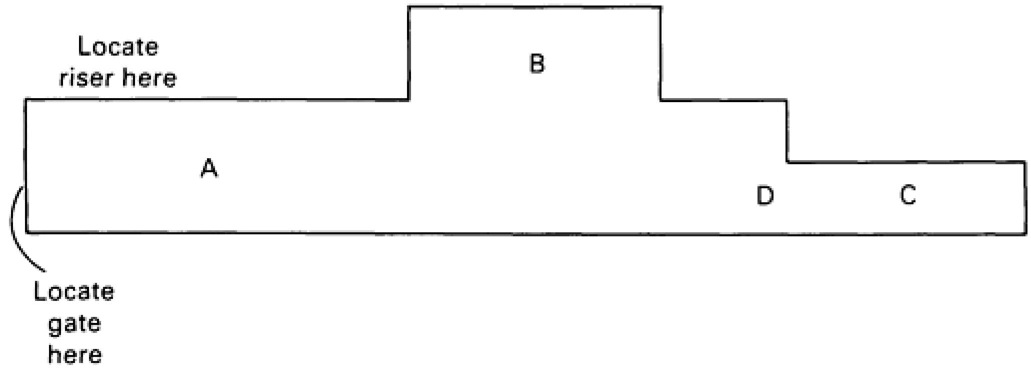

Fig. 15 Hypothetical casting used to illustrate the principles of feeding technique. Source: Ref 3.

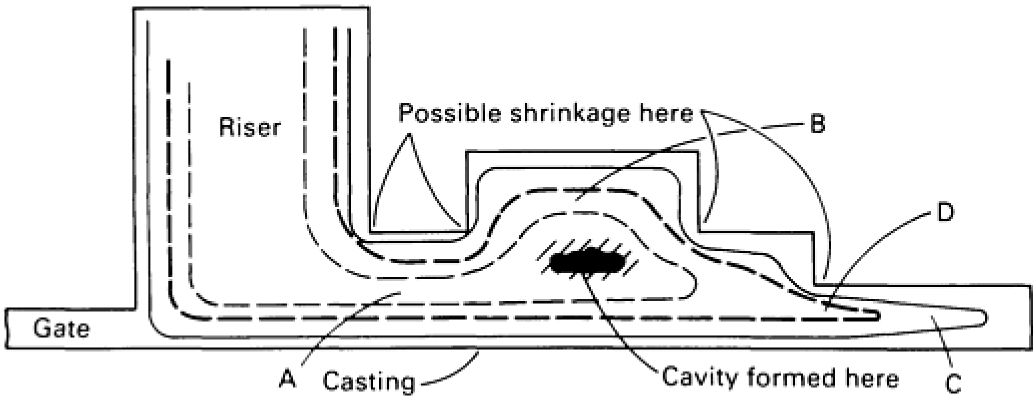

Fig. 16 Mode of freezing the casting in Fig. 15 without special precaution to avoid shrinkage. Source: Ref 3.

Feeding Ranges. The number and location of the feeders to be used must be consistent with the feeding range of the alloy. The feeding range is the distance that can be fed by a feeder on a bar or plate. It is generally desirable to divide the casting into a number of sections to determine the number of risers to be used. Because all parts of a casting must be within the feeding range of at least one of the risers, it is important to have quantitative information regarding feeding ranges. The feeding range values for group I and II copper-base alloys have not been well documented. In the absence of specific data for particular alloys, satisfactory results can often be attained by applying values that have been developed for carbon steels. The following approximate values for feeding ranges have been quoted in the literature, but should be used with caution:

Alloy	Shape	Feeding distance, T
Manganese bronze	Square bars	$4T$ to $10\sqrt{T}$, depending on thickness
	Plates	$5.5T$ to $8T$, depending on thickness
Aluminum bronze	Square bars	$8\sqrt{T}$

Nickel-aluminum bronze	Square bars	$<8\sqrt{T}$
Copper-nickel	Square bars	$5.5\sqrt{T}$

Use of chills can further increase feeding range. Consequently, the spacing between risers may be increased to about ten times the section thickness if chills are located midway between each pair of risers (Fig. 17).

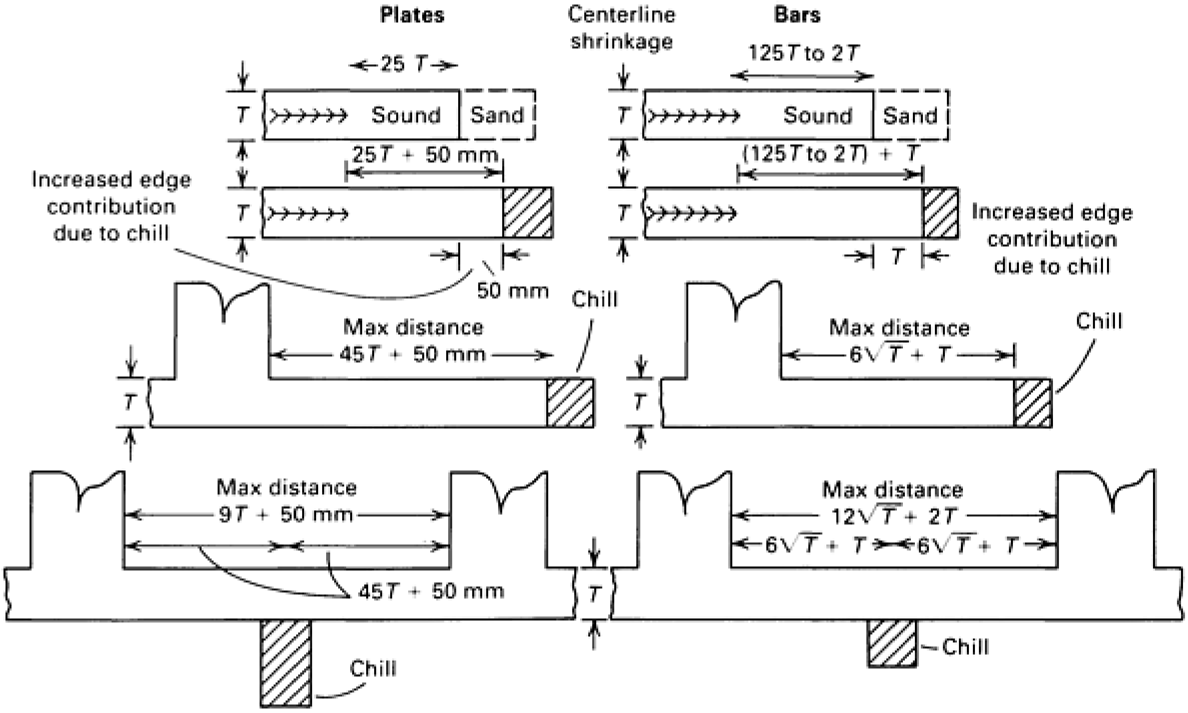

Fig. 17 Effect of chills in increasing feeding range of risers. Source: Ref 2.

Riser Size. From time to time, various methods have been proposed for the calculation of the optimum riser size to be used to feed a particular casting or casting section. One of the earlier methods was developed for steel castings at the Naval Research Laboratories (NRL). In this technique, an empirical "shape factor" defined as the length (*L*) plus the width (*W*) of the casting divided by the thickness (*T*), that is, $(L + W)/T$, is first determined. The correct riser size is obtained from a plot of V_R/V_C versus $(L + W)/T$, where V_R and V_C are the riser and casting volume, respectively.

Work sponsored by the American Foundrymen's Society has led to the development of a series of curves for aluminum bronzes, copper-nickel, and manganese bronzes (Fig. 18 19, 20, 21).

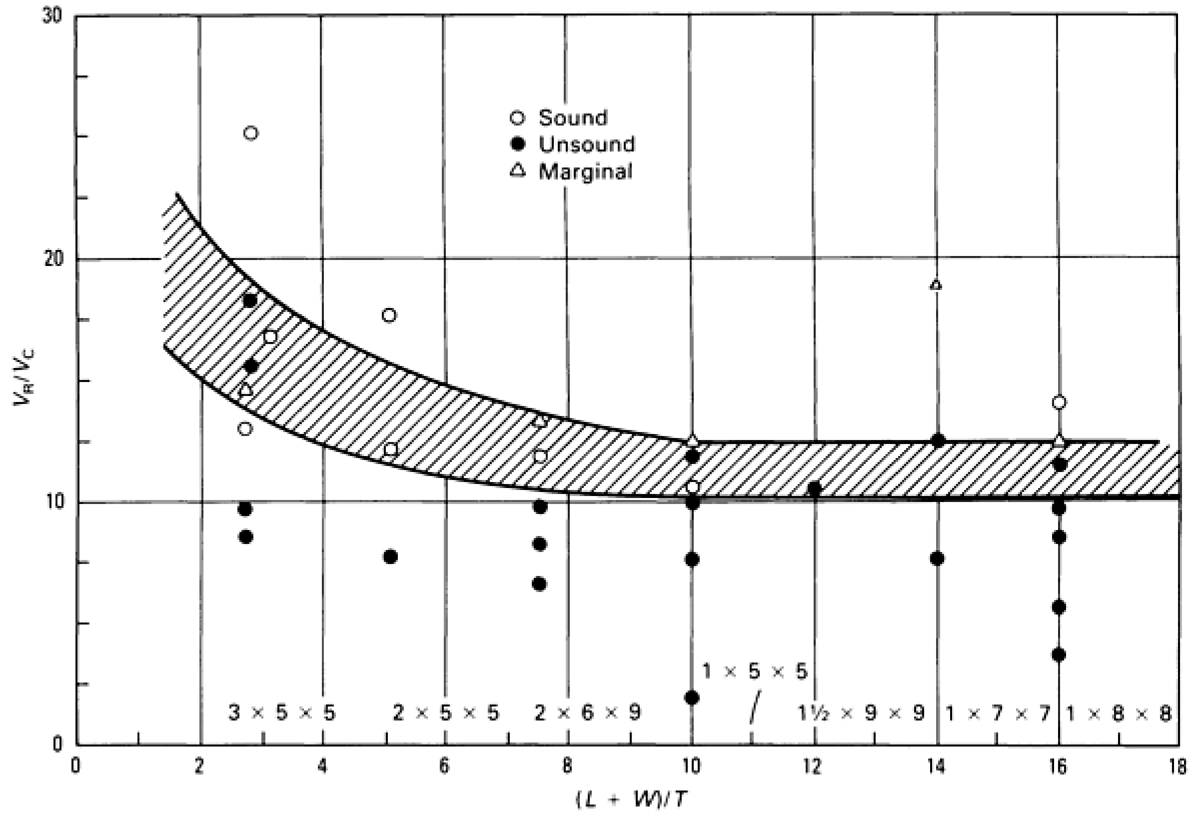

Fig. 18 Naval Research Laboratories (NRL)-type riser size curve for manganese bronze (alloy C86500). Source: Ref 4.

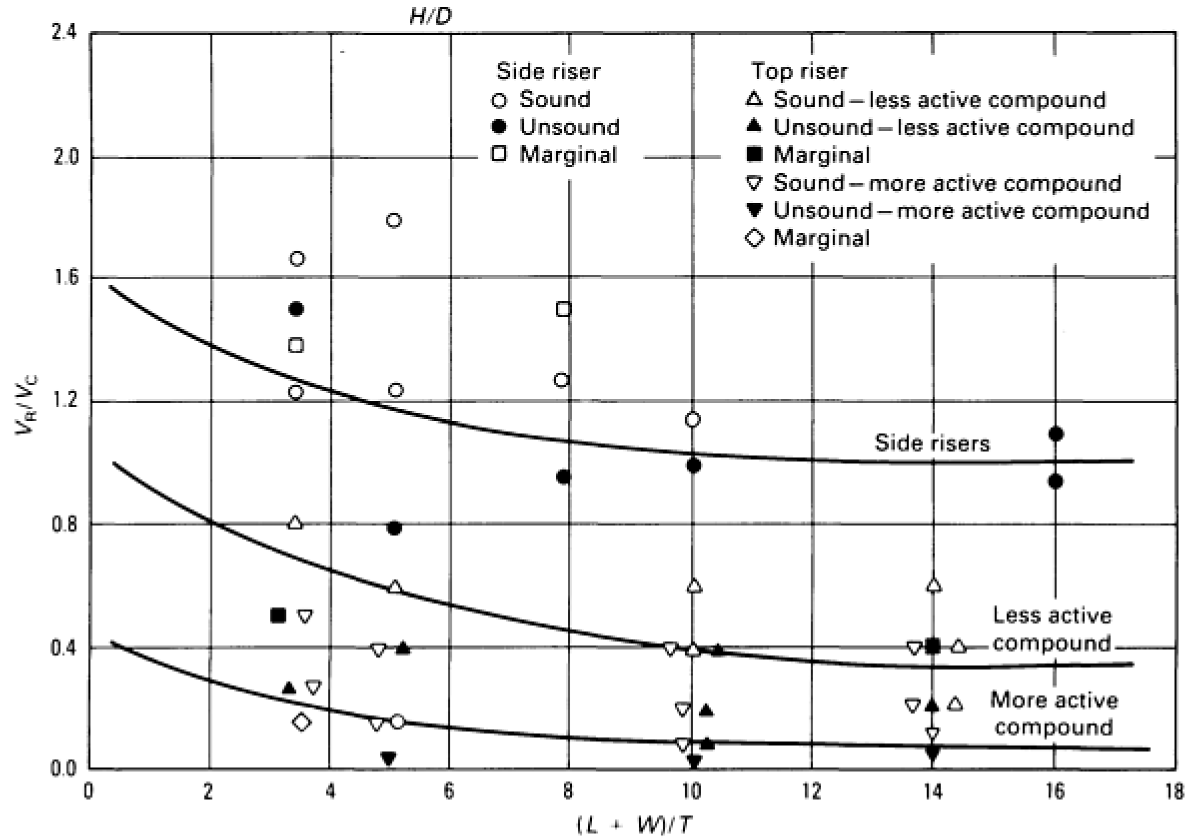

Fig. 19 NRL-type riser curve for manganese bronze (alloy C86500) using different types of exothermic hot topping and top risers. Source: Ref 5.

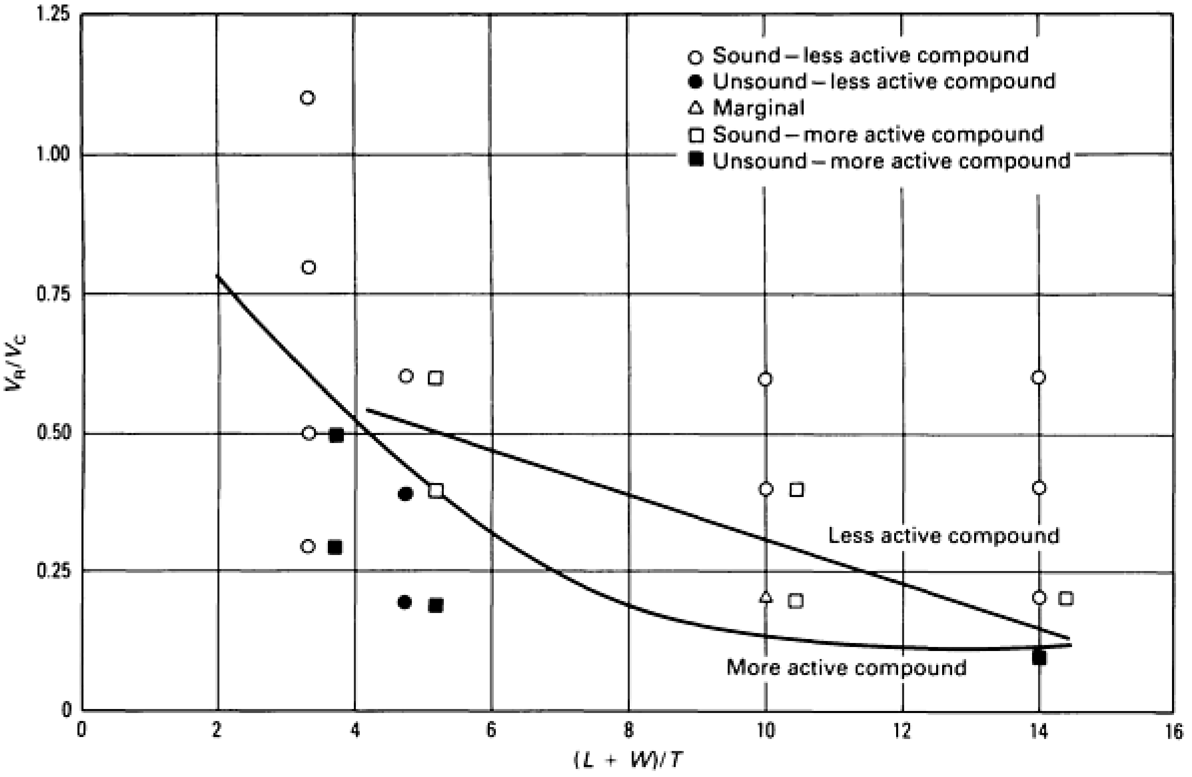

Fig. 20 NRL-type riser curve for aluminum bronze (alloy C95300) using different types of exothermic hot topping and top risers. Source: Ref 5.

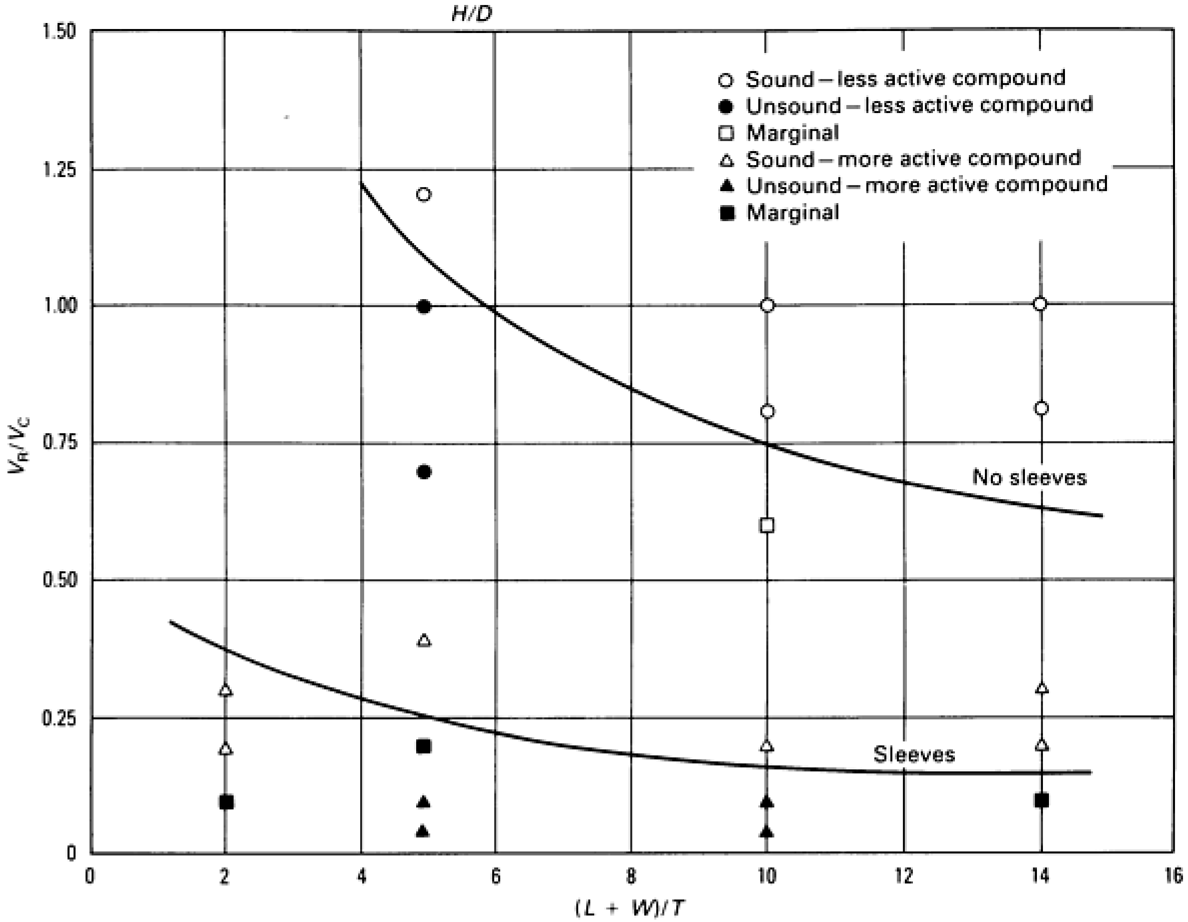

Fig. 21 NRL-type riser curve for Cu-30Ni (alloy C96400) using exothermic sleeves and hot topping versus hot topping alone. Source: Ref 5.

Figures 18, 19, 20, and 21 indicate that the riser volumes necessary for sound castings can be reduced and the effectiveness of feeding improved by the use of exothermic sleeves. Insulating sleeves also can be used to increase the effectiveness of the risers. Exothermic sleeves, which were once popular, have now largely been discontinued in favor of insulating sleeves, which are more economical to use and cause fewer problems.

In recent years, greater attention has been given to what has become known as the modulus method for calculating riser size, which includes the development of pertinent data and computer programs to check that riser volume is adequate. This method is now, and no doubt will continue to be, the most widely used technique in the industry.

Chvorinov's rule states that the freezing time, t, of a cast shape is given by the relationship:

$$t = k \cdot (V/A)^2 \qquad \textbf{(Eq 1)}$$

where V and A are the volume and surface area, respectively, of the cast shape, and k is a constant proportionality whose value is dependent on the thermal properties of the metal and the mold. For additional information on the thermal properties of copper, see the article "Aluminum-Base and Copper-Base Alloys" in this Volume.

For convenience, the term (V/A) in Chvorinov's equation is generally replaced by the symbol M, a value referred to as the modulus of the shape. Equation 1, above, can be rewritten more simply to read:

$$t = k \cdot M^2 \qquad \textbf{(Eq 2)}$$

Because Chvorinov's equation can be applied to any cast shape, it applies equally to that which is intended to be the casting itself and to the attached riser. With connected shapes, such as a riser and a casting, the surface area of each shape to be considered includes only those portions that contribute to the loss of heat during freezing.

For the riser to be effective in feeding, its solidification time, t_R, must be greater than the solidification time, t_C, for the casting. This can be written:

$$\frac{t_R}{t_C} = \frac{k.M_R^2}{k.M_C^2} = F^2 \text{ or } M_R^2 = F^2.M_C^2 \qquad \textbf{(Eq 3)}$$

Further simplified, this becomes:

$$M_R = F \cdot M_C \qquad \textbf{(Eq 4)}$$

This means that the modulus for the riser, M_R, must be greater than the modulus for the casting, M_C, by some factor, F. Experience has shown that the proper value of F depends on the metal being cast. A value of about 1.3 is preferred for the short freezing range copper-base alloys.

As a practical working equation, therefore, we may say that with these alloys the modulus of the riser should be about 1.3 times that of casting (or casting section) to be fed, or:

$$M_R = 1.3\ M_C \qquad \textbf{(Eq 5)}$$

Equation 5 merely gives us an empirical way of proportioning a riser so that it freezes more slowly than the casting. The other basic requirement of any riser is that it must have sufficient volume to provide the necessary amount of feed metal to the casting or casting section to which it is attached. These values can be calculated if necessary; however, it is much easier (though less precise) to use data of the type shown in Table 6. The numbers listed in the table indicate the minimum values for the ratio between riser volume and casting volume (as percentages) to ensure that the riser can, indeed, supply the necessary amount of feed metal to the casting. Five general classes of castings are shown, ranging from "very chunky" to "rangy." Notice that risers having a height-to-diameter ratio (H/D) of 1:1 are more efficient than when the H/D is 2:1. More important, it can be seen that insulated risers are far more efficient than those formed directly in the sand mold.

Table 6 Minimum volume requirements of risers

Type of casting	**Minimum V_R/V_C, %**			
	Insulated risers		**Sand risers**	
	***H/D* = 1:1**	***H/D* = 2:1**	***H/D* = 1.1**	***H/D* = 2.1**
Very chunky; cubes, and so on; dimensions in ratio 1:1.33:2[a]	32	40	140	198
Chunky; dimensions in ratio 1:2:4[a]	26	32	106	140
Average; dimensions in ratio 1:3:9[a]	19	22	58	75
Fairly rangy; dimensions in ratio 1:10:10[a]	13	15	30	38

Rangy; dimensions in ratio 1:15:30 or larger[(a)]	8	9	12	14

Source: Ref 2

(a) Ratio of thickness:width:length.

Feeder Shape. One of the requirements of the riser is to remain liquid longer than the casting; that is, from Chvorinov's rule:

$$(V/A)_R > (V/A)_C \qquad \textbf{(Eq 6)}$$

The shape with the highest possible *V*/*A* ratio is the sphere. However, spherical risers are rarely used in industry because of molding considerations.

The next best shape for a riser is the cylinder. The *H*/*D* for cylindrical risers is in the range of 0.5 to 1.0.

Riser Neck Dimensions. The ideal riser neck should be dimensioned such that it solidifies after the casting but slightly before the riser. With this arrangement, the shrinkage cavity is entirely within the riser, this being the last part of the casting-riser combination to solidify.

Specific recommendations for the dimensions of riser necks are contained in the literature for ferrous alloys. These should apply to short freezing range copper alloys and are given in Table 7.

Table 7 Riser neck dimensions

Type of riser	Length, L_N	Cross section
General side	Short as feasible, not over *D*/2	Round, $D_N = 1.2\ L_N + 0.1D$
Plate side	Short as feasible, not over *D*/3	Rectangular, H_N = 0.6 to 0.8*T* as neck length increases. $W_N = 2.5\ L_N + 0.18D$
Top	Short as feasible, not over *D*/2	Round, $D_N = L_N + 0.2D$

Source: Ref 6

(a) L_N, D_N, H_N, W_N: length, diameter, height, and width of riser neck, respectively. *D*, diameter of riser. *T*, thickness of plate casting.

Hot Topping. About 25 to 50% of the total heat from a copper-base alloy riser is lost from the exposed surface by radiation. In order to minimize this radiation loss and thereby increase the efficiency of the riser, some sort of cover should be used on the top surface. Any cover, even dry sand, is better than nothing at all. A reliable exothermic hot topping is one form of usable cover.

Chills. The heat abstraction of the mold walls can be increased locally by the use of chills. Though expensive, metal chills are particularly effective because they reduce the solidification time by a factor of more than 55. As mentioned earlier, chills can be used to increase feeding distances and thereby reduce the number of feeders required. When it is impractical to attach feeders at certain locations, chills are particularly useful for initiating directional solidification, for example, at junctions, and so on, which would otherwise be porous.

Padding. The process of solidification can also be controlled by means of padding. Padding is the added section thickness (usually tapered) to promote directional solidification, and the bulk of it should be as close to the riser as possible.

Interaction of Gates and Risers. The effectiveness of side risers can be increased considerably by using a gating system that enters the mold cavity through the riser. The advantages of this arrangement are:

- Cleaner molten metal enters the mold cavity
- Because the metal in the riser remains liquid for a longer time, steep thermal gradients are established to improve the soundness of the casting

Detailed information on computer programs for pouring and gating can be found in the Section "Computer Applications in Metal Casting" of this Volume, particularly in the articles "Modeling of Solidification Heat Transfer" and "Modeling of Fluid Flow."

Group III--Wide Freezing Range Alloys

The "workhorse" alloys of the copper-base group are the leaded red brasses and tin bronzes, virtually all of which have wide freezing ranges. These alloys have practically no feeding range, and it is extremely difficult to get fully sound castings. The average run of castings in these alloys contains 1 to 2% porosity. Only small castings may exhibit porosity below 1%. Attempts to reduce it more by increasing the size of the risers are often disastrous and actually decrease the soundness of the casting rather than increase it.

Experience has shown that success in achieving internal soundness depends on avoiding slow cooling rates. The foundryman has three possible means for doing this, within the limitations of casting design and available molding processes:

- Minimize casting section thickness
- Reduce and/or evenly distribute the heat of the metal entering the mold cavity
- Use chills and mold materials of high chilling power

In order to produce relatively sound castings, the following points should be considered.

Directional solidification, best used for relatively large, thick castings, can be promoted in various ways:

- Gate into hot spot
- Riser into hot spot
- Ensure that riser freezes last (consider riser size, insulation, and chills)
- Promote high thermal gradients by the use of chills, preferably tapered chills unless casting section is light (less than 12.5 mm, or $\frac{1}{2}$ in. thick)
- Make sure risers are not so large that they unduly extend the solidification time of the casting, which would generate porosity beneath or behind the riser

Uniform solidification, best used for smaller, thin wall castings, can be promoted in various ways:

- Gate into cold spots, using several gates for uniform temperature distribution
- Use no risers, except perhaps on gate areas
- Use chills on hot spots to ensure that they cool at the same rate as the rest of the casting
- Use chills on areas that must be machined, thereby moving porosity to areas where the cast skin will be left unmachined; that is, maintain pressure tightness

- Gate into areas away from machined sections to maintain pressure tightness
- Use low pouring temperature (care should be taken to avoid misruns)
- See whether increased gas content (no degassing, reduced deoxidation) or induced metal mold reaction increases pressure tightness
- Make castings as thin as possible to increase cooling rate and reduce machining

Heat Treatment

The only copper-base alloys susceptible to heat treatment are beryllium copper alloys, chromium copper alloys, and aluminum bronze alloys containing more than 10% aluminum.

Beryllium copper alloys can be heat treated by solution treating and aging. Solution-treating temperature limits must be observed if optimum properties are to be obtained from the precipitation hardening treatment. Exceeding the upper limit causes grain growth, which results in a brittle metal that does not fully respond to precipitation hardening. Solution heating below the specified minimum temperature results in insufficient solution of the beryllium rich phase, a cause of lower hardness after precipitation hardening.

After castings are solution treated, they are quenched in water. All castings, except those of alloy C82000, may be solution heated in air and water quenched immediately after removal from the furnace. Alloy C82000 must be solution treated in a protective atmosphere such as cracked ammonia or natural gas. The duration of solution treating depends on section thickness. For castings greater than 25 mm (1 in.) in thickness, the time depends on section thickness.

Following solution heating, the castings are precipitation hardened. Table 8 shows the heat-treating cycles for beryllium copper alloys.

Table 8 Heat treatment of beryllium copper alloys

Alloy	Solution heat treatment	Aging treatment
C81400	1 h at 980-1010 °C (1800-1850 °F)	2 h at 480 °C (900 °F)
C82000	1 h at 915-925 °C (1675-1700 °F)	3 h at 480 °C (900 °F)
C82200	1 h at 925 °C (1700 °F)	3 h at 455 °C (850 °F)
C82400	1 h at 800-815 °C (1475-1500 °F)	3 h at 345 °C (650 °F)

C82500	1 h at 800-815 °C (1475-1500 °F)	3 h at 345 °C (650 °F)
C82600	1 h at 800-815 °C (1475-1500 °F)	3 h at 345 °C (650 °F)
C82800	1 h at 800-815 °C (1475-1500 °F)	3 h at 345 °C (650 °F)

Chromium Copper. This alloy of Cu-1Cr can be heat treated in the same manner as beryllium copper. Here the solution treatment is 1 h at 980 to 1015 °C (1800 to 1860 °F), followed by a water quench. Next, the castings are precipitation hardened at 500 °C (930 °F) for 2 h. Because chromium is sensitive to oxidation, a protective atmosphere should be used to avoid an oxidized zone of approximately 3.05 mm (0.12 in.) on the casting surface. If heat treating is done in an air furnace, the castings must be machined after treatment to remove this oxide in order to obtain accurate conductivity and hardness measurements.

Aluminum bronze casting alloys containing more than 10% aluminum are heat treatable. These are alloys whose normal microstructures contain more than one phase to the extent that beneficial quench and temper treatments are possible. The copper aluminum alloys normally containing iron are heat treated by procedures somewhat similar to those used for heat treatment of steel, and have isothermal transformation diagrams that resemble those of carbon steels. For these alloys, the quench-hardening treatment is essentially a high-temperature soak intended to dissolve all of the α phase into the βphase. Quenching results in a hard room-temperature β martensite, and subsequent tempering reprecipitates fine α needles in the structure, forming a tempered β martensite. Table 9 shows typical heat treatments for three major aluminum bronze alloys.

Table 9 Heat treatment of aluminum bronze alloys

Alloy	Solution treatment	Tempering treatment
C95300	2 h at 900 °C (1650 °F)	1 h at 540-595 °C (1000-1100 °F)
C95400	2 h at 900 °C (1650 °F)	1 h at 565-620 °C (1050-1150 °F)
C95500	2 h at 900 °C (1650 °F)	1 h at 565-620 °C (1050-1150 °F)

Specific Applications

Copper alloy castings are used in applications that require superior corrosion resistance, good bearing-surface qualities, high thermal or electrical conductivity, and other special properties. These applications may be divided into six principal groups:

- Plumbing hardware, pump parts, and valves and fittings
- Bearings and bushings
- Gears
- Marine castings
- Electrical components

- Architectural and ornamental parts

Figure 22 illustrates the wide variety of intricate shapes and sizes into which copper and its alloys are typically cast.

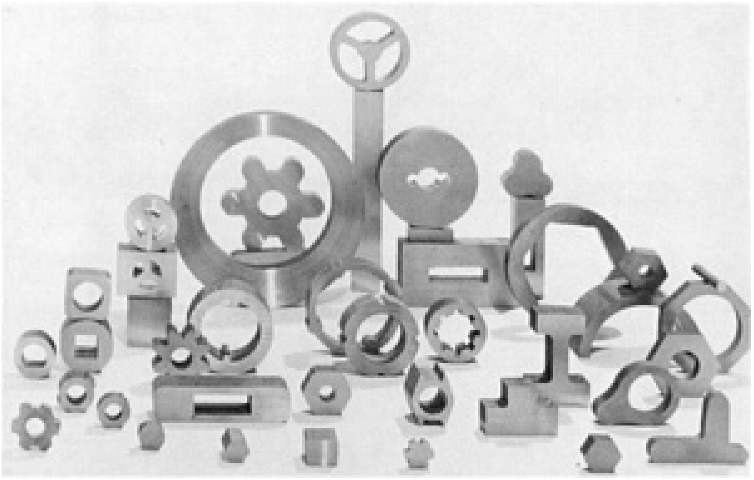

Fig. 22 Variety of intricate shapes and sizes obtained by using continuous casting methods to produce brass and bronze alloy parts. Courtesy of ASARCO, Inc.

Plumbing Hardware, Pump Parts, Valves, and Fittings. The requirements for such fluid-handling components are pressure tightness to avoid leakage; reasonable mechanical strength at low, room, and high temperatures to avoid bursting; good corrosion resistance; and ease of machining. In addition, for a pleasing appearance, as in water fixtures, the parts must be easily platable.

Plumbing fixtures and pump parts for the waterworks industry are usually produced in red brasses and semired brasses (alloys C83300 to C84800). Yellow brass (C85200) is sometimes used to cast plumbing fixtures. Similarly, pump parts are cast in silicon bronze (C87200).

A variety of alloys, however, are used to produce valves and fittings. These alloys are specified in ASTM B 763, and the list includes leaded red brasses, leaded semired brasses, silicon bronzes, silicon brasses, tin bronzes, leaded tin bronzes, high-leaded tin bronzes, nickel-tin bronzes, leaded nickel-tin bronzes, aluminum bronzes, leaded nickel bronzes, and so on.

Parts that do not require high strength are usually produced in red brasses, semired brasses, tin bronzes, and so forth, but when higher strength is required, the nickel-tin bronzes, high-strength yellow brasses, and so on, are preferred. For example, the valve stem in a control valve is cast in nickel-tin bronze (alloy C94700), whereas the facing is cast in alloy C83600 (Fig. 23).

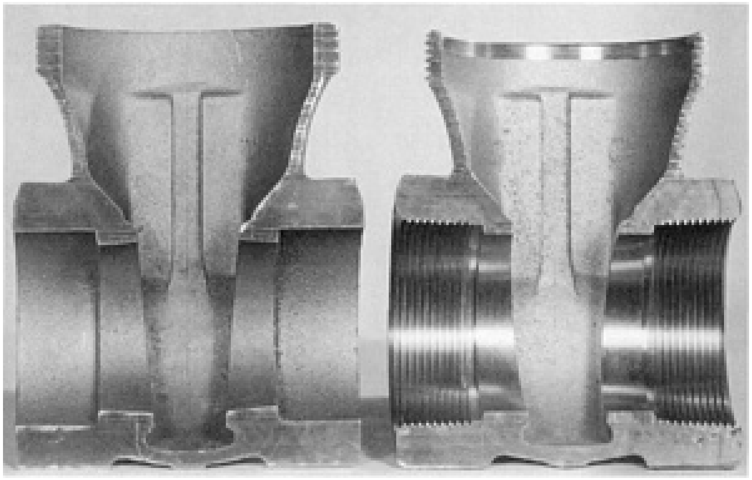

Fig. 23 Cutaway views of an as-cast and finish machined/threaded body of a 50 mm (2 in.) gate valve-union bonnet assembly rated at 1.0 MPa (150 psi). The body section was sand cast of C83600 alloy (Cu-5Sn-5Pb-5Zn composition) and weighs 2.4 kg (5.2 lb). Courtesy of Crane Company.

Equipment for handling more corrosive fluids, such as crude oil and salt water encountered in the oil field industry, is different from that of the waterworks industry. The requirements are corrosion resistance, pressure tightness, and better mechanical properties. The aluminum bronzes are widely used in the oil field industry to meet these requirements. Similar specifications apply to valves used in hydroelectric generating plants (Fig. 24). One such example is the reciprocating pump, in which all areas exposed to the corrosive fluids being pumped are made of aluminum bronzes (C95300 or C95800). Check valves and diaphragm backs for use in oil wells and chemical-processing equipment are cast in nickel-tin bronze (C94700).

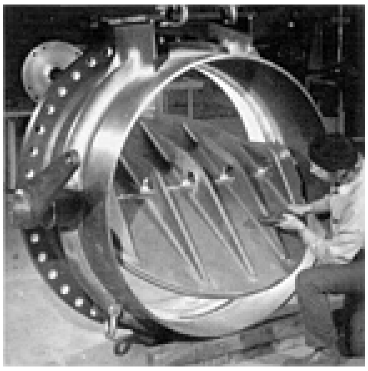

Fig. 24 A 1.37 m (54 in.) diam aluminum bronze stop valve for power generation cooling loop applications using a centrifugally cast body and a sand cast disc assembly. Seating surface is cold-rolled plate welded to the valve body with aluminum bronze spooled wire. Courtesy of Ampco Metal.

The requirements for pressure-tight valves and fittings for different gases are higher than those for liquids. Such components can still be produced in the semired brass (C83600). However, care must be exercised in the casting process to ensure that shrinkage porosity is avoided.

Pump parts, valves, and fittings are also produced for marine application. Alloys used for such applications are discussed in the section "Marine Castings" in this article.

Bearings and Bushings. Copper alloys have long been used for bearings because of their combination of moderate-to-high strength, corrosion resistance, and either wear resistance or self-lubrication properties. The choice of an alloy depends on required corrosion resistance and fatigue strength, rigidity of backing material, lubrication, thicknesses of bearing material, load, speed of rotation, atmospheric conditions, and other factors. Copper alloys may be cast into plain bearings, cast on steel backs, cast on rolled strip, made into sintered powder metallurgy shapes, or pressed and sintered onto a backing material.

Three groups of alloys are used for bearings and wear-resistant applications:

- Phosphor bronzes (copper-tin)
- Copper-tin-lead (low-zinc) alloys
- Manganese, aluminum, and silicon bronzes

Some of these applications are described below.

Phosphor bronzes (copper-tin-phosphorus or copper-tin-lead-phosphorus alloys) have residual phosphorus, ranging from a few hundredths of 1% (for deoxidation and slight hardening) to a maximum of 1%, which imparts great hardness. Often nickel is added to refine grain size and disperse the lead. Phosphor bronzes of higher tin content, such as C91100 and C91300, are used in bridge turntables, where loads are high and rotational movement is slow.

High-leaded tin bronzes are used when a softer metal is required at slow-to-moderate speeds and at loads not exceeding 5.5 MPa (800 psi). Alloys of this type include C93200, C93500, C93700, and C94100. C93700 is widely used in machine tools, electrical and railroad equipment, steel mill machinery, and automotive applications. Alloys C93200 and C93500 are less costly than C93700 and are used chiefly for replacement bearings in machinery. Alloy C93800 (15% Pb) and C94300 (24% Pb) are used when high loads are encountered under conditions of poor or nonexistent lubrication; under corrosion conditions, such as in mining equipment (pumps and car bearings); or in dusty atmospheres, as in stone-crushing operations and cement plants. These alloys replace the tin bronzes or low-leaded tin bronzes when operating conditions are unsuitable for alloys containing little or no lead.

Aluminum bronzes with 8 to 9% Al are used widely for bushings and bearings in light-duty or high-speed machinery. Aluminum bronzes containing 11% Al, either as cast or heat treated, are suitable for heavy-duty service (such as valve guides, rolling mill bearings, nuts, and slippers) and precision machinery applications.

Gears. When gears are highly loaded and well lubricated, the tin bronzes and nickel-tin bronzes are used. Specification ASTM B 427 gives the chemical compositions and mechanical properties of the five commonly used alloys; namely, C90700, C90800, C91600, C91700, and C92900. These are particularly advantageous when operating against hardened steel. It appears that the dispersion hardening of the δ phase in a solution-hardened matrix (by tin) provides the required strength. There is enough ductility to permit corrosion of minor misalignment with the hard steel mating part. Also, because of the dissimilarity of materials, no galling or scuffing is encountered.

When lubrication is irregular or omitted as in chemical applications, leaded materials are used. One such alloy is the leaded nickel-tin bronze containing Cu-20Pb-5Ni-5Sn. For gears exposed to harsh atmospheric conditions, manganese bronze (alloy 86500) has been successful.

Some typical applications are worm gears for rolling mills (alloy C91700), worm gears for oil well equipment (alloy C90700), and gearing of the stripper crane that removes the ingot from the ingot mold in the steel making industry (alloy C91700). Aluminum bronze is also used in worm gear applications (Fig. 25).

Fig. 25 Centrifugally cast aluminum bronze worm gear blanks being inspected. Courtesy of Wisconsin Centrifugal, Inc.

Marine Castings. The selection of materials for marine applications such as ship construction, desalination plants, and so forth, is governed by surrounding corrosive environments, which may include salt water, fresh water, or various corrosive cargoes such as oils, chemicals, and so on. Copper alloys generally give the greatest service life per dollar because of their excellent corrosion resistance in fresh water, salt water, alkaline solutions (except those containing ammonia), and many organic chemicals. The most commonly used alloys are the high-strength copper-nickels (both Cu-

10Ni and Cu-30Ni, that is, alloys C96200 and C96400), aluminum bronzes (especially the nickel-aluminum bronze, alloy C95800, and manganese-nickel-aluminum bronzes, alloy C95700), and manganese bronzes (alloys C86100, C86200, C86400, C86500, and C86800). These are used in pump bodies, valves, tees, elbows, propellers (Fig. 26), propeller shafts, propeller hubs (Fig. 27), hull gear, impellers, turbines, and the like. A new addition to the group of copper-nickels is alloy IN768, which contains chromium instead of niobium, as in alloys C96200 and C96400.

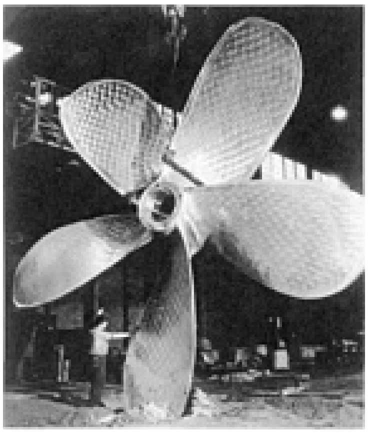

Fig. 26 Propeller for a 114,000 ton tanker measures 7.5 m (24.7 ft) in diameter and weighs 37.52 Mg (82,725 lb). Part was machined and polished from a single 53.75 Mg (118,500 lb) nickel-aluminum bronze casting. Courtesy of Baldwin-Lima-Hamilton Corporation.

Fig. 27 Vertical centrifugally cast ship propeller hub for controllable-pitch propeller blades is made of nickel-aluminum bronze, weighs 8.44 Mg (18,600 lb), and measures 1575 mm (62 in.) in diameter and 1270 mm (50 in.) in length. Courtesy of Wisconsin Centrifugal, Inc.

The most important alloys to cast propellers are the nickel-aluminum bronzes (C95800), manganese-nickel-aluminum bronzes (C95700), and manganese bronzes or high-strength yellow brasses (C86500). Manganese bronze propellers dezincify in salt water, and the aluminum bronzes should be preferred for such applications. Bearings for propellers and ship rudders, however, are produced in tin and leaded-tin bronzes such as alloys C90500 and C92200.

Electrical Components. Copper and copper alloys are used extensively in the electrical industry because of their current-carrying capacity. They are used for substation, transformer, and pole hardware components for power transmission, plating and welding of electrical-equipment parts, and turbine runners for hydroelectric-power generation.

Cast copper is soft and low in strength. Increased strength and hardness and good conductivity can be obtained with heat-treated alloys containing beryllium, nickel, chromium, and so on, in various combinations.

Pure copper and beryllium copper are used to cast complex shapes for current conductors, often with water-cooled passages. Conductivity of the fittings is not important, the principal requirements being corrosion resistance and strength. Such fittings can be produced in leaded red brasses (alloys C83300 or C83600), heat-treated nickel-tin bronze (alloy C94700), or manganese bronze (alloy C86500).

Beryllium copper (alloy C82500) is also used to cast carriers for plating work and a variety of shapes and sizes for the welding industry.

Aluminum bronzes are the most important alloys for producing components for the hydroelectric-power generation plants because of their good corrosion resistance. Although parts have been produced from alloys C95200 and C95400, heat-treated nickel-aluminum bronze (alloy C95800) and manganese-nickel-aluminum bronzes (alloy C95700) are the most useful because of their resistance to dealuminification.

Architectural and Ornamental Applications. The aesthetic applications of copper-base alloys in artistic, musical, and ornamental work are due to their excellent corrosion resistance, remarkable castability, and variety of colors. Bronze statues are cast in silicon bronze alloy (UNS C87200) because it has good fluidity and is free from pitting and corrosion, and the development of an adherent patina reduces the corrosion rate. Figure 28, a bronze casting which dominates the lobby of a federal building in Washington, D.C., shows the fine detail which can be produced using copper in ornamental applications. For this reason, yellow and leaded yellow brasses (alloys C85200, C85300, C85400, C85500, and C85700) are also used for a variety of internal and external hardware. Church bells are usually cast in copper-tin alloys containing about 19% Sn. These alloys contain a network of the brittle δ phase in the matrix, which reduces the damping capacity and produces a better tone.

Fig. 28 Twelve foot high bronze sand casting of the Great Seal of the United States located in lobby of the Federal Deposit Insurance Corporation building in Washington, D.C. Weight, 1.8 Mg (4000 lb).

A complete range of colors, from red to bronze and gold to silvery yellow and silver can be obtained by adjusting the composition. The artist can take advantage of these color combinations to produce ornamental castings such as door handles in red and semired brasses (C83600 and C84400), yellow and leaded yellow brasses, and nickel silvers (alloys C97300, C97400, C97600, and C97800).

Zinc and Zinc Alloys

Dale C.H. Nevison, Zinc Information Center, Ltd.

Introduction

DIE CASTING is the process most often used for shaping zinc alloys. The most commonly used zinc die casting alloys are UNS Z33521 (Alloy 3) and a modification of this alloy (UNS Z33522) distinguished by the commercial designation 7 instead of 3. The compositions of these alloys are given in Table 1, while the mechanical properties of zinc casting alloys are compared to those of other materials in Table 2. Although Alloy 3 is more frequently specified, the properties of the two alloys are generally similar. The second alloy listed in Table 1 (UNS Z35531) is used when higher tensile strength and/or hardness is required.

To address the increasing demand for high-performance high-quality die castings, a new family of zinc-base engineering casting alloys has been developed. For the last few years, market development emphasis for these alloys has focused on gravity casting, for which they have found increasing acceptance as engineering materials that provide superior properties, outstanding field performance, and excellent cost savings. Alloys such as aluminum, brass, bronze, and cast and malleable iron have been substituted in uses ranging from plumbing fixtures, pumps, and impellers to automotive vehicle parts and, recently, bronze bearing substitutes.

Three members of this family of alloys are generically identified industry-wide as ZA-8, ZA-12, and ZA-27. The composition is zinc plus aluminum, with small amounts of copper and magnesium.

The numerical components of the alloy designation indicate the approximate aluminum content. Small amounts of copper and magnesium are also added to produce the best combination of properties, stability, and castability. Commercial acceptance of ZA alloys has resulted in the issuance of national and international standards under ASTM B 669.

Alloy ZA-8 is the preferred choice for permanent mold casting, and it can be hot chamber die cast, providing further cost benefits. It offers excellent machinability, is antisparking, and has the best finishing characteristics for decorative parts.

Alloy ZA-12 is the general-purpose alloy, and it is often the first choice when converting from iron, brass, or aluminum. Usually cast in sand molds, it also performs well in graphite permanent molds and can be cold chamber die cast. The alloy has excellent pressure tightness, is antisparking, and is easily machined. There is growing evidence that ZA-12 has excellent bearing and wear characteristics.

Alloy ZA-27 is the ultrahigh-performance material, offering the highest strength and elongation. It is generally cast in sand molds, and like ZA-12 can be cold chamber die cast. It has excellent machinability and shows considerable promise for bearing and wear applications.

Die cast ZA-8, ZA-12, and ZA-27 alloys provide significant improvements in mechanical properties over current zinc materials. The ZA-8 alloy has been successfully used in the hot chamber die cast process; however, ZA-12 and ZA-27 alloys are usually cast using the cold chamber process.

The ZA alloys deliver the highest strength among the most widely used nonferrous alloys and match or exceed the strength of some cast irons. Ultimate tensile strengths range up to 441 MPa (64 ksi), depending on alloy and condition. Tensile yield strengths are as high as 379 MPa (55 ksi), which is roughly twice that of most commonly used casting alloys.

All three ZA alloys show hardness superior or equivalent to that of aluminum, brass, and bronze. This high hardness usually results in improved wear resistance and resistance to galling.

The allowable design stress or resistance to creep of the ZA alloys is significantly better than that of conventional zinc die casting alloys. The room-temperature design stress of ZA-27, for example, is approximately 90 MPa (13 ksi). Resistance to sustained loads allows for their use in many stressed applications at temperatures to 120 to 150 °C (250 to 300 °F).

The ZA-12 and ZA-27 alloys can provide equivalent, and in many cases superior, performance compared to the traditional cast bearing bronzes at a significantly lower cost. High load-carrying capacity, low wear rate, and good emergency running capability are well documented for high-load, low-speed, lubricated journal bearing conditions.

The 3, 5, 7, and ZA-8 and ZA-12 alloys are considered nonincendiary and spark-proof. This characteristic means that these zinc alloys will not ignite hazardous fuel-air mixtures, vapors, or particulate matter when struck by rusted ferrous materials. The nonmagnetic properties of zinc make it suitable for use in electronics and for delicate moving parts that would otherwise be adversely affected by magnetic disturbances.

Zinc-base alloys have good corrosion resistance in normal atmospheric conditions, in aqueous solutions, and when used with petroleum products. The corrosion resistance is enhanced by painting, plating, or chromate or phosphate treatment and is substantially improved by anodizing.

The ZA alloys readily accept a wide variety of decorative and corrosion-resistant surface finishes. Low cost components are painted to match adjacent parts, chromium plated to offer a durable luster (except ZA-27), and brush finished to take on the rich appearance of brass, bronze, or stainless steel at a fraction of the cost. Anodizing produces a thin, ceramiclike, abrasion-resistant film exhibiting excellent resistance to most natural and industrial corrosive materials.

Zinc die castings ranging in weight from a fraction of an ounce to 23 kg (50 lb) have been successfully produced. However, most zinc die castings comprise a wide variety of hardware items having weights near the low end of the above range.

Control of Alloy Composition

Zinc alloys for die casting are sensitive to variations in composition and impurity levels--generally more so than aluminum alloys. However, limitations on the permissible amounts of added elements or impurities in zinc are liberal enough that a reasonable program of control and generally sound shop practice are sufficient to maintain adequate consistency in alloy composition.

Agitation. Although agitation during melting will not affect alloy composition, it results in melt oxidation and should therefore be minimized. Overheating often results in loss of aluminum and magnesium through oxidation and in an increase in iron due to a decrease in the scavenging action provided by aluminum.

Use of Foundry Scrap. Clean scrap of acceptable composition returned from the foundry can be charged into the furnace in unlimited proportions, although use of 50% maximum of scrap per charge is recommended. Not surprisingly, the usual practice is to remelt zinc scrap runners, overflow wells, sprues, and castings. However, there are safeguards that should be employed to ensure that remelt does not disrupt the fine balance of additives in the melt.

The ability to remelt zinc process scrap many times without losing properties is a significant advantage to the die caster. However, caution should be exercised to keep this material clean and free of unwanted substances. It should be stored separately away from other metals if it is accumulated in batches. If conveyed back to a central melter, conveyors and the furnaces should be covered when maintenance work is being done nearby or overhead. Floors and tables should be kept clean.

If there is doubt as to the purity of the scrap, it should not be used in any proportion until it has been analyzed. Scrap returned for recycling must be free of oil and moisture. A safety hazard is created when oil or moisture is present on the metal being charged into the furnace.

Some zinc scrap can be electroplated. This material should be remelted separately and added back in small quantities or, better still, sold outright. If this is not practical, the scrap should be fed back moderately. The electrodeposits will separate and float to the top of the bath, where they can be skimmed off. Agitation will increase copper, nickel, and chromium levels and should therefore be avoided.

Castings that have had chemical surface treatments can generally be remelted as clean scrap. Under no circumstances should cadmium-plated, tin-plated, or soldered die castings be remelted. Caution should also be exercised when remelting returns from customer plants. These castings may contain lead plugs or other undesirable materials. It is usually recommended that the scrap not exceed 30 to 40% of the amount of newly prepared alloy.

Melt Temperature and Fluxing. High temperatures and flux can change the percentage of the alloying elements. No flux is needed when the melting stock is clean ingot, but 1.4 to 2.3 kg (3 to 5 lb) of a chloride or fluoride flux is added for each 450 kg (1000 lb) of metal when the melting stock is partly or totally comprised of trimmings, gates, and rejected castings. A few pounds of flux per ton of alloy will reduce the magnesium content, and greater flux additions can make the magnesium disappear completely. Consequently, it is necessary to control temperatures continuously, to flux properly, and to check the analysis.

Alloying Elements. The purposes served by the alloying elements and the effects of using these elements in amounts exceeding specified limits are summarized in the following paragraphs. Strict control of chemical composition is absolutely essential for avoiding any chance of intergranular (intercrystalline) corrosion, dimensional changes, or loss of mechanical properties. Specified compositions for zinc alloys are given in Table 1.

Aluminum is added to zinc for die casting to strengthen the alloy, to reduce grain size, and to minimize the attack of the molten metal on the iron and steel in the casting and handling equipment. Aluminum adds to the fluidity of the molten metal and improves its castability. As indicated in Table 1, aluminum contents range from 3.5 to 4.3% for Alloys 3 and 5. An aluminum content lower than 3.5% requires higher-than-normal metal temperatures for satisfactory castability. The higher temperatures result in undue attack on the dies. Other disadvantages of low aluminum are lower strength and less dimensional stability than alloys containing aluminum within the specified range.

When aluminum content is higher than 4.3%, it lowers the impact strength of the castings. The zinc-aluminum eutectic forms at about 5% Al. This eutectic alloy is extremely brittle and must be avoided.

Magnesium content must be carefully maintained within the ranges shown in Table 1. Magnesium is added primarily to minimize susceptibility to intergranular corrosion caused by the presence of impurities. Excessive amounts of magnesium

lower the fluidity of the melt, promote hot cracking, increase hardness, and decrease elongation. Cracking is generally confined to castings of complex form that are free to shrink in the die.

Copper, like magnesium, minimizes the undesirable effects of impurities and, to a small extent, increases the hardness and strength of the castings. Castings containing more than about 1.25% Cu are less stable dimensionally than those with less copper. The copper range for Alloy 5 is 0.6 to 1.25%. The lower limit places the alloy into the high-tensile and high-hardness range, while the upper limit is safely under the copper content that produces aging changes in castings at room temperature.

Iron in amounts up to 0.10% has little detrimental effect, but may contribute to problems in buffing or machining. Iron under 0.02% is in solid solution. Greater amounts form hard iron-aluminum compounds, which can produce comet tails during buffing and can dull tools during machining.

Nickel, chromium, silicon, and manganese are not harmful in amounts up to the solubility limit of each (0.02% Ni, 0.02% Cr, 0.035% Si, and 0.5% Mn). When these metals exceed their solubility limits, they form light intermetallic compounds with aluminum and can be skimmed off the surface of the melt.

Lead, cadmium, and tin at levels exceeding the limits shown in Table 1 can cause die cast parts to swell, crack, or distort. These defects can occur within 1 year. The maximum limit for lead, which can promote the occurrence of subsurface network corrosion, is 0.006%. Cadmium is detrimental in its effect at some concentrations and is neutral at others. As such, the maximum limit for cadmium is set at 0.005%. Tin, like lead, can promote subsurface network corrosion, and therefore is also restricted to the maximum safe limit of 0.005%.

Furnaces

In the past, the standard furnace at the hot chamber zinc die casting machine was a gas-fired unit that held a cast iron pot. Quite often, the furnace at the machine was also used for melting. Large installations generally had a central melting facility, usually gas fired and accommodating a cast iron pot. Hot metal was pumped or siphoned from the furnace into the transport crucible or ladle. The transport ladle was suspended from an overhead conveyor and filled and emptied by mechanical tipping mechanisms. Only one worker was required. However, the working conditions were far from satisfactory. Manual handling of the metal was heavy, hot, smoky, and dangerous.

Furnaces are frequently an integral part of the die casting machine. Most furnaces for melting and alloying, as well as for holding, are fuel-fired open-pot, immersion tube heated, or induction heated. Most pots for melting and containing molten zinc alloys are cast from gray or ductile cast iron. Ladles, if used, are of cast iron or pressed steel. Regardless of its type, the furnace should be equipped with controls so that the temperature of the molten zinc can be maintained within 6 °C (10 °F).

The furnace capacity required depends on the size of the casting machine, workpiece size, and production rate. Generally, a holding furnace should be able to hold at least four times the amount of metal required for 1 h of operation. The capacity range of melting furnaces is usually 450 to 9000 kg (1000 to 20,000 lb), although immersion tube furnaces can range up to 18 Mg (40,000 lb). Total furnace capacity is usually five to seven times the amount of metal required per hour.

A major innovation was the introduction of gas-fired immersion tube furnaces. Eliminating the need for pots, these furnaces use metal tubes immersed in the metal bath. The results are excellent; furnace efficiencies are increased considerably by this almost-direct method of heating. Immersion tubes are used for melting as well as holding furnaces and for heating molten metal launder systems. Many installations began using complete systems with immersion tubes to heat the melter, holders, and interconnecting launders.

The Launder System

The launder system consists of three main components: a central furnace, a number of metal feed furnaces (one for each die casting machine), and a launder system connecting the furnaces. The central melting furnace is arranged to feed the main launder continuously with molten zinc. Each casting station is equipped with a holding furnace that has a branch launder connecting it to the main launder.

The furnaces are fully enclosed, with tight-sealing lids and extremely thick walls. The castable main refractory does not contaminate zinc alloys and is backed up with heavy insulating material. The objective is to achieve such efficient sealing and insulation that very little heat is felt when the furnace is touched. The heat source is either immersed in the melt or located underneath the furnace lid (or a combination of both). The openings for charging and discharging are narrow and have heat locks to keep heat loss to a minimum. As long as the melting furnace metal is maintained at a recommended level, molten zinc flows by gravity from the ladling chamber, through an exit cast into the side of the furnace, and into the main launder. Because the channels are located well below the surface of the bath, surface dross from the charge end does not enter the ladling end.

This type of system--immersion zinc alloying, remelting, laundering, and holding--can be used to gravity feed a number of die casting machines. In this type of system, cold-charged metal has little, if any, effect on the temperature of the metal in the holding furnace of the die cast machine.

The laundering and holding system requires skimming only once a month, which reduces metal loss due to dross formation/removal. The minimal effort required to maintain the immersion system increases efficiency, while also improving the working conditions.

In a launder, the metal is not directly exposed to the atmosphere. The trough is lined with heavy insulation having extremely low thermal conductivity. This insulation is also nonwettable by molten zinc. The launders are also well insulated and sealed, and the cross-sectional area of the metal stream in the launder is small (26 cm^2, or 4 $in.^2$). The covers are heavily insulated and are hinged to permit inspection of any portion of the launder.

Metal conveyance throughout the launder system into the machine-feed furnace is free from turbulence. The metal is moved smoothly and continuously under a protective layer of stationary metal oxides. Most important, metal temperature fluctuations are virtually eliminated. In addition, almost all manual work is eliminated.

Scrap Return

Directly below the trim press is the scrap conveyor, which goes to the melting furnace. Also leaving the trim press is the finished parts conveyor, which directs the parts for further processing. The transfer conveyors are typically steel belts or oscillating conveyors.

An innovation is the overlapping steel belt. Each section of this belt is hinged on only one side, allowing the belt surface to swing free at the discharge point. This motion sheds the material being conveyed, minimizes carryover, and prevents the accumulation of material in the hinge points, which can be a primary cause of wear and jamming in the conventional hinged steel belt. The overlapping belt is designed to use standard belt components and can be used in conventional hinged steel belt frames.

Die Casting Machines

Die casting machines used for zinc alloys are usually of the hot chamber type (Fig. 1), in which the pressure chamber, or gooseneck, is submerged in the molten metal. With this type of machine, the metal is injected into the die in the shortest time and with the least decrease in temperature.

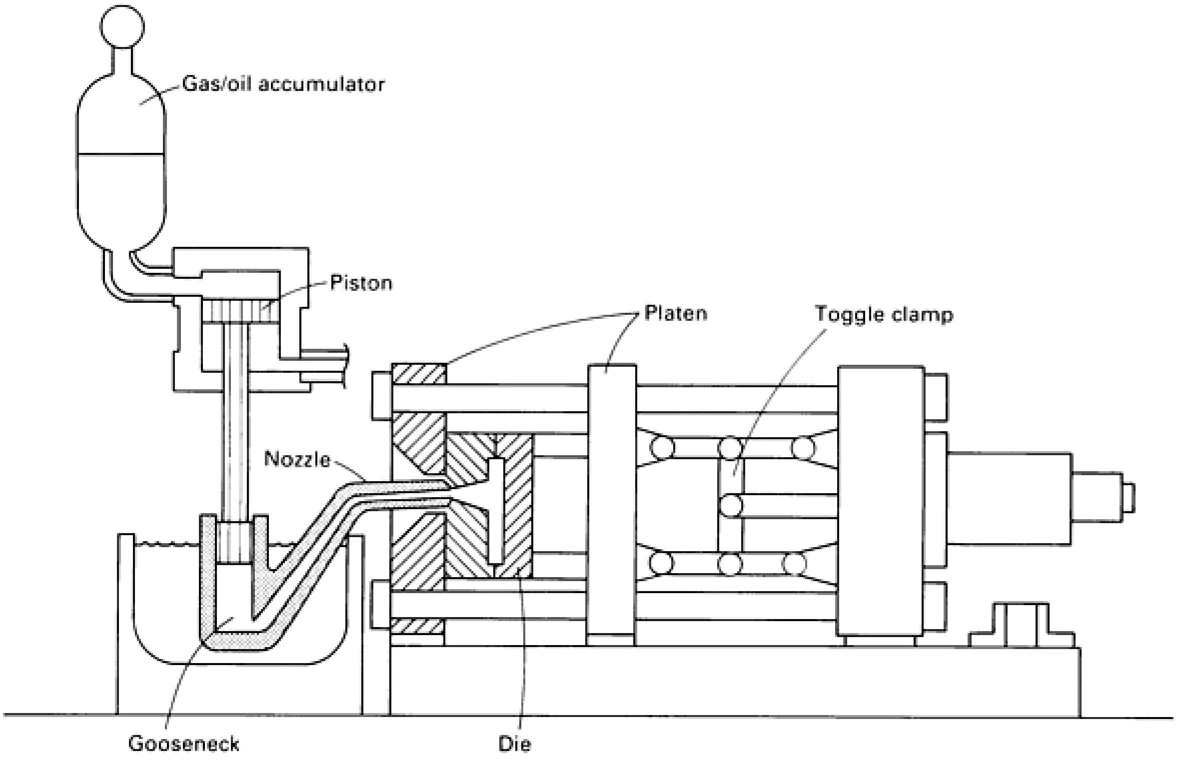

Fig. 1 Hot chamber machine used to make zinc die castings.

Selection of materials for the component parts of a die casting machine is less of a problem in casting zinc alloys 3, 5, and ZA-8 than in casting aluminum or copper alloys. Material requirements are less rigorous because zinc alloys are cast at relatively low temperatures and because molten zinc alloys do not rapidly attack ferrous metals. Pots, goosenecks, and other components of the machine that come in contact with the molten metal are usually made of gray or ductile cast iron, although they can be made of cast steel. Availability and cost usually determine selection. Sleeves and nozzle seats, because they receive high wear, have been made from nitrided alloy steel, hot-work tool steel (such as H13), high-speed tool steel, and stainless steel. Frequently, the sleeve and nozzle seat of the gooseneck are replaceable to permit inexpensive repair.

The injection cylinder can be either hydraulic or pneumatic. With the same stroke length, the amount of metal injected can be changed by increasing or decreasing the size of the cylinder bore. Injection pressures used for the die casting of zinc alloys usually range from 10.3 to 20.6 MPa (1500 to 3000 psi). The lower pressures are used for simpler castings; the higher pressures, for more complex ones. Good practice is to use the lowest pressure that will produce acceptable castings; however, a minimum pressure of 10.3 MPa (1500 psi) is essential for obtaining an acceptable combination of soundness, surface finish, and mechanical properties.

Ideally die casting installations that are to be automated would include the following features:

- Die casting machine designed for automation and equipped with closed-loop control of machine variables, reliable automatic central lubrication and hydraulic system, repeatable and recordable machine functions, interlocked cycle stop, and shutdown circuitry triggered by out-of-tolerance machine variables
- Constant-temperature molten metal supply with interlocked shutdown circuitry monitoring temperature tolerances
- Optimum designed and precision-built dies with closed-loop cooling and heating control
- Flexible, programmable multifunction die lubricator system to provide die release, surface cooling, and efficient lubrication of the moving die parts
- Integrated auxiliary equipment that matches the die casting machine in performance and physical

properties and is designed to endure the die casting environment

Early machines were designed and built for operator-controlled die casting and are not suitable for automation.

Zinc and Zinc Alloys

Dale C.H. Nevison, Zinc Information Center, Ltd.

Dies

Zinc alloys can be cast in single-cavity, multiple-cavity, combination, or unit dies. Dies that are designed to produce zinc alloy castings can seldom be used to produce castings of aluminum alloys or other metals that are cast at higher temperatures, because zinc alloys can be cast to thinner sections, smaller radii, and closer tolerances than aluminum, magnesium, or copper alloys. However, a die designed for casting the higher-melting alloys can be used for casting zinc alloys.

The cover half of a die must be equipped with a nozzle seat that will provide a good seal with the gooseneck of the machine. A sprue hole, or bushing, and spreader must be incorporated into the die to ensure feeding of the molten metal to the runners and to permit removal of the solidified sprue with the casting.

Die Materials. In the die casting of zinc alloys, die temperature is relatively low, usually ranging from 160 to 245 °C (325 to 475 °F). Therefore hot-work tool steels are not generally required for dies. However, for extremely long runs and for high dimensional accuracy, hot-worked tool steels such as H13 will provide optimum die life.

Die hardness in the casting of zinc alloys is less critical than for alloys of higher casting temperature. Steels prehardened by the manufacturer to any maximum hardness consistent with reasonable machinability can generally be used. The typical hardness is 29 to 34 HRC (280 to 320 HB).

Slides and Cores. Hardenable stainless steels such as type 440B are often used for cores. Hot-work tool steels such as H13 can be used for both cores and slides. Because these tool steels respond readily to nitriding, they can be selectively hardened; a component made from one of them can be treated for different properties in different areas. For example, the main portion of cores and slides can be nitrided for wear resistance, and the end portions can be masked to resist nitriding for better resistance to heat checking and spalling. Lubricating the slides and cores with molybdenum disulfide or colloidal graphite in oil helps to ensure smooth action and to minimize wear.

Clearance between the slides and the guides should be kept to a minimum to prevent the molten zinc from wedging between them. Ejector pins of nitrided H11 tool steel or 7140 alloy steel are available as stock items for insertion in the dies.

Die Life. The service life of a die casting die is directly related to the temperature of the metal being cast, thermal gradients within the die, and frequency of exposure to high temperature. Because of the relatively low temperatures of the dies (see the section "Die Temperature" in this article) and of the molten metal, die life for casting zinc alloys is generally much longer than for casting aluminum, magnesium, or copper alloys; it is not unusual for dies to last for 1 million shots. Maximum die life depends largely on having well-designed dies, trained operators, and a rigidly enforced program of machine and die maintenance. A deficiency in any of these areas will result in decreased die life.

Die Temperature

The temperature at which a die will run (level out) during continuous operation depends on the weight of the shot, the surface area of the shot, the cycle speed, and the shape of the die. When dies are too cold, cold shuts, laminations, internal porosity, incomplete filling, and poor finish with excessive flow marks are likely to result. Dies that are too hot cause shrinkage, heat sinks, excessive flash, spitting, poor ejection, soldering, and die erosion. For a new application, some experimentation is usually required to establish a satisfactory optimum die temperature.

The optimum die temperature for zinc is usually between 160 and 245 °C (325 and 475 °F). The lower end of this range is used for thick-section castings, and the higher end is for thin-section castings. When hardware finish is required, higher die temperatures (near 245 °C, or 475 °F) are generally required, regardless of the casting thickness. Once established, die temperature should be maintained within 6 °C (10 °F).

Some casting shapes require localized heating or cooling of the die above or below the established temperature. Metal overflows are often used to heat die areas surrounding the perimeters of castings that have thin sections far from the main runner. This method of local heating helps to fill thin sections and to improve casting finish. Conversely, water channels are frequently placed behind the runner area immediately adjacent to the sprue to provide localized cooling and to prevent soldering of the molten metal to the die.

Control of Casting Temperature

Research has shown that the variation in die temperature is one of the most important parameters affecting production rates and casting quality. To eliminate defects caused by excessively low die temperature, the die caster should design the die with excess cooling capacity and then use a temperature control system to modulate the flow of coolant in the die to achieve the desired die temperature. This incorporates the use of thermocouples, solenoid valves, and controllers. If necessary, heat can be added to the die through the use of heating elements inserted in the die. A complete system can be purchased that will control both heating and cooling using oil as the heat transfer medium. Some die casters have found the oil controller to be superior in overall performance and flexibility.

Metal temperatures for casting the zinc alloys range from 400 to 440 °C (755 to 825 °F). Generally, the lower end of this range is used for castings with thick sections, and the higher end is for castings in which section thickness is near minimum. In practice, a temperature of 415 °C (780 °F) is used for a wide variety of casting sizes and shapes.

For best results, including best casting finish, some experimentation is usually required to arrive at the optimum metal temperature for a given application. When the optimum temperature is established, it should be controlled within 6 °C (10 °F).

Die Lubricants

Selection of the optimum lubricant (die release agent) for a specific application often requires some experimentation because of the various operating temperatures and die shapes. An optimum lubricant is one that carbonizes at the operating temperature. A lubricant that carbonizes above the operating temperature will stain the casting, and one that carbonizes below the operating temperature will be used up on the first shot. The black oil and graphite lubricants have been replaced by water-base lubricants; this has reduced the fire hazard and smoky environments commonly found in die casting plants. Water-base lubricants are formulated to be an effective release agent and aid in cooling the dies.

Die Lubrication System

Because of the long periods spent spraying the die and the variety of spray patterns the operators will use in a day's production, a considerable amount of time can be saved by automating this operation. Installation of the spray unit also reduces the work load of the operator.

A number of die spray reciprocators have appeared on the market in recent years. Automatic die spray has been the most cost-effective measure in the die casting process. It resulted in a production increase of up to 25% and has a significant reduction in rejects (primarily because of improved surface finish). The die spray serves to release the casting, to lubricate moving die parts, and to cool the die surface. Selection of a spray system should involve consideration of the following requirements:

- Moving die parts should be lubricated by an appropriate central lubricating system built into the die and coupled to an external lubricator
- Die cooling should be accurately calculated and achieved by internal water channels. In marginal cases, additional cooling can be accomplished by the die spray. In such cases, the dilution is extended to avoid excessive use of the release agent and resultant buildup
- The die sprayer must be easily programmable to perform its function with reasonable repetitive

accuracy
- Essential features of the sprayer include the ability to spray two different media and air blast
- Lateral movement of the spray nozzles may be essential for reaching deep die cavities

Considerations of only the basic requirements when selecting a spray system will result in dissatisfaction. Knowledge of die size, special spray patterns, and so on, is also important. Once the system is operational, adjustments should require a minimum of time.

The spray system should be selected to allow for ease in movement when installing dies and/or making machine repairs. Each system has advantages and limitations. Most use air for spraying and blow-off. Some systems use air for movement, while others use hydraulic power either from a separate hydraulic power supply or from the hydraulic system of the die casting machine. Because of the air pressure fluctuation in most plants (anywhere from 550 to 825 kPa, or 80 to 120 psi), a hydraulic system gives more constant movement when spraying, and this in turn provides more control. Other areas that must be investigated before purchasing a spray system include the adequacy of the plant air supply, the need for a tank for die release, and the size of the area the spray pattern should cover (which depends on the die size to be run in the system).

Casting Removal

At this point in the installation, everything is operating semiautomatically. The only item needed to complete the system is a unit that physically removes the casting from the die cast machine, known as an unloader, extractor, robot, grabber, or drop system.

Unloaders vary widely in function. Some units will unload the machine, spray the die, and trim the castings. Others will only unload. Some systems are programmable, and others require the adjustment of limit switches and timers.

A drop-through system is the simplest means of unloading a die casting machine. However, there are several problems with the system. When a drop-through system is decided upon, a method of removing the dropped casting must be considered. Normally, a pit is dug under the machine, and a conveyor is installed to remove the castings. The pit is filled with water to be used as a quench. Quenching ensures the solidification of the casting when it reaches the conveyor, thus preventing bending. If the water is too shallow, the casting will hit the conveyor and will be bent.

Sensing a falling part in one way is quite simple, using a limit switch, photo detector, infrared detector, or a radio wave device. The problem is to determine whether or not the complete shot has left the die.

There are several methods of determining if the entire die is clear for the next cycle. One is to weigh each shot as it leaves the die. This method appears simple, but it must be accomplished under water or after the casting leaves the water. Another method is to use a radio wave device to scan both halves of the die in conjunction with a heat detector for the sprue bushing to determine whether the sprue has been removed.

The equipment mentioned is not easily set up, and it requires frequent servicing. The only positive way to determine whether or not the die is clear for another cycle is to have an operator standing by, watching each cycle and clearing anything that sticks to the die.

After considering the problems and economics involved, the drop system is not as simple as it may seem. It does, however, perform well for many companies.

Grabbers. A slightly more complex method of casting removal is the grabber. This equipment, although not inexpensive, is relatively low in cost compared to other good casting removal units. Its ability to handle a wide variety of tasks, however, is limited by its lack of mobility. This type of equipment performs well, but the purchaser must take the limitations into consideration. One advantage of some grabbers is their ability to spray and sense, which reduces the total capital investment. The grabbing mechanism on most units can be modified to handle a variety of dies; this is sufficient for the average die caster. The grabber design is compatible with other die casting industry equipment; controls, both electrical and hydraulic, are standard, using basic design concepts to minimize complexity. These units can be purchased with their own hydraulic power sources, or they can be connected to the hydraulic system of the die casting machine. Whatever system is used, the unit has been designed with ease of maintenance in mind.

The unloader is not attached to the die casting machine, but supports itself. This type of equipment is sometimes more sophisticated than the above types and is generally self-sufficient, relying only on input and/or output signals to control its operation. Some unloaders can be connected to the hydraulic system of the die casting machine, reducing the overall cost. Various accessories are available with unloaders. Some unloaders can be purchased with a trim press, or spray system and sensing unit. Others are strictly unloaders that can be reprogrammed by the changing of limit switches and rotating cams. The unloader differs from the grabber in its versatility and its programmability.

Each system has been developed with the die casting machine in mind. Except for one or two specific items, these machines are designed using the standard relay logic and hydraulic systems of the die casting machine industry. For the most part, the unloader is a more sophisticated and versatile grabber.

The robot, or programmable unloader, is the most versatile of all the types of unloading equipment. The robot can be moved through a series of operations and can store each operation in memory. It is the most expensive of all unloaders and the most sophisticated. Robots can usually be serviced by trained maintenance personnel because most of the work needed to correct a malfunction consists of removal and replacement. However, with all of its versatility, the robot can handle only 70 to 80% of the average dies. With additional equipment, the robot can handle approximately 90% of the average dies.

The most important aspects of the robot are the reduced time it takes to program and the speed at which it operates. Some robots can be programmed to operate several pieces of equipment at the same time. The robot can also be programmed to spray the die with a very precise pattern.

The choice between a robot and an extractor is subject to individual consideration. Generally, a single-purpose extractor is more reliable, more cost effective, and simpler to program and operate than a robot. Although the repetitive accuracy of robots and extractors is well known, placing any casting accurately in a trim press is not an easy task.

As with any type of casting removal, there must be a method of detecting the casting once it has been removed from the die. This detecting can be accomplished with limit switches, photocells, infrared probes, or tactile sensors. Infrared sensors can sometimes be triggered by the surrounding environment instead of the casting and therefore may not be completely reliable.

Tactile sensors consist of multiple probes or antennas connected to a low-voltage detection system. When the probes make contact with the casting, the detection circuit is complete, and the next step of the casting cycle is initiated. Detection systems having as many as 12 probes are common; therefore, multiple-cavity gates and different portions of the same casting can be sensed. For example, deep bosses or similar features that tend to stick in the die can be individually monitored.

The above sensing systems (infrared or tactile) are possible only when a robot is used because it is necessary to bring the complete shot accurately to the probes. Newer sensing systems have memory capability in that all the multiple probes do not need to contact the casting simultaneously. This feature allows a "fly through" of the shot to permit quicker sensing with no loss in reliability. In the fast-running zinc machines, such a capability is economically significant. Any of these detection devices must be mounted in some predetermined position near the casting removal location.

Trimming. In finish trimming (not mere breaking of the casting from the gate), the part must almost always be quenched in water-soluble coolant/lubricant similar to that used in machining zinc castings. Failure to include soluble oil usually causes the trim die plates to solder, with consequent tearing of the trimmed part. Quenching several hundred pounds of shots per hour in a small tank requires either a heat exchanger for the quenching fluid or connection to a larger remote reservoir so that the heat can be dissipated naturally. Another method would be to use a spray and to recycle from the tank. If the robot or extractor dips the shot in a quench tank and then places it in a trim press, a drag-out conveyor can be fitted into the tank to remove the flash that settles to the bottom.

The primary reason for mating a robot to the die casting machine is that the die casting process is a single-position oriented process; that is, the process begins with molten metal and ends with a part always in the same location and identically oriented with respect to fixed points in space. This sequence can be compared to the operation of a trimming press, which is a two-position process:

- Random-oriented positions in containers ahead of the press

- Fixed-oriented position on the location of the trimming die

Present-day robots, on the other hand, can only be effective in transferring parts that have fixed or identical orientation relative to some reference point. Therefore, although a robot can operate or service a die casting machine, it cannot operate a trim press in the same manner as a trim operator.

However, if advantage is taken of the fact that the robot preserves position utility (part orientation) after it has unloaded a die casting machine, then a robot can be used as the connecting link between the tandem processes of casting and trimming. To remove the trimmed part, gates, runners and overflows, conveyors, or chutes are required.

An alternative to the cast-trim operation using a robot is the removal of the part from the casting machine to pipe- or screw-type conveyors that feature a buffer storage capacity because the robot has the capability of placing a shot on such a conveyor, which is usually at least 2 to 2.5 m (6 to 8 ft) above the floor level. With a buffer storage conveyor, the entire system is not shut down for trim press problems.

Automation of the process requires some method of trimming the casting. Three basic choices can be considered:

- Die casting and in-die degating
- Die casting machine and automatically loaded trim press
- Die casting automatically with separate trimming department

Separate trimming was a preferred method in the past; this method suited the manual casting shop. The current range of sophisticated machinery makes this choice less attractive. The first and second choices listed above result in decidedly higher productivity. Because of the limited production use of in-die degating, the second choice is preferred at this time. The production line concept also favors the integrated or interconnected trimming, where the orientation of the cast component is retained; thus, the casting can be easily transferred to a following machine for further machining operation.

The frequently heard objection regarding the breakdown of one unit stopping the entire line is less valid with the currently offered machinery than it was in the past. Solid-state technology, improved limit switches, and state-of-the-art hydraulics possess proven track records. The statistics of the early 1970s are no longer valid. One can state that the single largest cause of stoppages is die failures.

Hydraulically operated presses are used for cast-trim operations, and various designs (vertical, inclined, and horizontal) have been used to help overcome the problem of part, flash, overflow, and gate removal from the trimming location. The robot can accurately place the shot of castings on a location and can remove the part, gate, and flash off the location, but such a procedure almost always causes a delay in the casting cycle, forcing some economic trade-offs. The use of a shuttle press can overcome this problem. Another advantage of the robot in a cast-trim operation is in meeting the requirements of the Occupational Safety and Health Administration Power Press Standard concerning no hands at the point of operation by elimination of the press operator.

Conveyors

The last item required for any installation is some method of removing castings from the trim press. A conveyor may not seem very important, but it can be the weak link in a trouble-free system. The conveyor must give workers time to perform their jobs and must supply adequate storage capacity. The most widely used conveyor is the belt type, which can withstand the most adverse conditions. However, pipe- or screw-type conveyors, which feature a buffer storage capacity, should not be ruled out. With a buffer storage conveyor, it is not necessary to have personnel always stationed at the end of the conveyor. This feature not only allows ease of administration but also permits secondary operations linked to the conveyor to be done at an incentive pace. Other conveyors would probably be flat-top or roller conveyors, depending on the specifics of the particular job.

Design Advantages

Some of the design advantages of die castings in general can be realized to a greater extent in zinc alloy die castings than in die castings of aluminum or copper alloys.

Section Thickness. The minimum section thickness for zinc alloy die castings depends on the surface area of the casting, the metal flow in the die, and the location of the gate. Even in large castings, a relatively thin section can be cast if it does not extend over the entire cross section of the casting and throttle the flow of the metal. Sections should be as thin as possible (consistent with castability and adequate strength and stiffness). Thin sections reduce metal costs and improve productivity as the castings solidify faster in the die, thus shortening the production cycle.

The sections of a die casting should always be as uniform as possible, with gradual transitions where the function demands differences in thickness. Cores can often be incorporated into a die to maintain uniformity of thickness. Metal saver cores are used to avoid a thick mass of metal, which would be difficult to cast and unnecessarily heavy.

For some applications, the mass of a zinc die casting is an advantage. Phonograph turntables have been die cast with weights up to 5 kg (11 lb). The heavy rim section contributes to the steadiness of rotation. On a smaller scale, zinc alloy flywheels have been used in computer tape decks and radio tuning mechanisms.

The die parting must usually be at the maximum diameter or section of the casting. The designer of a casting should visualize the casting in the die, shaping the part to facilitate its removal from the die and arranging for resulting flash to be in a convenient position for efficient removal. Die costs and flash removal costs are minimized when the parting is in one plane at right angles to die motion. By parting the casting on a face that must be machined, the flash can be removed simultaneously.

The ejector pins will leave small marks on casting surfaces unless special lugs are incorporated or the ejectors can act on the feed metal and overflow. The die should be designed so that these marks will not leave disfiguring blemishes on visible faces of the finished casting.

Ejector pin marks on most die castings can be raised or depressed by not more than 0.4 mm (0.015 in.). Ejector pin marks are surrounded by a flash of metal. If end use permits, ejector pin mark flash will not be removed but can be crushed or flattened. Complete removal of ejector pin marks and flash by machining or hand scraping operations should be specified only when requirements justify the expense involved in the additional operations.

Wall taper is normally between 1 and 2° per side. Shallow ribs, however, require more taper (5 to 10°), although small tapers are more acceptable for ribs in line with shrinkage, as for the spokes of a wheel.

Ribs. A thin section that requires reinforcement with ribs (rib thickness should not exceed the section thickness of the area it adjoins) may still provide lower overall weight than unribbed sections of greater thickness. The judicious placement of ribs often aids metal flow into thin sections, and ribs or beads that are discreetly placed at thin sections where trimming is required and where the casting is to be gated diminish the chances of warping and reduce trimming costs. Many die castings can be made as thin as metal stampings in shapes that cannot be duplicated in one-piece stampings and at lower tool cost.

Bosses or similar metal concentrations that are heavier than adjacent thin walls can result in unequal shrinkage. This sometimes gives rise to so-called shrink marks or shadow marks, which are actually shallow depressions on the face of the casting opposite the thickened section. Such marks may be unsightly, especially if the surface is to receive a lustrous finish. The effect can be minimized by making the variation in thickness as small and as gradual as conditions permit. Shadow marks can be masked by ribs or low-relief designs and seldom occur in sections over 2.5 mm (0.1 in.) thick. Ribs are often faired to bosses where load concentrations occur in service and help to distribute the load over a larger area of the casting.

Tapped bosses are stronger than threaded studs because external threads cause a notch effect under shock loads. Therefore, tapped bosses are always preferable and are sometimes as economical as threaded cast studs. However, tap and chip clearance must be allowed beyond the last thread of the hole, or a through hole must be provided. Holes to be tapped should usually be countersunk 2.5 mm (0.1 in.) larger than the thread for ease of tapping and assembly, especially when the hole is cored.

Undercuts. Because die costs are often greatly increased and casting rates decreased when undercuts are cast, the general rule is to design to avoid undercuts. If undercuts exist on the exterior of the die casting, slides or movable cores

that substantially increase die costs are needed to eject the casting. The interior of a die casting or undercuts require the use of a loose piece that is withdrawn from the die with the casting and must be replaced in the die for subsequent castings.

When a loose piece is judged worthwhile, several are made to avoid delays. Zinc die castings can be used as loose pieces to form undercuts.

When the quantity of castings required is large, a costly and complex die may be fully justified by even a small net savings per casting. A comparatively uniform section can be obtained, despite complex shapes, by the judicious use of cores and slides that form undercuts. The metal saved can justify the additional die cost.

Fillets and Blends. Sharp corners are always a source of weakness and should be avoided by the use of fillets. Even the smallest fillets have an appreciable strengthening effect. A minimum radius of 0.4 mm (0.015 in.) is suggested in place of sharp corners, and larger radii are desirable when conditions permit their use. Fillets of 0.4 mm (0.015 in.) radius are barely noticeable even on outside edges, and a 0.8 mm (0.03 in.) radius is seldom evident except on close inspection.

It is common die casting practice to use a fillet having a minimum radius of 1.5 mm (0.06 in.) on inside edges. A slight radius on outside corners of castings reduces die cost and promotes the durability of any subsequent finish. Buffing or polishing is likely to cut through the finish at sharp outside edges, while organic finishes tend to thin out and give inadequate protection along sharp edges.

Plain Flat Surfaces. Large areas of plain flat surfaces should be avoided if very smooth finishes are required. Such surfaces lead to many rejections and increased costs. Broad surfaces should be slightly curved, crowned, or broken by beads, steps, or low relief so that they can be cast without imperfections, which will be magnified by glossy finishes. Such simple expedients mask these slight imperfections. Textured finishes can be applied to such surfaces in the die by photoengraving or other means.

Lettering. When die cast lettering, numerals, trademarks, diagrams, or instructions are required, they should be designed and placed to facilitate die construction and removal of the casting from the die. Normally, the designer should specify raised lettering because it is easier to cut a design into a die surface than to make a raised design on the surface. Depressed lettering on the casting is much more expensive and deteriorates with time because of erosion by the molten alloy.

When the engraving may not project above the surrounding surface of the casting, raised engraving on a panel sunk into the surface of the casting can generally be used. Engraving is preferably done on surfaces parallel or nearly parallel to the die parting. It should never constitute an undercut, which could interfere with the ejection of the casting from the die. In many designs, engraving is effectively used for scale or graduation markings. When the engraving is depressed in the casting, the recesses are often filled with paint or are wiped in to provide contrast with surrounding areas.

Bending and Forming. The ductility of zinc makes it possible to incorporate integral rivets, to shape integral flanges to curving contours, to bend hollow arms, to spin out undercuts, to form projections, or to twist parts of the casting through 90° or more. It is possible to use a flat parting that provides parallel bosses, cored holes, or studs at right angles to the parting and then to form the casting so that the axes of these elements are no longer parallel. Thin plates with cast bosses or holes at right angles to the surface require much less expensive dies than if cast to a curved shape.

Inserts are generally used for one or both of the following reasons:

- To provide greater strength, hardness, wear resistance, ductility, flexibility, or some other property not possessed, at least in the same degree, by the die casting alloy
- To provide shapes of parts or passages that cannot be cored or cast or are less expensive or better as inserts

Inserts can usually be cast in place, but there are many cases in which they are applied after casting in holes cored for the purpose. The object of casting the insert in place is either to anchor it securely or to locate it in a position where it could not be placed after casting.

When inserts are designed for casting in place, they should be provided with knurling, holes, or grooves to ensure firm anchorage. Provision should be made for a sufficient thickness of the casting alloy around the insert to give the required support.

In the case of inserted studs, the thread should end at least 2.5 mm (0.1 in.) from the casting; otherwise, it may be filled by molten metal. Because of possible variations in the diameter of inserts, a shoulder or other sealing surface should be provided between the end of the thread and the casting to prevent any flash around the insert from entering the threads. In service, a washer resting against such a shoulder will avoid any tendency for tightening of the nut to pull the stud from the casting.

Machining. Zinc die castings are manufactured to very fine tolerances as-cast, and if any machining is necessary, the cuts required are usually light. A minimum machining allowance of 0.25 mm (0.01 in.) is recommended, along with a maximum of 0.5 to 1 mm (0.02 to 0.4 in.). Machining operations are made easier by the good machining qualities of zinc die casting alloys.

Design drawings should show where machining is to be done and should indicate how much metal is to be removed in machining, unless this is left to the judgment of the die caster. Surfaces to be machined should be of minimum area, consistent with other requirements, and when possible should be positioned to simplify machining. If possible, location should be from the fixed die half. For example, flats can often be trued by simple grinding if the surfaces to be ground are accessible. Placing flats (such as boss faces) all in one plane expedites grinding. Such surfaces should be slightly above surrounding areas that do not require machining.

When the number of castings to be produced from a die is small, the die cost must be kept low. In such cases, it is sometimes preferable to avoid expensive machining on the die and to perform additional machining on the castings.

Small holes ($\leq$3mm, or 0.12 in.) in thin sections are often drilled or punched in preference to coring because the flash from cored holes must normally be removed by such operations. It is almost as quick to drill or punch the full depth of the hole as to remove flash. The drilling operation can be simplified by casting a start for the drill.

Minimizing Trimming Costs. Castings should be designed to minimize trimming costs. Flash occurs at die partings, and its removal usually constitutes a considerable factor in the cost of the casting. This is one phase of machining that is practically unavoidable, but the cost can be minimized by positioning the parting so that flash removal is easily and quickly accomplished. In the production of very long runs of small, thin castings, carefully made dies can be economically employed to produce flash-free castings.

Flash is commonly removed from larger castings by a trim die through which the casting is forced by a press. If the parting is in a single plane, preferably, at right angles to the motion of the die, the flash is easily sheared, but if the parting is not in a single plane, greater cost is incurred in flash removal.

When the flash occurs at a flange or bead, rather than in a recess or on a flat surface, flash removal is facilitated. Flash can often be designed to occur on a surface or edge where machining is required, eliminating a separate flash removal operation.

Coring of the internal form of a die casting can vastly increase the complexity and cost of tooling and should therefore be avoided if possible. This is not to say that coring is to be completely eliminated, because without it many of the advantages of die casting cannot be realized. Coring takes two different forms. On the one hand, there is the coring of internal shapes, while on the other there is the coring of holes.

Holes cast in die castings produced by the use of cores require taper. Very small cored holes should be avoided where possible. The cores tend to overheat and are easily broken or bent. It is normally more economical to drill small holes. Drilling out small cored holes can be troublesome because any misalignment of drill and hole can break the drill.

Gears and Components With Irregular Outlines. When a die casting is removed from the die, it often has a surrounding flash, which is usually removed by a trimming pool. If the component has an irregular outline, the production of this tool can be costly, and the problem can be alleviated if it is possible to incorporate a shroud following a regular form. This has the additional advantage of strengthening the casting.

Means of Attachment. Studs formed as an integral part of the casting usually cost less than inserted studs and in general constitute a highly economical means of fastening a casting to a mating part. Production rates are seriously impaired when separate inserts must be placed in hot dies before each shot.

Integral studs should not be so small in diameter as to be fragile or easily damaged in handling; if such studs are made at least 6 mm (0.24 in.) in diameter on large or medium-size castings, little trouble is experienced. With small, light castings, proportionately smaller studs can be safely used.

All studs should have a liberal fillet where they join the body of the casting. When the radius at the base of a stud interferes with a square edge in the hole of the mating part, the radius can be formed in a recess at the base of the stud.

Threads. The ability to cast threads is a major advantage of the die casting process. Cast threads should be specified wherever their use reduces cost over that for cut threads.

Most external threads can be cast. It is common practice to cast coarse external threads over 20 mm (0.8 in.) in diameter if they are located at a die parting. Threads at a parting usually have flash removed by the trim die, but chasing is sometimes done to produce a truer thread. The weight of a component with a cast screw thread is important. If it is heavy, mechanical bruising may damage fine threads. Pitch errors are likely to be greater than with cut or rolled threads. It is advisable to limit the length of engagment to one-half a diameter. Tooling costs will be higher than for unthreaded components because of the accuracy necessary in die sinking and the increased die maintenance.

Most internal threads are more expensive cast than cut. Cast internal threads are occasionally useful for very steep pitches, and whatever the pitch, the thread can be carried down to a shoulder or to the bottom of a blind hole. All holes requiring fine threads are tapped, and cast interior threads under 20 mm (0.8 in.) in diameter are rarely economical.

Soldering, Welding, and Use of Adhesives. Zinc alloy die castings are not easy to solder, because of the aluminum content of the alloy. Furthermore, the soldered joint may be subject to intergranular corrosion arising from the lead and tin of the solder diffusing into the alloy. These disadvantages can be overcome by plating the casting with a metal such as copper and soldering onto the plated surface. Care must be taken to ensure that no soldered die castings (plated or nonplated) are remelted with other scrap die castings. A very small amount of solder can spoil a large batch of alloy when the two are melted together.

The repair welding of zinc alloy die castings is recommended only when the damaged casting cannot be replaced. In such cases, and for emergency repairs, a procedure has been developed for building up the damaged part by welding, using an alloy rod of the same composition as the casting with the gentle heat of a slightly reducing oxyacetylene flame. Stud welding has been used, but it is not satisfactory, because the alloy adjacent to the stud is weakened and may break.

When appropriate, zinc die castings can be bonded with a range of modern high-strength adhesives, particularly those based on epoxy and phenolic resins. The final choice of adhesive for any application should be discussed with the adhesive supplier.

Finishes for Die Castings. For many applications, surface finish is not important, but where necessary, a wide range of applied finishes can be used. Finishes for die castings can be functional, decorative, or both. Almost any desired texture, such as simulated cloth, leather, or woodgrain, can be cast simply and economically.

Chromium plating is the most widely used finish for zinc alloy die castings. Normally, to obtain a high-quality bright chromium finish on castings, they must be buffed and polished before plating. However, a combination of modern zinc die casting and plating techniques substantially reduces or, in some cases, eliminates the need for mechanical polishing.

If a finish is decorative rather than protective, this does not imply that it requires only casual consideration; electroplating must be carried out to an exacting specification if it is to be satisfactory. For example, an unplated die cast door handle on an automobile would suffer little corrosion (apart from discoloration) in service, while a poorly plated one would soon exhibit blistering and pitting. Therefore, plating is normally required only for appearance, but when it is used, it must be of sufficient quality to provide long-term durability.

Polishing. Where polishing is necessary, the following points must be kept in mind. Sharp corners and edges are difficult to polish without damaging their outlines; a radius of 0.8 mm (0.03 in.) will help polishing and plating. Large flat

surfaces are difficult to polish evenly, but undulations will be less noticeable if the surface has a slight crown (1.5 mm/100 mm, or 0.015 in./in.). Small recesses and acute angles are impossible to reach with a polishing wheel.

Chromate Finishes. Chemical treatments prevent the growth of white corrosion products on the surface when the castings are exposed to stagnant moisture, such as condensation. This treatment results in a dull green-yellow finish.

Painting. Most types of paint can be successfully applied, but surface preparation and pretreatment are very important.

Clear Lacquers. Many attempts have been made to formulate clear lacquers to preserve the bright finish of polished zinc. The recently developed nonyellowing polyurethane lacquers containing rubeanic acid show promise for this application. Acrylic lacquers are also being used, but they are less resistant to mechanical damage.

Electropainting (Electrophoretic Painting). The electropainting of die castings is well established. The process requires specially formulated water-base soluble resin paints, and this imposes some limitations on the colored pigments that can be used. The advantage of electropainting, in which the parts to be painted are made cathodic relative to the steel tank containing the paint, is that a very dense and uniform paint film can be applied to a complex surface, so that one coat of electropaint can replace two coats of conventional paint. It is possible to achieve a high gloss with electrodeposited paints, but color matching with other paints still presents problems, especially over long production runs. Only one coat can be electrodeposited because the dry paint is an insulator. Some paint manufacturers recommend giving zinc die castings a chromate treatment before electropainting.

Plastic Coatings. Epoxy powder coatings are being increasingly used for zinc die castings as an alternative to heat-curing paints. The process is economical because the only labor required is loading and unloading the conveyor that carries the castings past the spray gun and through the curing oven. Matte or glossy coatings are formed about 0.04 mm (1.5 mils) thick.

Plated Finishes. Where zinc alloy die castings are correctly designed, properly produced and carefully prepared plated finishes are very satisfactory. They have excellent decorative value and, given a coating of sufficient thickness and good adherence, a very long life. Copper and nickel can both be plated directly onto zinc alloy, but it is nickel applied over a preliminary deposit of copper that is most commonly used to enhance the corrosion resistance of the casting, coupled with a chromium finish.

For special effects, die castings plated with copper can be treated to simulate antique bronze. Nickel can also be wire brushed or polished with a coarse abrasive to give various attractive satin finishes before chromium plating. Black chromium is another finish with decorative possibilities.

Vacuum Metallizing. Die castings that need a bright finish but are unlikely to be damaged by rubbing or knocks can be vacuum metallized. Color effects, such as those of brass, can be created by immersing parts in a dye solution that tints the protective lacquer very evenly.

Anodizing. A process for anodizing zinc and zinc alloy die castings has been developed that provides excellent resistance to salt water and detergent solutions and good resistance to abrasion. The finish is available only in matte, light green, gray, and brownish tints.

Applications for Zinc Die Castings

The automotive industry is the largest user of zinc die castings. Some of the important mechanical components made as zinc alloy die castings are carburetor bodies (Fig. 2a), bodies for fuel pumps, windshield wiper parts, control panels (Fig. 3), grilles, horns, and parts for hydraulic brakes. Structural and decorative zinc alloy castings include grilles for radios and radiators, lamp and instrument bezels, steering wheel hubs, interior and exterior hardware, instrument panels, and body moldings.

Fig. 3 Zinc die cast automotive arm rest control panel with a chromium plated surface for decorative and corrosion-resistant purposes.

Other applications include the electrical, electronic, and appliance industries, business machines and other light machines of all types (including beverage vending machines, Fig. 2b), and tools. Building hardware, padlocks, and toys and novelties are major areas of application for zinc die castings.

Other Casting Processes for Zinc Alloys

Although the vast majority of zinc castings are produced by hot chamber die casting, several other casting processes are also employed. These include sand casting, permanent mold casting, and plaster casting. Also beginning to be applied are such emerging processes as squeeze casting and semisolid casting. Zinc-matrix metal-matrix composites (MMCs) have also been produced by various foundry methods.

Sand Casting. The ZA alloys, especially ZA-12 and ZA-27, are being increasingly used in gravity sand casting operations. The wide freezing range of the ZA-27 alloy (~109 °C, or 200 °F) means that control of solidification is especially important for this alloy. The use of chills or patterns that promote directional solidification is recommended.

Permanent mold casting is done using both metallic and machined graphite molds. Cast iron or steel is most commonly used for metallic permanent molds. The use of graphite molds permits as-cast tolerances similar to those obtained in die casting. Machining time is reduced or eliminated, making the graphite process attractive for intermediate production volumes (500 to 20,000 parts per year). More information on permanent mold casting is available in the article "Permanent Mold Casting" in this Volume.

Squeeze casting is a process in which the liquid metal solidifies under pressure in closed dies held together by a hydraulic press. Essentially, the metal is forged to near-net or net shape while it solidifies. Metal-matrix composites are manufactured by squeeze casting by infiltrating a porous ceramic preform with the liquid metal under pressure. This process has been employed to cast MMCs with ZA alloy matrices and silicon carbide or alumina chopped-fiber reinforcements. More information on this process is available in the article "Squeeze Casting" in this Volume.

Semisolid Casting. Zinc casting alloys are also being processed by semisolid casting. In this process, alloys are poured with negative superheat (that is, the pouring temperature is between the liquidus and the solidus). Vigorous mechanical agitation of the cooling metal melt prevents the formation of normal dendrites and maintains the solid fraction of the melt in the form of rounded, primary particles (see the article "Semisolid Metal Casting and Forging" in this Volume). One semisolid metal processing method that has been applied to ZA alloys is the Gircast process. As shown in Fig. 4, this stir casting process involves three major steps:

- The alloy temperature is elevated to TC_1, which is higher than the liquidus temperature T_L ($TC_1 > T_L$)
- The agitator is lowered, and the paddles are rotated to stir the metal at a temperature TC_1. The crucible is then cooled to a temperature TC_2 intermediate between the solidus and the liquidus temperature ($T_S < TC_2 < T_L$)
- The following operations are then performed simultaneously: (1) the agitator is stopped, (2) the paddles are raised, and (3) the induction heating means are retracted downward to release the crucible. The thermocouple is retracted upward. As soon as operations 1 to 3 have been executed, the centrifuged casting motor is started

Magnesium and Magnesium Alloys

Henry Proffitt, Haley Industries Ltd., Canada

Introduction

MAGNESIUM ALLOY CASTINGS can be produced by nearly all of the conventional casting methods, namely, sand, permanent, and semipermanent mold and shell, investment, and die casting. The choice of a casting method for a particular part depends upon factors such as the configuration of the proposed design, the application, the properties required, the total number of castings required, and the properties of the alloy. The discussion here will focus on the variety of alloys, furnaces, and associated melting equipment, and on the casting methods available for manufacturing magnesium castings.

Magnesium Alloys

A large range of magnesium-base alloys is available for the production of castings. Sand castings (and investment castings) can be made in all of the available alloys (see the article "Sand Molding" in this Volume). However, not all alloys are suitable for production by all casting methods. For example, alloys normally cast by the permold process are somewhat limited in number, and those used in the die casting process are even more restricted.

The method of codification used in North America to designate magnesium alloy castings is taken from ASTM Standard Practice B 275 (Table 1). It gives an immediate, approximate idea of the chemical composition of an alloy, with letters representing the main constituents and figures representing the percentages of these constituents.

Table 1 Standard three-part ASTM system of alloy designations for magnesium alloys

First part	Second part	Third part
Indicates the two principal alloying elements	Indicates the amounts of the two principal elements	Distinguishes between different alloys with the same percentages of the two principal alloying elements
Consists of two code letters representing the two main alloying elements arranged in order of decreasing percentage (or alphabetically if percentages are equal)	Consists of two numbers corresponding to rounded-off percentages of the two main alloying elements and arranged in same order as alloy designations in first part	Consists of a letter of the alphabet assigned in order as compositions become standard
A-Aluminum E-Rare Earth H-Thorium K-Zirconium M-Manganese Q-Silver S-Silicon T-Tin Z-Zinc	Whole numbers	A-First compositions, registered ASTM B-Second compositions, registered ASTM C-Third compositions, registered ASTM D-High-purity, registered ASTM E-High corrosion resistant, registered ASTM X1-Not registered with ASTM

As an example, consider the three alloys AZ91A, AZ91B, and AZ91C. In these designations:

- A represents aluminum, the alloying element specified in the greatest amount
- Z represents zinc, the alloying element specified in the second greatest amount
- 9 indicates that the rounded mean aluminum percentage lies between 8.6 and 9.4
- 1 signifies that the rounded mean of the zinc lies between 0.6 and 1.4
- A as the final letter in the first example indicates that this is the first alloy whose composition qualified assignment of the designation AZ91
- The final serial letters B and C in the second and third examples signify alloys subsequently developed whose specified compositions differ slightly from the first and from one another but do not differ sufficiently to effect a change in the basic designation.

The nominal compositions of the alloys used for sand, investment, and permold castings are shown in Table 2, and those for die castings are shown in Table 3.

Table 2 Nominal compositions of magnesium casting alloys for sand, investment, and permanent mold castings

Alloy	Composition, %

(a) Manganese content to be dependent upon iron content.

(b) The proposed alloy to have very low limits for iron, nickel, and copper. HP, high purity

Although alloys used for the die casting process are somewhat limited in number, more of the aluminum-zinc-manganese alloys (for example, the AZ91 type, particularly the high-purity grade) are now being used. A large, growing application for die castings is the automotive market.

Magnesium castings of all types have found use in many commercial applications, especially where their lightness and rigidity are a major advantage, such as for chain saw bodies, computer components, camera bodies, and certain portable tools and equipment. Magnesium alloy sand castings are used extensively in aerospace components.

Sand Casting. Magnesium alloy sand castings are used in aerospace applications because they offer a clear weight advantage over aluminum and other materials. A considerable amount of research and development on these alloys has resulted in some spectacular improvements in general properties compared with the earlier AZ types (Ref 1).

Although there has been, and still is, a large volume of castings for aerospace applications being produced in the older, conventional AZ-type alloys, the trend is toward the production of a greater proportion of aerospace castings in the newer zirconium types.

Although the magnesium-aluminum and magnesium-aluminum-zinc alloys are generally easy to cast, they are limited in certain respects. They exhibit microshrinkage when sand cast, and they are not suitable for applications in which temperatures of over 95 °C (200 °F) are experienced. The magnesium-rare earth-zirconium alloys were developed to overcome these limitations. Sand castings in the EZ33A alloy do in fact show excellent pressure tightness. The greater tendency of the zirconium-containing alloys to oxidize is overcome by the use of specially developed melting processes.

The two magnesium-zinc-zirconium alloys originally developed, ZK51A and ZK61A, exhibit high mechanical properties, but suffer from hot-shortness cracking and are nonweldable.

For normal, fairly moderate temperature applications (up to 160 °C, or 320 °F), the two alloys ZE41A and EZ33A are finding the greatest use. They are very castable and can be used to make very satisfactory castings of considerable complexity. In addition, they have the advantage of requiring only a T5 heat treatment (that is, precipitation treatment).

When a demand arose in some aerospace engine applications for the retention of high mechanical properties at higher elevated temperatures (up to 205 °C, or 400 °F), thorium was substituted for the rare earth metal content in alloys of the ZE and EZ type, giving rise to the alloys of the type ZH62A and HZ32. Not only were there substantial improvements in mechanical properties at elevated temperatures in these alloys, but good castability and welding characteristics also were retained.

The thorium-containing alloys, however, exhibited a greater tendency for oxidation, requiring greater care in meltdown and pouring. The mildly radioactive nature of the dross and sludges from processing these alloys and the disposal of these byproducts are associated problems with this alloy group.

A further development aimed at improving both room-temperature and elevated-temperature mechanical properties produced an alloy designated QE22A. In this alloy, silver replaced some of the zinc, and the high mechanical properties were obtained by grain-refinement with zirconium and by a heat treatment to the full T6 condition (that is, solution heat treated, quenched H_2O, and precipitation aged). However, problems were experienced with both of these alloys. The use of thorium has become increasingly unpopular environmentally, and the price of silver has become very unstable in recent years. Hence, there has been a considerable amount of research and development work on alternative alloy types.

The most recent alloy emerging from this research was an alloy containing about 5.0% Y in combination with other rare earth metals (that is, WE54A), replacing both thorium and silver (Ref 2). This alloy has better elevated-temperature properties and a corrosion resistance almost as good as the high-purity magnesium-aluminum-zinc types (AZ91C). The alloys used for investment casting are very similar to those used for the sand casting process.

Permanent Mold Casting. In general, the alloys that are normally sand cast are also suitable for permanent mold casting (see the article "Permanent Mold Casting" in this Volume). The exception to this are the alloys of the magnesium-zinc-zirconium type (for example, AZ51 and ZK61A), which exhibit strong hot-shortness tendencies and are consequently unsuitable for processing by this method.

Die Casting. The alloys from which die castings are normally made are mainly of the magnesium-aluminum-zinc type, for example, AZ91 (see the article "Die Casting" in this Volume). Two versions of this alloy from which die castings have been made for many years are AZ91A and AZ91B. The only difference between these two versions is the higher allowable copper impurity in AZ91B.

More recent development work on this alloy type has produced the high-purity version of the alloy in which the nickel, iron, and copper impurity levels are very low and the iron-to-manganese ratio in the alloy is strictly controlled. This high-purity alloy shows a much higher corrosion resistance than the earlier grades.

General Applications

The most important feature of magnesium castings, which gives rise to their preferred use compared with other metals and materials, is their light weight. Because of this, magnesium castings have found considerable use since World War II in aircraft and aerospace applications, both military and commercial. More recently, as a result of a general requirement for lighter weight automobiles to conserve energy, there has been a growing use of magnesium in the automotive field, principally as die castings.

Magnesium, however, has other important casting advantages over other metals:

- It is an abundantly available metal
- It is easier to machine than aluminum
- It can be machined much faster than aluminum, preferably dry

In the die casting process, it can be cast up to four times faster than aluminum. Die lives are considerably longer than with the aluminum alloys, because much less welding onto the die surfaces takes place. When protected correctly, particularly against galvanic effects, it behaves in a very satisfactory manner. Modern casting methods and the application of protective coatings currently available ensure long life for well-designed components.

Today's state-of-the-art technology makes it possible to produce parts of considerable complexity having thin-wall sections. The end product has a high degree of stability as well as being light in weight.

Melting Furnaces and Auxiliary Pouring Equipment

Furnaces for melting and holding molten magnesium casting alloys are generally the indirectly heated crucible type, of a design similar to those employed for the aluminum casting alloys. The different chemical and physical properties of the magnesium alloys in comparison to aluminum alloys, however, necessitate the use of different crucible materials and refractory linings and the modification of process equipment design.

When magnesium becomes molten, it tends to oxidize and burn, unless care is taken to protect the molten metal surface against oxidation. Molten magnesium alloys behave differently from aluminum alloys, which tend to form a continuous, impervious oxide skin on the molten bath, limiting further oxidation. Magnesium alloys, on the other hand, form a loose, permeable oxide coating on the molten metal surface. This allows oxygen to pass through and support burning below the oxide at the surface. Protection of the molten alloy using either a flux or a protective gas cover to exclude oxygen is therefore necessary.

Molten magnesium does not attack iron in the same way as molten aluminum, and the metal can therefore be melted and held at temperature in crucibles fabricated from ferrous materials. It is common practice, therefore, especially with larger castings, to melt and process the molten magnesium alloy and to pour the casting from the same steel crucible.

Figure 1 shows the cross-sectional design of a typical fuel-fired stationary crucible furnace of the bale-out type, from which metal for small castings can be hand poured using ladles (see the article "Melting Furnaces: Reverberatory Furnaces and Crucible Furnaces" in this Volume). This use of metallic crucibles allows the crucible to be supported from the top by means of a flange, leaving a space below the crucible. Not only is this a distinct advantage in the transfer of heat to the crucible charge, it also ensures that there is room for easy removal of any detached scale that might form on the outer surface of the crucible during the melting operation. The furnace chamber has a base that slopes toward a cleanout door.

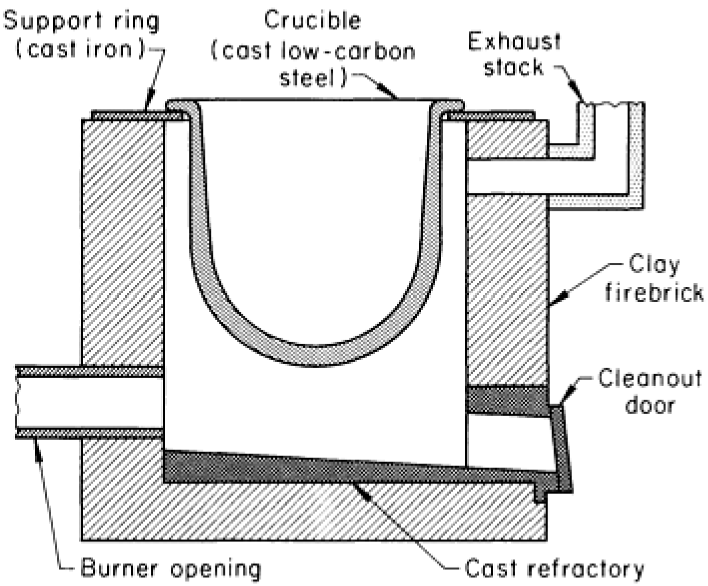

Fig. 1 Cross section of a stationary fuel-fired furnace for open-crucible melting of magnesium alloys.

A progressive thinning of the crucible walls can occur, which may tend to be localized in fuel-fired furnaces because of flame impingement. There is the possibility of molten-metal leakage if the wall thickness is not checked regularly.

With scale, there is also the possibility of reaction between the iron oxide and the molten magnesium, which can be explosive in character. Furnace bottoms must therefore be kept free from scale buildup. It is important also to have a run-out pan capable of taking the full crucible content in the event of leakage.

More recently, and especially in cases where it is difficult to check on scale formation, it is possible to use steel crucibles that are clad with a nickel-chrome alloy on the outside heating surface in order to eliminate scaling and still not detract from the heating efficiency of the furnace.

The furnace lining refractories are important, because molten magnesium reacts violently with some refractories. High-alumina refractories and high-density "super-duty" firebrick of a typical 57% Si and 43% Al composition have been found to give satisfactory results.

The cleanout door on fuel-fired furnaces can be easily opened for its intended purpose. With electric-resistance crucible furnaces it is common practice to seal the cleanout door with a sheet of low melting point material, such as zinc, which will not act as a barrier to molten magnesium alloy in the event of a run-out, but will prevent the "chimney" effect, which can accelerate oxidation of the crucible.

Burning, which can occur at or above the melting point of the alloy, is prevented by the use of either a flux sprinkled on the molten metal or a suitable fluxless technique using a gas mix containing 1% SF_6. Both procedures will be described in detail later in this article. Increasingly stringent environmental controls in the foundry have rendered the older sulfur-dioxide domed bale-out furnace unacceptable.

The type and size of furnace used is largely dependent on the type of casting operation. A small jobbing foundry, carrying out a batch-type operation in a wide range of different alloys, normally uses the lift-out crucible technique. Larger-scale operations, typically operating on a more restricted range of casting alloys, may employ a larger bulk melting unit from which the molten alloy for the casting operation is distributed to holding crucible furnaces. In the crucible furnaces, metal treatments are carried out, and the metal is either poured directly from the crucible or hand ladled to the casting molds.

In cold-chamber die casting operations, the supply of molten alloy to the machine is maintained by hand ladling or by automated means. The hot-chamber process is becoming more popular. A cold-chamber machine differs from a hot-chamber machine in that the cylinder and injection plunger are not submerged in the molten metal. Because the injection mechanism in a hot-chamber machine is submerged in the furnace bath, the operation is faster and the plunger pressure

can be adjusted to force the molten metal into the finest die detail. Electromagnetic pumps can also be used for this purpose. The overriding consideration in metal transfer is that the metal must be transferred in as nonturbulent a manner as possible in order to avoid oxidation, which can give rise to oxide skins and inclusions in the final casting. Excessive oxidation has ruled against the use of direct-fired reverberatory furnaces similar to those used quite satisfactorily for aluminum alloys.

Crucibles. The indirect heating crucible method of melting is of comparatively low thermal efficiency. Electric coreless induction furnaces, although much higher in initial capital cost, have lower running costs and occupy less floor space than fuel-fired units (see the article "Melting Furnaces: Induction Furnaces" in this Volume).

Crucibles range in size from about 30 to 910 kg (60 to 2000 lb). In the lower range, they may be constructed as steel weldments. The steels normally used are of low carbon content, that is, less than 0.12% C. Because of the extremely adverse effect of nickel and copper on the corrosion resistance of magnesium alloys, these two elements in the steel must be restricted to less than 0.10% each.

Magnesium melting operations, particularly if a flux melting procedure is used, normally result in the formation of a sludge with a comparatively low thermal conductivity at the bottom of the crucible. If this material is not periodically removed, overheating of the crucible can result in this area, accompanied by excessive scaling of the crucible. Excessive oxide buildup on the crucible walls can have the same effect. Records of the number of charges being melted should be kept for each crucible as a routine safety measure.

Less buildup is normally experienced with the fluxless method of melting. It is a very desirable procedure, however, to periodically withdraw the crucibles from use and allow them to soak, filled with water, to remove all buildup.

Pouring Ladles. For smaller castings, hand ladling can be conventionally used, with pouring ladles taking molten alloy from a bale-out-type furnace. Pouring ladles can be bucket shaped for the slightly larger range of castings and hemispheric shaped for the smaller ones. Both types of ladles however, should be constructed from low-carbon, low-nickel steel and be about 12 gage (2.67 mm, or 0.105 in., thick). A typical design of a bucket type ladle is shown in Fig. 2. Essential design features include an overflow guard and a bottom-pour spout to avoid the possibility of the pour being flux contaminated.

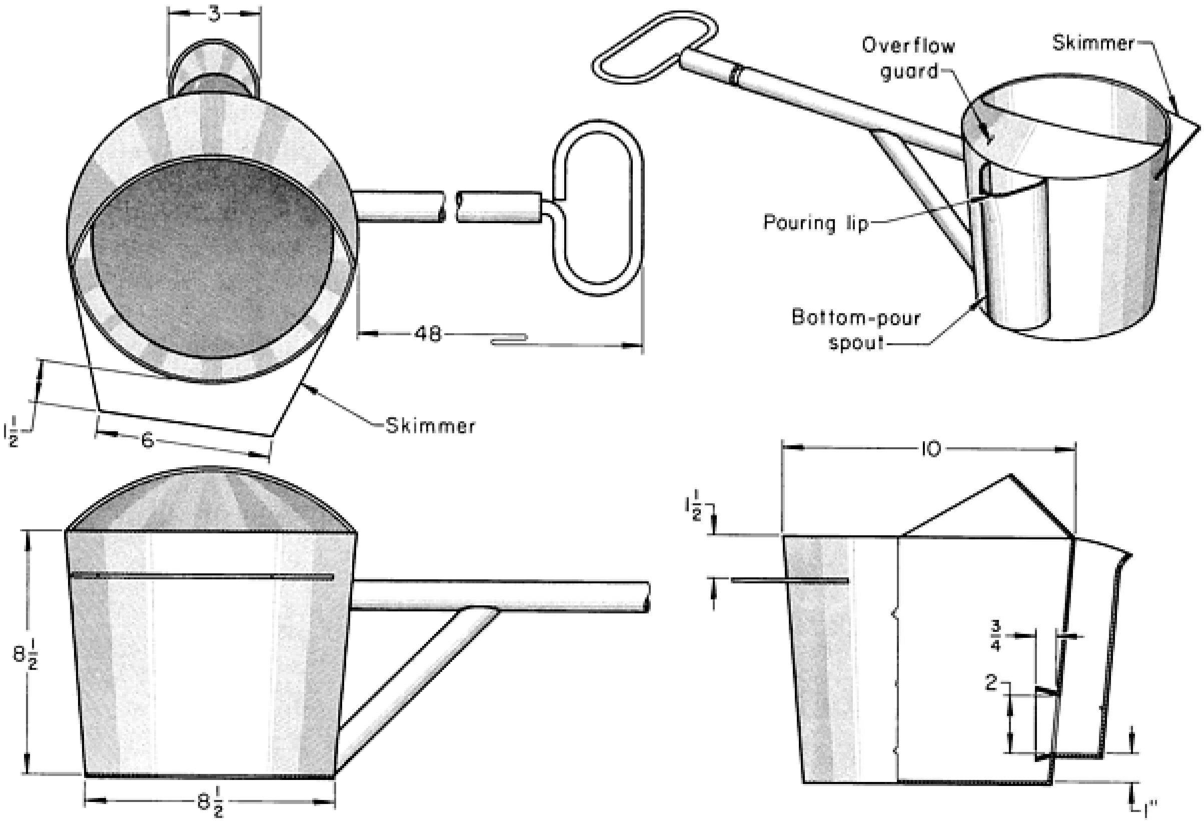

Fig. 2 Construction details of a typical ladle used for pouring magnesium alloys. Dimensions given in inches.

Other essential items of metal handling equipment include sludge removal ladles, sludge pans to contain this material, stirrers, puddling tools, and skimmers. All of these pieces of equipment should have the same steel composition as the crucible.

Thermocouples. Accurate temperature control is critical to the processing of magnesium alloys. Iron-constantan- or chromel-alumel-type thermocouples are recommended. There should be a permanent type of installation such that temperature determinations can be made at appropriate stages in the melting and metal treatment process. Light-gage thermocouples in thermocouple protection tubes of either mild steel or nickel-free stainless steel should be used.

Melting Procedures and Process Parameters

There are basically two main systems, flux and fluxless, for the melting and pouring of magnesium alloys. Each of them, if done correctly, is perfectly capable of producing good metal for the casting process. Many of the precautions taken apply equally to both methods.

The Flux Process. The basic requirement in melting magnesium is to exclude oxygen from the molten magnesium as it melts. Because early attempts to develop a system using gaseous protection were not completely satisfactory, successful melting procedures became possible only when flux methods were developed. In the course of time, suitable fluxes for handling both the magnesium-aluminum-zinc-manganese and the magnesium-zirconium-containing alloys emerged, and corresponding techniques for producing clean, flux-free castings were developed. These procedures have been successfully used for several decades (Ref 3). A typical flux-melting procedure would be for the crucible with a small quantity of flux (about $1\frac{1}{2}$% of charge weight) placed in the bottom, to be preheated to dull red heat.

The metal charge to be loaded must be clean, dry, and free from oil, oxide, sand, and corrosion. There should be no foreign metals present.

Contamination by even tiny pieces of sand or debris from other alloys must be prevented by close control of melt parameters. No oxide-contaminated material should be allowed to enter the melt charge. All materials that contain dirt or oxide should be separately refined and ingotted before being recycled into production melts.

"Bridging" of the metal charge in the crucible should be avoided, the object being to feed the remainder of the charge progressively into the crucible and maintain an advancing level of liquid alloy. During this procedure, additional flux is lightly sprinkled onto the melt surface.

There are separate proprietary fluxes for each type of magnesium alloy (that is, AZ types and magnesium-zirconium types). Supplier instructions for these fluxes must be precisely followed, and their use must be restricted to the type of alloy for which they were developed. During the meltdown process, localized overheating of the charge must be prevented. The process of chlorination of the melt for refining purposes is no longer considered to be an acceptable practice unless effective steps are taken to collect chlorine fumes.

The Fluxless Process. With the flux technique, particularly in the field of die castings, the presence of flux gave some operational difficulties even with hot-chamber die casting processes. Flux inclusions in the castings were not uncommon, creating a major hindrance to the greater use of magnesium.

A significant breakthrough in this area resulted in the development of a fluxless process for use in the melting, holding, and pouring of magnesium alloys (Ref 4, 5, 6, 7, 8, 9). This involved the use of air/sulfur-hexafluoride gas or air/carbon-dioxide/sulfur-hexafluoride gas mixes of low ($\leq 2\%$) SF_6 concentration.

The protection afforded the magnesium being melted was very effective, with the added advantage that the mix was nontoxic and odorless. This process became immediately accepted by both the ingot producers and the die casting sections of the foundry industry, because it answered this objection to the flux melting method.

The new melting process was next extended to the sand casting process (Ref 10). There were two aspects of the sand process that had to be allowed for. The temperatures for pouring the magnesium alloys, particularly the zirconium alloy (see Fig. 3), were appreciably higher than for the die casting alloys. Also, the sand process is generally a more open method, in that the molten alloy cannot be enclosed to the same degree as with die castings. For these reasons the gas mixture used by the sand caster is generally richer in sulfur-hexafluoride content, and sometimes, particularly with the magnesium-zirconium alloys, the parent gas is carbon dioxide.

Fig. 3 Pouring of a sand mold for a magnesium-zirconium alloy casting using the fluxless technique. Courtesy of Haley Industries Ltd.

The melting process using fluxless methods proved to be much more acceptable to the die casting process, and in practice melting losses were considerably reduced (by about half in some cases). The reasons for the much higher melting losses with flux melting are, first, the entrapment of small globules of metal in the sludge at the bottom of the crucible and the difficulty of recovering such metal. With the absence of flux in the fluxless method, the amount of sludge at the bottom of the crucibles is greatly reduced.

Grain Refinement. The earlier procedure of superheating the melt to 870 to 925 °C (1600 to 1700 °F) followed by a rapid cooling to process temperature is no longer popular or acceptable because it considerably shortens crucible life and can increase the iron content of the alloy melted.

With these AZ-type alloys, the present-day system of grain refinement is by the use of tablets of hexachlorethane or hexachlorbenzine for grain refinement and degassing. With the magnesium-zirconium alloys, very effective grain refinement is achieved by the zirconium addition. To achieve the optimum fineness of grain, it is necessary for the melt to be supersaturated with soluble zirconium. Insoluble zirconium complexes can also be present in the melt, resulting from contaminations of different types. Aluminum and silicon are very undesirable for this reason. Thus, it is necessary for an excess of zirconium to be added to the melt, over and above that which is theoretically required, to provide the required soluble zirconium level.

It is also necessary, for the same reason, to maintain the heel of zirconium-bearing material at the bottom of the crucible into which the insoluble zirconium complexes settle. To prevent any of this liquid heel from being poured off into the castings, an adequate amount of molten alloy (that is, about 15% of the charge weight) is left behind after the casting molds have been poured.

Undue disturbance of the melt during pouring must be avoided. Great care must be taken not to overpour, and the melting procedure must allow adequate settling time. The normal control check carried out on the AZ alloy is to fracture a small test sample cast in sand for visual examination. For the magnesium-zirconium alloys, a small chill cast bar is fractured and visually examined. Comparison is made with norms on which the grain size has been checked metallographically. The grain size value regarded as satisfactory is 0.03 mm (0.0012 in.). A very important factor, which normally requires continuous surveillance, is the possibility of cross-contamination by alloy mixing.

Alloying. Most foundries purchase prealloyed ingot, which is subsequently charged into the melting furnace with a proportion of the process scrap. In the case of some die casting operations, the amount of process scrap generated is low, and it becomes economically feasible to have this scrap remelted and ingotted before it is reused. With the AZ alloys used in the sand casting and die casting operations, little correction to the composition is necessary. However, the magnesium-zirconium alloys contain alloying constituents that tend to be lost during each remelt operation and need to be added each time the material is remelted. Such corrections can be made by adding the pure metals themselves (such as zinc, misch metal, and so forth), or hardener alloys with a fairly high content of the alloying element. Zirconium added as a master alloy of about 30% in magnesium and cerium rare earths added as a master alloy with a content of 20% rare earths in magnesium are examples.

Composition control must allow for the fact that the addition of a master alloy to correct one element may lead to a dilution of the melt, causing the content of other elements to be reduced. Normally, these master alloys are added into the melt by placing them into a preheated steel basket, from which they readily dissolve into the melt.

A "puddling" technique involving either manual or mechanical stirring, followed by a settling procedure to allow insoluble zirconium complexes to settle, produces the required degree of supersaturation of the melt with zirconium. Care must be taken not to hold the melt too long or to allow the melt temperature to fall, however, because losses of zirconium will result.

Melt Treatments. In the melt-down operation, oxidation of the metal must be prevented by the sprinkling of flux on the melting metal or, in the case of fluxless techniques, by the efficient use of sulfur hexafluoride/carbon dioxide atmosphere. Depending largely on the type of alloy and the melting and casting process used, the gas may consist of sulfur hexafluoride/air, or sulfur hexafluoride/carbon dioxide/air mixtures. For example, with the die casting process, in which comparatively low casting temperatures are used and the molten metals can be effectively enclosed, sulfur hexafluoride/air mixture with a low sulfur hexafluoride content (typically <0.25%) provides adequate protection.

With sand castings, particularly with the magnesium-zirconium alloys, higher melt temperatures are used. To provide adequate protection, it is normal to employ a carbon dioxide/sulfur hexafluoride or carbon dioxide/air/sulfur hexafluoride mixture. It is also normal for the sulfur hexafluoride content of the mixture to be increased up to a maximum of 2%.

Gas Content and Grain Size. Currently, the process of chlorination with the AZ-type alloys to clean and degas the melt is rarely acceptable on environmental and safety grounds. Also, the earlier process of grain refinement by superheating these alloys to a high temperature (that is, 850 °C, or 1560 °F), followed by a rapid cool to casting temperature is unacceptable on both technical grounds, because of the increased iron pickup from the crucible, and economic grounds, because of the shortening of crucible life due to the high furnace chamber temperatures. These earlier techniques have been replaced by the use of carbon inoculation, using hexachlorethane or hexachlorbenzine. These materials, added in the form of compressed tablets, simultaneously provide degassing and grain-refining effects.

With the zirconium alloys, the situation is different in that a separate degassing or grain refinement treatment is no longer necessary, both of these features being taken care of by the addition of zirconium.

With flux melting of the aluminum-zinc-manganese-type alloys, fluxes high in magnesium chloride are employed, but there are inherent dangers if these fluxes are used with the zirconium alloys. However, special proprietary fluxes have been developed for the zirconium alloy to avoid these problems.

Foundry Control Procedures. When sand casting an AZ-type alloy, apart from conducting standard spectrographic control of composition, it is normal to pour a sand cast round bar approximately 19 mm ($\frac{3}{4}$ in.) in diameter and then fracture it for visual examination. Examination of this fractured surface and comparison with sand cast standards serve as a useful check of the degree of grain refinement achieved.

With the zirconium alloys, a grain size check is usually carried out on a standard chill cast bar that is fractured and examined in a similar way. This test satisfactorily determines whether the zirconium content is at an acceptable level for a prescribed degree of grain refinement. Comparison standards are set up to ensure that the grain size meets a 0.03 mm (0.0012 in.) size limit. Chemical composition control is normally carried out spectrometrically using cast slugs poured into a steel mold.

A large proportion of the sand castings made in magnesium alloys are for aircraft or military requirements, for which very stringent checks and inspections are required. Normally, samples for tensile testing must be provided from each melt. These are either separately cast test bars made in a sand mold or coupons attached to the parent casting. Frequently, complete destructive testing of sample castings is called for to further demonstrate the quality level of the workpiece. For the die castings, the standard control procedures involve not only visual and dimensional checks but also inspection of the castings by fluoroscopic screening.

Pouring Methods. The method of pouring depends on the casting process. Thus, pouring can vary from dip ladling from a bale-out crucible, to more automated systems using metered shots of molten alloy, to a die casting machine. The automated hot chamber machine is another possibility, and large sand castings are currently being poured directly from the crucible in single or multiple crucible pours.

In the flux-melting method, the dried flux on the top of the molten metal must be completely removed by careful skimming. Just as important is the complete removal with a steel wire brush of any loose flux on the rim of the crucible or the pouring lip.

During this operation, and until pouring is complete, oxidation is controlled by dusting the surface of the molten metal with a mixture of equal parts of coarse sulfur and fine boric acid. Proprietary material is available for this purpose. The surface of the metal should be left as undisturbed as possible until the melt is ready to pour. At this stage the skin formed by the protective agent is pushed back to ensure that none of it enters the molten metal stream. During the actual pour, the metal stream can be adequately protected by dusting with sulfur.

When pouring, it is undesirable for the molten alloy to enter the sprue direct from the pouring ladle, because this tends to cause any oxide on the metal stream to be carried directly into the mold. If a properly designed pouring box that allows for a degree of separation is used, this will not occur.

Because the flux melting process results in a quantity of residual flux-bearing material at the bottom of the crucible, the pouring crucible should never be completely emptied to avoid pouring some of this material off into the molds. With the zirconium alloys, this is even more important, and about 15% of the charged weight is retained as a heel. With these alloys, the heel will contain residual zirconium and zirconium complexes in addition to the flux and some entrapped magnesium particles.

In the fluxless melting method, there is still some surface oxide, which should be carefully skimmed from the melt surface, while maintaining the flow of the protective gas. The gas flow can be temporarily discontinued while the crucible is removed from the furnace, but the gas flow must be continued until the pouring is completed.

The same protective gas mix used for melting is used on the metal stream during pouring and is used to flush the molds to supplement the action of the inhibitors. The heel left behind can be smaller in volume than the sludge from the flux melting procedure because there is no residual flux. The clean, sludge-free portion of the heel can be recycled into subsequent melts.

Pouring. Small sand, permold, or die castings can be poured from hand ladles. For this purpose, clean, preheated bottom-pour ladles can be used to dip the molten alloy from open crucibles. The same precautions against oxidation must be observed as with direct pouring from the crucible. Oxidation and burning of the metal in the hand ladle can be minimized by sprinkling powdered sulfur on the metal surface.

For hand ladling a special flux pot can be used into which the ladle is immersed between pours to dissolve nonmetallics and also keep the ladle hot. The ladle must be drained until it is free of flux. "Double-filling" the ladle, avoiding undue agitation, and taking more metal than is actually needed for the pour are measures that help prevent the carry-over of flux into the castings.

The possibility of flux contamination and associated corrosion problems and the tedium of the precautions listed above have spawned the development of automated pouring and fluxless methods in both the low- and high-pressure die casting fields.

Safety Precautions. The usual precautions for handling other molten metals are even more exacting with magnesium. These include the use of face shields and fireproof clothing by plant personnel. With magnesium there is a greater hazard in that moisture, from whatever source, increases the danger of explosion and fire: when moisture comes in contact with

molten magnesium, it generates hydrogen, a potential source of explosion. Certain minimum precautions must therefore be observed:

- All scrap must be clean and dry; corroded material should be precleaned
- Any fluxes, which tend to be hygroscopic, must be kept dry and stored in airtight containers
- Ladles, tools, and anything that will come into contact with molten magnesium must be completely dry and preheated
- The danger of molten magnesium coming into contact with iron oxide scale must be avoided

Sand Casting

Sand castings are produced in a wide range of alloys, weighing from a few ounces to as much as 1400 kg (3000 lb). Successful production of sand castings became possible only when the means for preventing metal/mold reactions from occurring were developed. This was achieved by the addition of suitable inhibitors to the sand mix used in the manufacture of the mold and the cores. These inhibitors include the following, used singly or in combination: sulfur, boric acid, potassium fluoborate, and ammonium fluosilicate.

The amount of inhibitor that must be added to the sand in order to prevent metal/mold reaction depends on the moisture content of the sand. The original process was called the green sand method (see the article "Sand Processing" in this Volume), in which the bond is produced by the natural clay present in the sand being activated by the addition of water or by the use of the clay products southern or western bentonite. Diethylene glycol is frequently added to the latter type of mix in order to minimize the amount of water necessary and to prevent the sand from drying out. In these green sand mixes, the water content can be in the range 2.0 to 4.0%. A correspondingly high inhibitor content is therefore required.

The amount of inhibitor is also dependent upon the pouring temperature, the type of alloy being cast, and the casting section thickness. The higher the pouring temperature, the higher the reactivity and the need for larger inhibitor additions. The heavier the casting section, the slower the cooling rate. The inhibitors, particularly the more volatile ones, are more easily lost from the mold surface and need to be replenished from the mold areas at a distance from the heavy section.

The green sand molding process is still used extensively for the manufacture of a wide range of sand castings. It has certain limitations, but is economical because the sand can be reused repeatedly. To reuse the sand, it is necessary only to restore the moisture, inhibitor, and glycol contents and then to suitably mull the sand mixture. There is no loss of expensive binder materials used in the modern chemically bonded sands. Automated sand-mixing equipment, with delivery of the sand mix to the point of use, is commonly employed.

Molding Sands. It is essential to carry out various sand control tests, as described elsewhere, in order to maintain a consistent sand mix. In most magnesium foundries making a wide range of sizes of castings, the molding sand and inhibitor type and amount are normally adjusted to suit the heaviest section being cast.

Molding sands must have high permeability in order to allow free passage of the generated mold gases away from the metal/mold interface, that is, 60 to 90 AFS (see the article "Sand Molding" in this Volume). For this reason, the basic sand used should be comparatively coarse grained. This is especially important because most additives tend to reduce permeability.

Unfortunately, these relatively coarse sands tend to produce rough casting surfaces. The choice is therefore between a good casting surface on the one hand and the venting of generated mold gases on the other. For this reason, it is of the utmost importance to assist the venting of mold or cores and any other reduction in gas generation.

The natural venting through the body of the core must be augmented by additional vent channels drilled into the core. These channels must be capable of rapidly taking gases outside of the mold by means of core prints. Assisted evacuation of these gases is sometimes used.

Natural-bonded sand can and has been used quite satisfactorily for small molds, but very careful control is needed to maintain satisfactory results because of its relatively high clay content and poor uniformity. Better and more consistent results are obtained by the use of a synthetic sand mix. A washed and graded silica sand is used, with the bond being provided by carefully controlled additions of western or southern bentonite. The essential properties of these two types of bentonite are quite different, and by joint use and controlled blending an optimum balance of desired properties can be obtained. Western bentonite imparts toughness (a combination of high green strength and low deformation). Because these green sand mixes are repeatedly reused, losses of moisture, inhibitors, and so forth can occur, and these materials must be restored at each remulling (see the article "Sand Processing" in this Volume). Frequent and regular testing of the properties and composition of the sand is imperative. Also, mulling must be carried out on a controlled basis. The composition and typical properties of some molding sands are shown in Table 4 (Ref 11). A variant of these molding sand mixes, which has also been used successfully, employs a modified type of bentonite using an oil as a mixing agent for bonding.

Table 4 Typical compositions and properties of magnesium molding sands

Ingredient or property	British		American						
	Synthetic	Natural	Synthetic					Semisynthetic	
Clay	. . .	8	. . .	. . .	. . .	. . .	. . .	1	1
Bentonite	4	. . .	3	3-7	4	3	3	3	5
Moisture	$2\frac{3}{4}$	5-6	$2\frac{1}{2}$-$3\frac{1}{2}$	$1\frac{1}{2}$-$2\frac{1}{2}$	$2\frac{1}{4}$-$3\frac{1}{4}$	$2\frac{1}{2}$	$1\frac{1}{4}$-$2\frac{1}{4}$	3	$2\frac{1}{2}$-3
Sulfur	4	6	$4\frac{1}{2}$	$1\frac{1}{4}$-$2\frac{1}{4}$	2	3	2	$1\frac{1}{2}$	3

Compressive strength (green, psi)	8-10	10-13	11-15	7-11	8-12	8-10	9-12	10-12	8-10
Permeability (green)	100	30-40	80-100	120-180	50	90-150	80-90	80-100	100-140

Control over the properties and additives is as important as it is with the conventional green sand process. More efficient air extraction is necessary to remove burnt oil fumes and render the process environmentally acceptable for present-day standards. Essentially, the type of sand mix chosen is largely dependent upon the molding process used and the sand cast product being made.

Advantages and Disadvantages of Green Sand Molding. Green sand molding is the least expensive of the sand casting processes. This is because only small amounts of additives are needed each time the sand is mulled, and it is not necessary to use expensive reclamation systems in order to recycle the sand. However, the process does not lend itself to the production of cast components of high complexity. Also, it is not capable of producing castings that satisfy the level of dimensional accuracy currently being demanded for many applications.

Fortunately, technology in the mold- and core-making fields has advanced sufficiently to keep pace with these challenges. The first breakthrough, which occurred during the World War II era, was the development of the shell molding process (also known as the Croning process) for the manufacture of shell cores and molds. Almost concurrently the carbon dioxide/silicate process came into general use. Both of these processes improved the quality and dimensional accuracy of castings. Also, the core breakdown characteristics were much improved from those of the earlier oil sand cores.

The carbon dioxide/silicate process, originally developed for cores, was adapted to the manufacture of molds of much improved dimensional accuracy and good breakdown. The reclamation of these, to enable sand to be recycled, proved to be difficult. With the carbon dioxide/silicate process, there was appreciably less moisture present after the molds were gassed than there was with green sand. It was therefore possible to considerably reduce the amount of inhibitor addition.

In the carbon dioxide/silicate process, the sand is fully hardened by passing carbon dioxide through the core *in situ* in the core box. This eliminates most of the distortions that occurred with the oil sand core and affords a significant energy saving. It is also possible to use the cores in a mold very soon after they are produced.

Following this development there were a number of further advances involving various types of phenolic, furan, and epoxy resins of the chemical self-set or gas-hardening type. The latter group involves hardening by the use of air, carbon dioxide, sulfur dioxide, methyl formate, or organic amines.

Preference for the different proprietary systems vary from foundry to foundry, but in general they all produce molds and cores much superior to those obtained from the green sand molds or oil-sand/baked cores. It is largely these improvements in materials and processes that have enabled the foundry industry to produce complex castings such as those illustrated in Fig. 4, 5, and 6 (Ref 12).

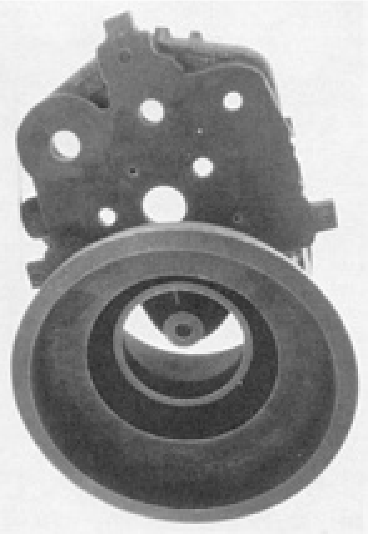

Fig. 5 Typical engine gearbox for a private or commuter turboprop aircraft cast from QE22A magnesium alloy with T6 temper. Courtesy of Haley Industries Ltd.

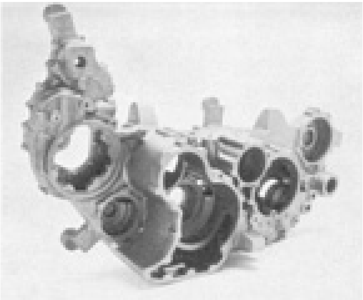

Fig. 6 Gearbox housing for a military fighter aircraft composed of ZE41A magnesium alloy of T5 temper. Courtesy of Haley Industries Ltd.

The aircraft gearbox housing shown in Fig. 6 is a sand casting in ZE41A-T5 alloy made by the furan chemical-set process. It contains 56 cores within its configuration. A number of these are small-diameter cores forming complex oil passageway configurations. The accurate positioning of these cores and the thin-wall sections in this casting are made possible only by the use of this type of process.

Casting solidification rates can be increased locally by the use of metallic chills or by the use of zircon sand to help in producing an optimum solidification pattern in the casting. Proprietary sprays, which are compatible with molten magnesium alloy, are often used to improve the surface hardness of the mold and thereby reduce the effects of molten metal impingement.

The gap between the cope and drag may be sealed by the use of a proprietary core paste material, to prevent metal leakage or flashing in the casting. Light torching of the mold, using a nonoxidizing acetylene flame, which deposits carbon on the metal contact surface, improves fluidity.

Coremaking Procedures. Major cores, other than small pipe cores, are normally produced in a silica sand mix and should have approximately the same grain fineness as the molds themselves. Frequently, smaller cores, particularly those of small diameter and long length, may be of a different type of sand mix than that used for the molds. This factor becomes particularly important if the process allows a substantial amount of core sand to enter the mold sand system during shakeout. Subsequent recycling of the main sand burden may therefore change in grain size distribution. In fact, the introduction of new sand used for the cores may have a desirable "sweetening" effect on the main sand system. It would be normal for the molds to be made from a sand mix with a high content of recycled/reclaimed sand.

The sand mixes used for core production must also contain an inhibitor addition, usually of a type similar to that used for the mold. The binders used for cores are similar to the types used in the mold. However, because magnesium alloys have a comparatively low heat content, not as much heat is available for the breakdown of the core as for other metals. Careful choice of binder type and of the percentage of binder is important.

Other desirable features of cores are:

- They must be capable of being handled and drilled for venting without deterioration
- They must have good shelf life and not be affected by atmospheric conditions of storage
- They must be entirely stable and not distort in storage
- The larger cores must be capable of incorporating chills, when necessary, in the core to produce directional solidification within the casting

For these reasons it is desirable to choose a core binder and core system that produce a degree of strength and dimensional stability to prevent sagging without the necessity for core dryers or bottom boards.

The carbon dioxide/silicate process has been used extensively for cores for magnesium alloys, and is a good example of the earlier gas-hardening process. Details of the carbon dioxide/silicate and shell molding methods can be found elsewhere in this Volume (see the article "Sand Molding").

Modern resin binder systems in which the core sand mix is hardened by an acidic activating agent or by the passage of acid gases such as sulfur dioxide *in situ* in the core box have gained considerable popularity. Cores can be made by automated equipment that can be very closely controlled to perform all of the necessary functions of coremaking.

Hot-box methods of core production, also used extensively for magnesium castings, are essentially the same as for other metals and are described in the articles "Sand Molding" and "Coremaking" in this Volume.

Magnesium is widely used for aerospace and race car engine applications, where the particular attributes of the metal and its weight-saving potential are required. The ability to incorporate complex small-diameter oil passageways by coring is an important requirement. Using some of the improved core binders and coremaking processes described, those requirements can be met. If much higher production costs can be tolerated, it is possible to produce even smaller-diameter cores by the use of special processes described in Ref 13. These include the production of ceramic cores, salt cores, wire cores with wash coatings, quartz glass cores, fiberglass cores with ceramic coatings, and wire helix cores with wash coatings. The latter process can be used to manually produce cores with a diameter as small as 2 mm (0.079 in.). For many casting designs, it would be quite impossible to produce these passageways machining operations.

Shrinkage Allowances. Nominal shrinkage allowance data for the various alloys is available and can serve as a general guide. It is generally much safer, however, to establish factors for shrinkage under a particular set of foundry conditions.

Gating practices for magnesium have been largely developed to accommodate some of the specific chemical and physical characteristics of the metal and its alloys. Probably the most important of these is the pronounced tendency of the alloys to oxidize. This is particularly the case with those alloying constituents such as rare earth metals and thorium. The second factor is the very low density of these alloys. Magnesium has only two-thirds the weight of aluminum at a comparable volume.

Because of these two factors, minimizing turbulent effects in a mold must be a major objective in any casting method. Turbulence causes the formation of oxide skins and films (dross) being folded into the flowing metal and appearing later in the casting as inclusions or surface pits. The technique for introducing the molten alloy into the mold cavity must therefore be one designed to minimize turbulence. For example, the metal must be introduced at the level of the lowest part of the casting.

Gravity pour systems are normally used, with the metal passing from a pouring cup down a sprue and into a runner system situated at the bottom of the mold. One or more sprues may be used, these normally being tapered so that the metal is choked at their bases. This prevents the aspiration of air. Particularly long sprues should be broken by an intermediate step.

During the pour, the pouring cup or box should be kept full. From the bottom of the sprue, the design is such that the metal is allowed to take only a horizontal or upward flow. The normal procedure is for the metal to pass through a runner channel and then through gates into the bottom-most region of the casting.

It is standard practice to position screens or filters to interrupt the metal flow before it enters the mold cavity to remove any oxide resulting from pour turbulence. The local cross section of runner bar is enlarged locally so that the flow of the molten alloy is not impeded. The screens may consist of a piece of perforated steel sheet, often with coarse steel wool as a backup. There are also proprietary woven screens of stainless steel wire. These are preformed into a wedge shape to fit easily into a matching cavity formed in the running system. The use of these filters ensures a degree of consistency and is normally a preferred technique. Apart from their essential function of removing oxide, filters also regulate the metal flow into the mold cavity.

The design of the runner bar itself can also help to remove dross (slag). Thus, if the cross-sectional area in the runner bar is increased (that is, compared to the sprue), the flow rate decreases, and oxide can be skimmed from the metal stream before it enters the mold cavity. To enhance this effect, the cross section of the runner channel is made fairly large and long, and is taken beyond the last gate into the casting.

The design of the runner system should be such that the runner bar is completely filled before any metal can flow through the gates into the casting. It is desirable, therefore, for as much of the casting as is possible to be formed in the cope, or to use a three-part mold with the runner system in the lowest section. At all times, metal spurting must be prevented. This can be achieved by making the runner bar cross section larger than the sprue cross section, and the total cross section of the gates larger than the runner channel cross section. It is customary to use a ratio of dimensions such as 1:2:4 or 1:4:8, according to the experience of the particular foundry.

Molten metal should never be allowed to fall within the mold from one level to a lower level, because the entrapment of gas/air and oxide inclusions will result. In order to avoid misruns, particularly in thin-cast sections, it is accepted practice to have fast pouring rates, high pouring temperatures, and more numerous gates that are closely clustered around the casting.

A particular problem to avoid if possible is a design mold in which a thick section and a thin wall are at the same level as the metal being poured. The metal flow will be preferential to the thick section, which may result in misruns in the thin section. Proper design of the gating system can overcome this problem. For additional information, see the article "Gating Design" in this Volume.

Risers. The function of risers in magnesium castings is similar to that in other metals (see the article "Sand Molding" in this Volume). Magnesium alloy sand castings have a high propensity for shrinkage. For this reason, a larger amount of risering is required than with most other cast metals. Because of this and the relatively high cost of some alloys, it is necessary to increase the feeding efficiency of risers, while still reducing their total volume. This can be achieved by the use of insulating sleeves that encase the risers. Another important advantage of this technique, resulting from the improved casting yield, is the reduction in the amount of recycled process scrap. For additional information, see the article "Riser Design" in this Volume.

Chills, which may consist of cast-to-form iron castings, zircon sand, or cores containing steel shot, are used extensively to promote progressive or directional solidification of the casting from the bottom to the top in the gravity pouring system. Heavy sections or bosses in the casting that are remote from direct riser feed should be chilled so that they conform to the general pattern of directional solidification within the casting. The very fine grain of the magnesium-zirconium alloys is mainly derived from the very marked grain refining effect of the zirconium content. However, with the nonzirconium alloys, chilling, in combination with a good grain refinement technique, produces a fine grain and superior mechanical properties.

Shake-Out. Small castings, up to about 90 kg (200 lb) cast weight, should be allowed to stand after casting until they have cooled to below 260 °C (500 °F). This is because the magnesium alloys tend to exhibit hot-shortness cracking tendencies; if the castings are removed from the molds too soon, they may show cracks.

The larger the casting, the longer they should be allowed to cool before shake-out. Traditional methods for removal of the casting from the mold use vibratory screens equipped to separate chills by the use of electromagnets, a noisy and dusty process, however.

Modern methods include placing the mold on a revolving table in an airtight chamber and bombarding it with steel shot to break down the mold. The process must be controlled to avoid abrasion of casting surfaces. It is very important, subsequently in the process, to acid etch the castings to remove any possible surface contamination, thereby precluding reduced corrosion resistance.

In order to preserve optimum corrosion resistance, the use of a nonmetallic abrasive medium, such as alumina, instead of steel shot for cleaning the casting is desirable.

With the resin-bonded sand, thermal reclamation is becoming popular because the product obtained is very clean and is equivalent to new sand. It can therefore be used at a high percentage for mold production. For additional information, see the article "Shakeout and Core Knockout" in this Volume.

Current Applications. The production of sand castings to the extremely high level of dimensional quality currently demanded by the aircraft designer is dependent upon the quality of the pattern and core box equipment. These normally consist of precision equipment manufactured in metal and plastic. Wooden pattern equipment, although appreciably cheaper, is rarely used for this type of application. It is, however, quite suitable for castings where the production numbers are low and the dimensional quality requirement is not as stringent.

One particular feature of modern mold and core production that has encouraged its widespread use for the manufacture of complex gearbox-type castings for aerospace application is the capability to include complex coring systems within these designs. It is possible, for example, to incorporate very complex systems of small-diameter oil passageway cores and, often surrounding these, some very thin wall sections. In some cases, complex designs that previously could only be made by the investment casting method can now be made by these refined sand casting methods. The examples shown in Fig. 4, 5, and 6 show applications that use these techniques.

Investment Casting

Throughout the history of magnesium alloy castings, designs involving cast components that were very complex, embraced very thin wall sections, had fine surface finish, and attained tight dimensional tolerances became the market for investment casting (see the article "Investment Casting" in this Volume).

As already mentioned, the gap between modern sand casting and investment casting has been considerably narrowed. However, the investment casting process is still capable of producing castings of tighter tolerances and thinner wall sections than those of sand castings.

The disadvantages of the investment process are the cost of the casting in terms of both capital equipment and cost per casting. There is also a much greater restriction on the size of the casting that can be produced.

The same alloys can be cast by this process as with sand casting. The processes used are mainly "jointless" in character (that is, lost wax or frozen mercury). This gives, among other things, a general improvement in dimensional accuracy by the elimination of the parting line.

Permanent Mold Casting

The salient features of the permanent mold casting method are:

- This process should be considered when the design of the part is within the capability of the process. There are two main types of permanent mold casting, depending on whether metal cores (permold) or destructible sand cores (semipermanent mold) are used. It is not currently possible to equal the size or complexity obtainable by the sand casting process
- The fact that the mold or die can be repeatedly reused is a very big advantage over sand casting; however, the total number of castings required from a given die must be capable of amortising the high initial capital cost of the die, and so forth
- In general, the surface finish and dimensional tolerances are superior to those obtainable from a comparable sand casting
- A distinct disadvantage to the process is the fact that there is very little scope for modifying the casting design or the running system, once the die is constructed
- Nearly all of the alloys that can be sand cast are suitable for use in this process. One exception is the high-zinc alloy with no rare earths present (that is, ZK61A), which is extremely hot short and is deemed uncastable

If steps are taken to accommodate the general tendency for hot shortness in the other alloys, a whole range of castings can be economically produced. The precautions that should be taken to minimize the effects of hot-shortness cracking include provisions for adequate draft. Extreme care is needed when retracting the metal cores not to put undue stress on the hot casting; when two or more cores are being used, they should be extracted simultaneously.

There are also practical limitations on the intricacy of the shapes that can be cast. In particular, deep ribs and complex coring are not practical.

In general, because of faster solidification, mechanical properties tend to be superior to those of sand castings.

Low-Pressure Die Casting Process. In this process the metal dies that are used are basically similar to those employed for permanent mold casting. The main difference between the two processes is that in the low-pressure process the molten metal enters the mold from below under a low pressure. The solidification pattern is inverted. The feed to the solidifying casting comes from below. In recent years, this method has become popular for the manufacture of high-quality automotive wheels (Ref 14).

Die Casting

The die casting process is ideally suited to high-volume production of the type of cast components shown in Fig. 7 and 8. The high cost of the die can be amortised by the large production volume.

The process is a fast production method capable of a high degree of automation, one for which certain magnesium alloys are ideally suited. The number of alloys that can successfully be cast by this process is much more restricted than is the case with sand castings. The alloys typically cast include AZ91A, B, and E; AM60; AS41; and AZ61. Four hundred shots per hour from a hot-chamber machine have been reported.

Two important advantages shown by magnesium die castings are that molten magnesium does not weld onto the die in the same way as does aluminum; therefore, the expensive dies last much longer. Dies last two to three times longer than with

aluminum. Also, magnesium can be machined four times faster than aluminum. The relative machinability ratings of magnesium compared to other metals are:

Metal	Relative power required
Magnesium alloys	1.0
Aluminum alloys	1.3
Brass	2.3
Cast iron	3.5
Mild steel	6.3
Nickel alloys	10.0

These factors, combined with the fact that magnesium is only two-thirds the weight of aluminum (Fig. 9), account for the growing popularity of magnesium die casting, particularly in the automotive field.

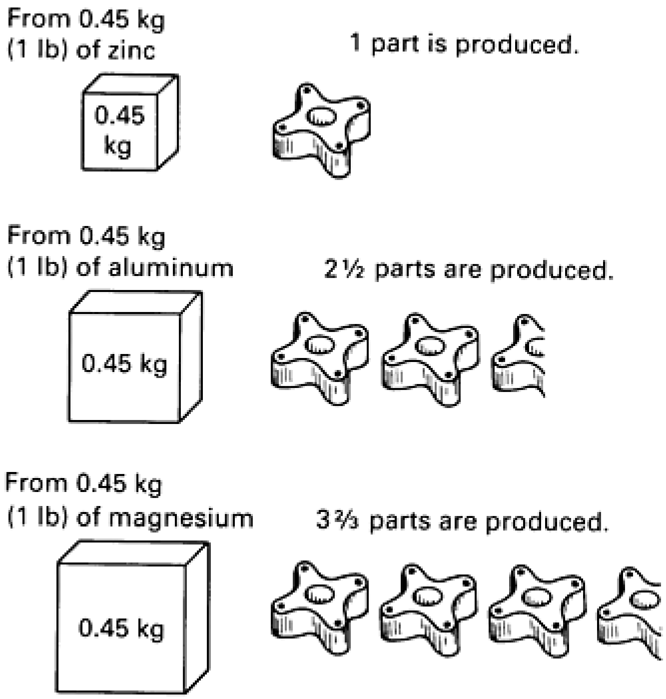

Fig. 9 Comparison of the density of magnesium with the densities of zinc and aluminum to illustrate the light weight properties of magnesium alloy die castings.

The excellent machining characteristics of magnesium offer the following advantages:

- Reduction in machining time
- Tool life as much as ten times greater than for other commercial metals
- Excellent surface finishes with one cut
- Minimum tool buildup
- Well-broken chips, minimizing handling
- Lower machining costs

The same methods of supplying metal to the die, such as the hand-ladling and autopour methods, can be applied.

One other process that can also be advantageously applied to magnesium is the hot chamber process, in which the supplying container is immersed in the bath of molten alloy, thereby keeping it replenished and at the correct pouring temperature. This latter process is made possible only by the fact that iron is not attacked by the molten magnesium alloy at the bath and pouring temperatures involved in die casting magnesium.

In this high-production die casting process, economics demand that wherever possible the delivery of the metal into the die be automated. This can be achieved very readily in the hot chamber process (Ref 15), but in the cold chamber process the molten metal must first be delivered into the shot chamber before being injected into the die.

Machines. A large number of machines of both the hot and cold chamber type are currently in use. The cold chamber method is often preferred because of the higher injection pressure that can be employed. The machines must be equipped with a means for ensuring that no water comes into contact with the magnesium.

Dies. The materials used for the manufacture of the dies are similar to those used for aluminum, with dies and cores typically of hot-work tool steels (for example, H11 and H13) heat treated to 44 to 48 HRC. Nitriding the die surfaces is often done. The die life can be appreciably lengthened if the die surface is finished to a 0.38 μm (15 μin.) finish. Stress relieving as well as repolishing the surface of the die after approximately 25,000 shots is sometimes carried out to retain this high finish. Under modern conditions, any process variables (such as too rapid an injection speed, giving rise to larger dimensions across the parting line) can be fairly easily controlled.

Lubrication of the surface of the die by the use of a fine mist of one of the water-free proprietary lubricants is the standard method and is best done using automated lubricating systems.

Die Temperature. Modern processes have facilities to control the die temperature, which should be in the optimum die temperature range of 260 °C ± 14 °C (500 °F ± 25 °F). After the dies are preheated into this temperature range, the heat supplied by repeated casting is normally sufficient to maintain the required temperature. In fact, there is usually a need to cool the die to stay within this range. Thus, dies are provided with a means for water cooling. Such control over die temperature is necessary to maintain casting quality. If die temperature is too low, misruns are likely to occur; if it is too high, die soldering, hot tears, and shrinkage can result.

Control of Metal Composition. The production of sound magnesium alloy die castings that are free from any contamination from oxide or flux and show superior corrosion resistance depends largely on the degree of control exercised over metal cleanliness and on the method of melting and handling the metal.

Very rarely is it possible or desirable to recycle the typical die casting process scrap directly into the casting furnace. This is because scrap is normally highly contaminated with lubricant, and the slug or biscuit from the runner system normally requires a refining process, casting off into ingot, before it can be reused. Some die casters carry out this procedure themselves, while others have the material treated on a contract basis.

Whatever method of recycling is used, the basic requirement is that the process scrap be absorbed into the melt charges as it arises. Each charge should consist of the same ratio of rerun material (normally ingot) and new-metal ingot as that which is being currently created in production.

As with other methods of casting, both methods of melting (that is, flux and fluxless) are in current use. Most die casters, however, favor the fluxless procedure for the reasons already stated.

Much closer attention must presently be paid to the whole aspect of metal handling because of the growing importance of the newer high-purity AZ91D alloy. The very good corrosion resistance, which is a feature of this alloy, is dependent upon retaining a very low nickel, iron, and copper content.

Flux Process Parameters. Refining the magnesium die casting alloys consists of heating the melt charge to approximately 705 °C (1300 °F), adding flux, and stirring the melt thoroughly to allow the flux to absorb the oxide present. The melt is then allowed to stand for 10 to 15 min to allow the oxide-laden flux to settle as sludge to the bottom of the crucible.

The flux generally used is a mixture of magnesium chloride, potassium and other chlorides, plus a smaller amount of calcium fluoride. The amount of flux varies from 1 to 3% of the melt, depending on the cleanliness of the charge.

Care must be taken to make sure that any recycled turnings are dry before attempts are made to melt them. Also, in the casting process, contamination of the melt with flux may result in corrosion of the final casting. Charred lubricant products or oxides impair the castability and mechanical properties of the casting. During the metal-handling procedure, any excessive tendency to oxidize and any noticeable difference in viscosity are indications that the metal has not been refined properly.

Fluxless Process Parameters. This method of melting, which has already been described, has become very popular with the die caster. It avoids many of the problems associated with flux, including the risk of corrosion due to flux inclusions.

There is also an economic advantage to the use of the fluxless process in that melting losses, primarily due to the entrapment of metal globules in the sludge formed with flux melting, are greatly reduced. Problems with sludge removal from the flux-melting process are either eliminated entirely or very much reduced.

Periodic analysis of the melt is necessary because with repeated melting, losses of beryllium, manganese, and aluminum can occur. Aluminum is present in the alloy to provide strength, hardness, and castability, but too much aluminum results in brittleness. Zinc improves the castability of the alloy and, to a degree, its corrosion resistance. Zinc, like aluminum, improves the mechanical properties. Hot shortness, however, increases with increasing zinc content. Manganese, up to its limit of solubility, improves the corrosion resistance.

With the high-purity AZ91D alloy the limits for the contaminating elements are (Ref 16):

- 0.005% Fe (Fe = 0.032 Mn maximum)
- 0.0010% Ni (10 ppm)
- 0.0400% Cu (400 ppm)

The iron to manganese ratio must be controlled. Beryllium is sometimes added in quantities up to 0.001% to reduce the burning tendency of the molten alloy.

Design Parameters. Considerable effort has been applied to the formulation of design criteria (Ref 17). As a general rule of thumb for the designer, wall thicknesses can be $\frac{1}{100}$ the distance to the gate:

$$t = \frac{D}{100} \qquad \textbf{(Eq 1)}$$

where t is the uniform wall thickness and D is the distance from the gate. These thicknesses can be as small as 0.9 mm (0.035 in.). Typical relationships between minimum wall thickness and surface area are:

Minimum wall thickness,		Surface area of die cast magnesium part	
mm	**in.**	**m^2**	**$in.^2$**
1.78-2.51	0.070-0.099	$\leq$ 0.052	$\leq$ 80
$\geq$ 2.51	$\geq$ 0.100	>0.052	>80

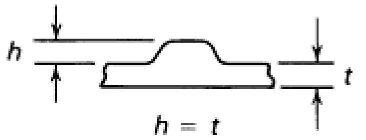
The various relationships between draft and wall depth for interior walls and between draft and cored hole depths are all calculable.

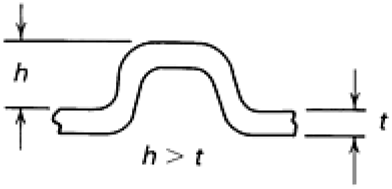
Most surfaces vertical to the parting plane of the die should be tapered so that the casting can be readily ejected. Shrinkage forces are considerable, and it is important to have sufficient ejectors to ensure that the casting is not damaged. Draftless magnesium castings can also be made to the competitive advantage of magnesium.

Also, since many of the die casting alloys show a tendency toward stress corrosion, it is important for designers to be able to calculate the induced stress levels to ensure that these fall below limiting values for the alloy in question.

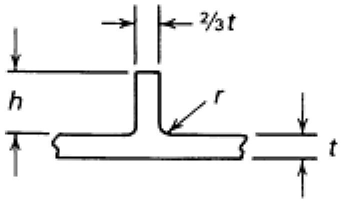
Some of these important design features are shown in Fig. 10. Today's design data replace much of the earlier rule-of-thumb practices. Some basic requirements still apply, such as:

- Ample fillets
- Rounded corners
- Blended sections
- Avoidance of remote heavy sections
- Strengthening thin sections by the use of ribs
- Radii that are as large as possible (that is, larger than for zinc alloy die castings)

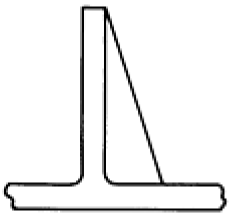




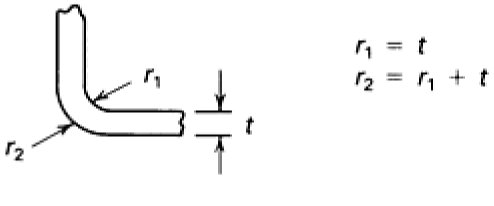
Cored out to avoid undesirable heavy section

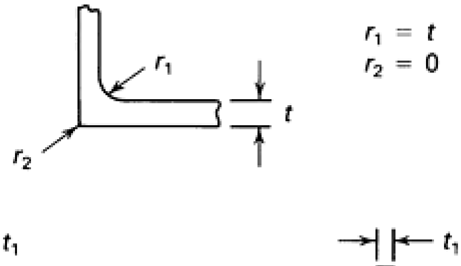


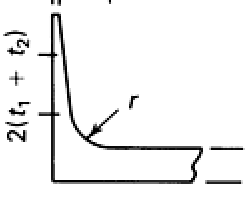
Rounded-off corner is desirable, $r = 0.5$ to 1 mm min



Uniform wall thickness rib reinforcement







Angular transition increases strength.

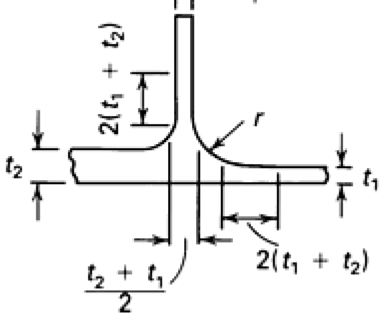


Fig. 10 Design parameters to aid stress reduction in magnesium alloy castings.

Casting Finish. The best surface finish on magnesium alloy die castings is obtained by close control over the process variables. These include die temperature, cavity filling, die lubrication, metal temperature, holding time in the die, and the smoothness of the die surfaces.

Tolerances. Typical tolerances are shown in the following tables. Typical tolerances for noncritical dimensions are:

Dimensions	Tolerance	
	mm	in.
Length up to 25 mm (1 in.)	±0.25	±0.010
Additional tolerance for each 25 mm (1 in.) in length		
25-305 mm (1-12 in.)	±0.038	±0.0015

Typical tolerances for critical dimensions are:

Dimensions	Tolerance	
	mm	in.
Length up to 25 mm (1 in.)	±0.10	±0.004
Additional tolerance for each 25 mm (1 in.) in length		
25-305 mm (1-12 in.)	±0.038	±0.0015

These tolerances represent ordinary production practices and are based on dimensions that are not affected by die parting or moving parts. If those factors cannot be ignored, these tolerances must be increased to compensate for their effect on the die casting dimensions.

Casting Defects. In die castings, misruns and cold shuts probably represent the most frequent form of defect. There can be several causes of these two types of defects, mostly process related. They may, for example, be caused by extremely slow filling of the die, excessive application of lubrication, incorrect metal or die temperature, dirty metal (that is, excessively oxide laden), slow casting speed, or incorrect shot weight in the cold chamber process.

There is also a greater tendency for porosity in die castings, most often resulting from gas trapped within the casting. If this effect is serious, it can be minimized by conducting an evaluation of the running, gating, venting, and lubricating system. An increase in total vent area to at least half the gate area often lessens the number of cold shuts. An increased injection pressure may eliminate cold shuts altogether.

Because of the possibility of gas-related porosity, die castings are not normally thermally treated other than with the occasional use of a low-temperature stabilizing treatment.

For additional information on casting defects, see the article "Testing and Inspection of Casting Defects" in this Volume.

Cobalt-Base Alloys

Timothy J. Pruitt, Zimmer, Inc.; Michael J. Hanslits, Precision Castparts Corporation

Introduction

COBALT-BASE ALLOYS were developed in the late 1930s for applications in aircraft turbochargers. The common alloys of today were born from Vitallium, a high carbon dental alloy of the composition Co-27Cr-5Mo-0.5C. These alloys offer better wear- and heat-resistant properties than those associated with the iron-base alloys. Many of the hot section turbine blades and vanes originally developed from cobalt-base alloys have since been replaced by high-temperature nickel-base alloys. Yet the cobalt alloys are still widely used for their excellent high-temperature strength properties up to 815 °C (1500 °F). The development of new cobalt-base alloys has not kept pace with other alloy systems, but approximately 20 cobalt-base alloys are commonly used today. These are typically segregated into either heat- or wear-resistant grades. Nominal compositions and applications of the most common alloys are presented in Table 1, and Fig. 1 shows some applications of cobalt-base alloys.

Table 1 Nominal compositions and some applications for cobalt-base alloys

Alloy	Composition, %[(a)]								Applications
	C	Mn	Si	Cr	Ni	W	Fe	Others	
Wear-resistant alloys									
Alloy No. 3	2.0-2.7	1.00	1.00	29.0-33.0	3.00	11.0-14.0	3.00	. . .	Cutting tools, wear strips, valve seats
Alloy No. 6	0.9-1.4	1.00	1.50	27.0-31.0	3.00	3.5-5.5	3.00	1.5 Mo	Valve seats, punches, wear plates

These alloys still find wide application in the aircraft industry, but have seen extensive development as both medical implant devices and chemical-resistant hardware, such as pump housings, valves, impellers, wear plates, and cutting tools. The investment casting process is well suited to making complicated configurations for these applications, as is emphasized in this article. In general, the cobalt-base alloys are easy to work with in the foundry and exhibit good casting properties, including:

- Good fluidity
- Low melting points
- Freedom from dissolved-gas defects
- Low alloy losses due to oxidation

Areas that may be of concern to a caster include:

- Cost
- Contamination of subsequent heats (furnace lining)
- Crack prone characteristic of certain wear-resistant grades
- Generally poor machining qualities

Manufacture and Remelting of Master Ingots

The manufacture of master ingots for cobalt-base alloys has progressed well, and now includes technologies such as vacuum induction melting, vacuum arc remelting, argon-oxygen decarburization, and electroslag remelting. These processes produce clean, chemically homogeneous ingots. As with any alloy, it is important to begin the investment casting process with the highest quality alloy economically feasible for the end product. Remelting cobalt-base alloys is typically conducted in air, although a few alloys are melted and poured in vacuum. Alloys that contain reactive elements such as titanium, aluminum, tantalum, and zirconium should be melted and poured in vacuum. These include MAR-M 302, MAR-M 509, and AiResist 215. Vacuum casting processes are sometimes used even when they are not needed to meet chemical composition requirements. Examples of alloys that do not contain reactive elements and are adaptable for air casting are HS-21, HS-25, and WI-52.

Air Melting Practices

The Crucible. When air melting cobalt alloys, consideration must be given to the type of crucible or crucible lining to be used. Typically, melting is conducted in a rammed furnace lining or a prefired ceramic crucible. Common ceramic compositions include alumina, silica, zirconia, and magnesia. The use of silica materials may result in a pickup of silicon from the ceramic lining and is not strongly recommended.

When using rammed linings, care must be taken to ensure that the lining has been properly cured and fired before the melting of cobalt alloys. Residual moisture in the lining can result in hydrogen pickup in the first few charges of a new lining. This gas can diffuse to the molten metal and result in internal or external defects similar in appearance to those caused by improper feeding practice. It is therefore recommended that an addition of 0.5 wt% ferrosilicon or ferrotitanium be added to the first two or three melts of the lining.

The use of prefired crucibles is the more desirable alternative. Many of these considerations are of no concern in a vacuum application in which oxidation and other reactions are minimized.

Gas Covers. Air melting should be conducted with an inert-gas cover, when possible. Argon gas is well suited for this and can be dispensed over the melt surface by a variety of methods. A single port to blow argon over the melt is often preferred, while elaborate sealed chimneys also have been successfully used. Whatever the method, the purpose is to keep oxygen from reacting with the molten metal.

Deslagging

The surface reactions that take place in air melting produce slag, a common condition in all air melting operations. Deslagging procedures vary considerably throughout the industry, but the use of slag rods is common for this purpose. It is suggested that rods be of the same or similar alloy as that being melted in order to reduce melt contamination. It is also recommended that a cold rod be used for each attempt at removing slag. A cold rod tends to pick up the slag more readily than one in continuous use. Some casters prefer to use slag coagulants or surface conditioners to aid in slag removal. Slag formation can be further reduced by precise process controls to limit the amount of time the metal is in the molten state before pouring. Slag should also be removed just before the pour to avoid the formation of a new layer requiring a repetition of the deslagging process. Teapot-type ladles and pouring spouts that incorporate dams are also quite successful at minimizing slag defects in castings.

The temperature of the melt can be monitored using a dip tip thermocouple. Although the use of radiation pyrometry is desirable for a hands-off operation, the slag content of the air-melted surface can greatly affect temperature readings. Therefore this approach is not recommended.

Preheat and Pouring

Ceramic mold preheat and the metal pouring temperature can affect the castability of the alloy and the resulting quality of the product. Mold temperature ranges common to the casting of cobalt-base alloys are 760 to 1150 °C (1400 to 2100 °F); the metal pouring temperature varies from 1425 to 1595 °C (2600 to 2900 °F). Melting ranges for cobalt-base alloys are listed in Table 2. Naturally, these are process ranges, and the exact process parameters depend on the casting configuration, quality requirements, and specific alloy. The parameters selected do have a pronounced effect on the resulting casting: Consideration must be given to the effect on the ability of the metal to fill the mold cavity without creating a hot tear or undesirable solidification shrinkage. Hot tears are common to the higher carbon (>0.40 wt%) cobalt alloys and can be avoided with alloy chemistry adjustments, less rigid mold materials, and slower cooling rates from the

casting temperature. Wrapping molds in selected areas with an insulating material often reduces hot tears and does not greatly alter the solidification of the total system.

Table 2 Melting ranges for cobalt-base alloys

Alloy	**Melting range**

MAR M 509	1290-1400	2350-2550

Biomedical alloy		
ASTM F75	1315-1345	2400-2450

Fluidity of cobalt alloys can also be adjusted chemically. A standard spiral casting test can aid in determining the castability of an alloy before chemical adjustments are made. In air casting, silicon and manganese levels should be adjusted to the high end of the specification range to maximize their effects. In vacuum casting, these types of adjustments are unnecessary and can be more easily controlled with casting parameters. The option of adding these constituents to the master ingot or directly to the melt at the time of casting is usually determined based on the experience of individual foundries.

Gating and mold configuration also can contribute greatly to the success of producing an acceptable casting. Proper gating of cobalt alloy castings involves the same principles as those used for other superalloys and will not be expanded upon in this article.

Cobalt-base superalloys tend to be complex combinations of elements; each alloy is designed for a specific purpose. The matrix of these alloys is face-centered cubic. Modern alloys typically gain their strength through a number of complex carbides (depending on chemistry) and, in some alloys, through the use of solid-solution strengthening. Other alloys, such as J-1570, gain strength through intermetallic compounds (in the case of J-1570, Ni_3Ti).

A list of alloys and their possible phases is provided in Table 3. These phases represent a wide variety of alloying concepts that are used to produce a desired carbide morphology and matrix combination to yield the best properties for specific applications. Many different types of carbides have been identified in these alloys, including MC, M_6C, M_7C_3, $M_{23}C_6$, and Cr_2C_3, where M represents the metal atom. Mechanical property data are provided in Table 4. Figure 2 shows the as-cast microstructures of three alloys.

Table 3 Phases in cobalt-base superalloys

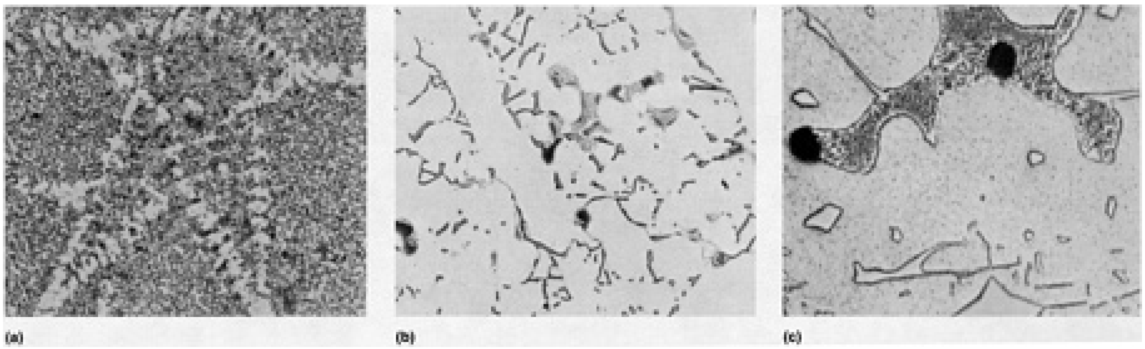

Fig. 2 As-cast microstructures of three cobalt-base alloys. (a) Alloy 98M2 investment cast ring with large primary carbides in a matrix of secondary carbides and Co-Cr-W solid solution. (b) MAR M 509 alloy showing MC and $M_{23}C_6$ carbides. (c) MAR M 302 alloy showing gray islands of primary eutectic carbide, light MC particles, and small, dark $M_{23}C_6$ precipitates in the matrix. All three 500×.

These carbides can be greatly affected by the casting parameters and resulting solidification rates. For example, there is a common lamellar carbide phase comprised of both an $M_{23}C_6$ and probably M_6C in as-cast HS-21. This phase is often considered to reduce ductility due to its brittle nature. It is possible to control the frequency and size of the phase through chemistry modification to reduce total carbon or to revise casting parameters to increase solidification rates and thus retard precipitation. Several of the cobalt alloys can be altered by similar techniques to obtain microstructural control of the precipitates.

Heat Treatment

Several options are available in the thermal treatment of cast cobalt-base alloys. In general, the choices are:

- Solutioning at temperatures above 1095 °C (2000 °F) for several hours to put the secondary phases into solution
- Solutioning plus aging at a lower temperature to precipitate a desired phase effectively
- Homogenization, that is, prolonged treatment at a temperature near the incipient melting point, thus reducing composition gradients to a minimum
- Homogenization plus aging
- Aging from the as-cast condition

True solutioning of the alloys is rare. It is possible to see marked effects in the microstructures at temperatures in excess of 1175 °C (2150 °F), but processing temperatures are typically in the 1205 to 1260 °C (2200 to 2300 °F) range. Aging can be done at temperatures as low as 760 °C (1400 °F), but it is necessary to ensure that the effects of aging are not lost because of an operating temperature in excess of the aging temperature. The ultimate thermal processing alternatives employed depend on the application, alloy, and desired properties. Suggested thermal treatments are listed in Table 5.

Table 5 Recommended heat treatments for cobalt-base alloys

Alloy	Heat treatment
Alloy No. 3	900 °C (1650 °F) for 4 h, furnace cool
Alloy No. 6	900 °C (1650 °F) for 4 h, furnace cool

Alloy No. 12	900 °C (1650 °F) for 4 h, furnace cool
Alloy No. 19	900 °C (1650 °F) for 4 h, furnace cool
Star-J	As-cast
98M2	As-cast
Alloy No. 21	815 °C (1500 °F) for 5 to 50 h, air cool
Alloy No. 25	1205 °C (2200 °F) for 1 h, air cool
Alloy No. 31	As-cast
X-40	1175 °C (2150 °F) for 1 h and water quench + 815 °C (1500 °F) for 4 h and air cool + 980 °C (1800 °F) for 2 to 4 h and oil quench + 730 °C (1350 °F) for 16 h and air cool
X-45	1175 °C (2150 °F) for 1 h and water quench + 815 °C (1500 °F) for 4 h and air cool + 980 °C (1800 °F) for 2 to 4 h and oil quench + 730 °C (1350 °F) for 16 h and air cool
WI-52	1010 °C (1850 °F) for 2 h and oil quench + 1290 °C (2350 °F) for 20 h and air cool + 650 °C (1200 °F) for 20 h and air cool
FSX-414	As-cast
MAR M 302	As-cast
MAR M 509	1095 °C (2000 °F) for 2 h and water quench + 790 °C (1450 °F) for 2 h and air cool + 720 °C (1325 °F) for 24 h and air cool
ASTM F75	1230 °C (2250 °F) for 3 h and air cool

Nickel and Nickel Alloys

John M. Svoboda, Steel Founders' Society of America

Introduction

NICKEL-BASE ALLOY CASTINGS are widely used in corrosive-media and high-temperature applications. The principal alloys are identified by designations of the Alloy Casting Institute (ACI) (now called the High Alloy Product Group) of the Steel Founders' Society of America and are included in ASTM specifications A 494 and A 297 and Federal specifications (QQ). There are also many proprietary grades for severe-corrosion applications, as well as heat-resistant alloys. In addition to these conventionally processed alloys, directionally solidified (DS) and single-crystal (SC) alloys are also being processed (see the article "Directional and Monocrystal Solidification" in this Volume). The various types of cast alloys can be classified as:

- Nickel
- Nickel-copper
- Nickel-chromium-iron
- Nickel-chromium-molybdenum
- Nickel-molybdenum
- Nickel-base proprietary
- Directional solidification/single crystal

The cast nickel-base alloys, with the exception of some high-silicon and proprietary grades, have equivalent wrought grades and are frequently specified as the cast components of a wrought-cast system. Compositions of cast and equivalent wrought grades differ in minor elements because workability is the dominant factor in wrought alloys, while castability and soundness are the dominant factors in cast alloys. The differences in minor elements do not result in significant differences in serviceability.

Tables 1 and 2 provide designations and compositions for corrosion-resistant, heat-resistant, and DS/SC alloys. It should also be noted that extensive data on mechanical properties, microstructural characteristics, and corrosion properties of nickel-base castings can be found in Volumes 1, 9, and 13, respectively, of the *ASM Handbook.*

Table 1 Compositions of cast corrosion-resistant nickel-base alloys

Compositions

Cast Nickel. The ASTM A 494 CZ-100 grade covers the requirement for a cast nickel alloy. A higher-carbon or a higher-silicon grade is occasionally specified for greater resistance to wear and galling. The minor elements within specified limits (Table 1) provide for excellent castability and the production of sound, pressure-tight castings. The usual practice is to produce the alloy with 0.75% C and 1.0% Si. When properly produced, the carbon is present in the matrix as a finely distributed spheroidal graphite. A reduction in mechanical properties results if flake graphite is present. A maximum carbon content of 0.10% or less is occasionally specified when castings are welded into wrought nickel systems. Low-carbon CZ-100, however, is a difficult material to cast, with no significant advantage over the higher-carbon option under any known service conditions.

Cast nickel-copper alloys are designated in ASTM A 494 as M-35-1, M-35-2, M-30H, M-25S, and M-30C and in Federal specification QQ-N-288 as A, B, C, D, E, and F (see Table 1). The lower-silicon grades (≤2.0% Si) are commonly used in corrosion applications in conjunction with wrought nickel-copper and copper-nickel alloys as pump, valve, and fitting castings. The higher-silicon grades (>2.0% Si) combine corrosion resistance with high strength and wear resistance. Grades containing the highest silicon contents (>4% Si) are used when exceptional resistance to galling is desired. The high-carbon composition (QQ-N-288-F) is used where improved machinability is more important than ductility and/or weldability.

Nickel-Chromium-Iron Alloys. The cast nickel-chromium-iron CY-40 is included in ASTM A 494. Its composition is given in Table 1. The cast alloy differs from the parallel wrought grade in carbon, manganese, and silicon contents for improved castability and pressure tightness.

Heat-resistant nickel-chromium-iron grades HW and HX (Table 2) are covered in ASTM A 297. HW alloy (60Ni-12Cr-23Fe) is especially well suited to applications in which wide and/or rapid fluctuations in temperature are encountered. In addition, HW exhibits excellent resistance to carburization and high-temperature oxidation. This alloy performs satisfactorily at temperatures up to about 1120 °C (2050 °F) in strongly oxidizing atmospheres and up to 1040 °C (1900 °F) in oxidizing or reducing products of combustion, provided that sulfur is not present in the gas.

HW alloy is widely used for intricate heat-treating fixtures that are quenched with the load and for many other applications (such as furnace retorts and muffles) that involve thermal shock, steep temperature gradients, and high stresses. Its structure is austenitic and contains carbides in amounts that vary with carbon content and thermal history. In the as-cast condition, the microstructure consists of a continuous interdendritic network of elongated eutectic carbides. Upon prolonged exposure at service temperatures, the austenitic matrix becomes uniformly peppered with small carbide

particles except in the immediate vicinity of eutectic carbides. This change in structure is accompanied by an increase in room-temperature strength, but no change in ductility.

HX alloy (66Ni-17Cr-12Fe) is similar to HW but contains more nickel and chromium. Its higher chromium content gives it substantially better resistance to corrosion by hot gases (even sulfur-bearing gases), which permits it to be used in severe service applications at temperatures up to 1150 °C (2100 °F).

The cast nickel-chromium-molybdenum alloys, designated CW-12MW, CW-7M, CW-2M, and CW-6MC in ASTM A 494 (Table 1), are used in severe service conditions that usually involve combinations of acids at elevated temperatures. The molybdenum in these compositions improves both resistance to nonoxidizing acids and high-temperature strength.

The cast nickel-molybdenum alloys, designated N-12MV and N-7M in ASTM A 494 (Table 1), are most frequently applied in handling hydrochloric acid at all concentrations and temperatures, including the boiling point. Nickel-molybdenum alloys are also produced under proprietary names.

Nickel-Base Proprietary Alloys. In addition to the more common nickel-base alloys, there are a number of trademarked, proprietary alloys and other nickel-base alloys that are widely used in corrosive service. Many of these alloys have excellent general corrosion resistance and are most commonly used in applications for which stainless steels are inadequate. Others are used in specialized applications and should not be considered substitutes for stainless steel. Producers should be consulted when applying these alloys, particularly in applications for which there is no history of use.

Heat-Resistant Alloys. Casting are classified as heat resistant if they are capable of sustained operation while exposed, either continuously or intermittently, to operating temperatures that result in metal temperatures in excess of 650 °C (1200 °F). Many alloys of the same general types are also used for their resistance to corrosive media at temperatures below 650 °C (1200 °F), and castings intended for such service are classified as corrosion resistant. Although there is usually a distinction between heat-resistant alloys and corrosion-resistant alloys, based on carbon content, the line of demarcation is vague--particularly for alloys used in the range from 480 to 650 °C (900 to 1200 °F).

Table 2 lists a number of nickel-base casting alloys used for high-temperature applications. In addition to the HW and HX grades mentioned above in the discussion on nickel-chromium-iron alloys, a number of proprietary alloys are listed. These materials, often referred to as superalloys, contain appreciable amounts of chromium and cobalt, with aluminum and titanium added for strengthening. The effects of aluminum and titanium on the structure and the resulting properties of nickel-base alloys are discussed in the section "Structure and Property Correlations" in this article.

Directionally solidified and single-crystal alloys have the highest elevated-temperature strengths of any of the nickel-base alloys. Directional solidification is accomplished by removing all of the heat from one end of the casting. This is done by establishing a strong thermal gradient and passing it from one end of the casting to the other. In this way, large, columnar grains are produced that are oriented such that they provide maximum strength in service.

Alloys developed for single-crystal casting are characterized by the absence of grain-boundary strengthening elements such as carbon, boron, zirconium, and hafnium. The removal of these alloying elements results in materials with very high incipient melting temperatures. Figure 1 compares the macro grain structures of equiaxed (conventional), directionally solidified, and single-crystal nickel-base alloy turbine blades. Table 2 lists several compositions of DS/SC alloys.

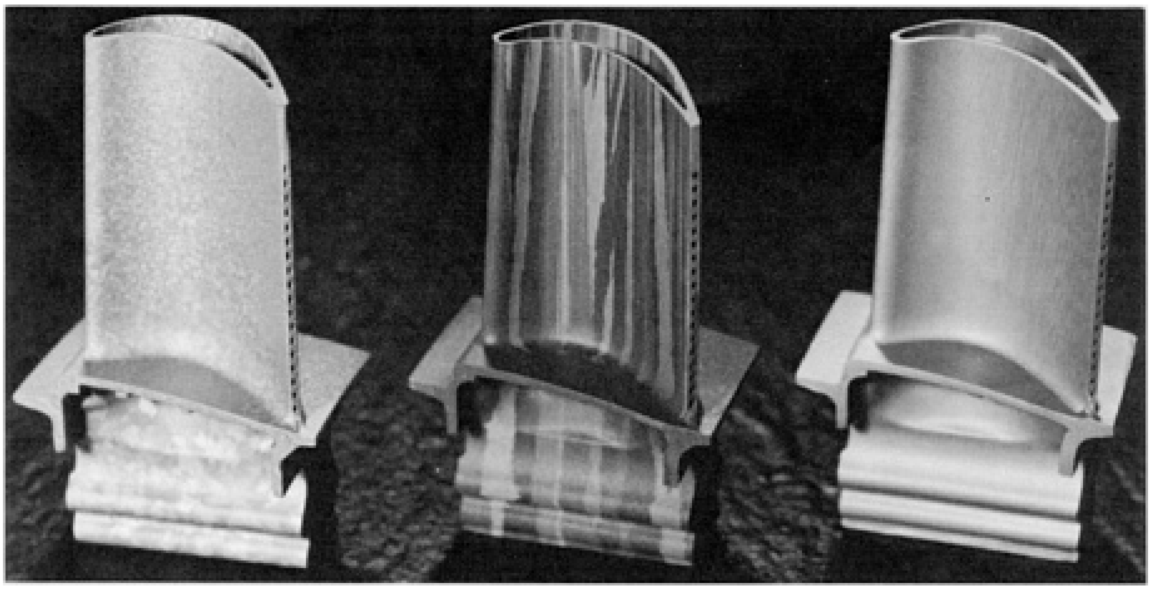

Fig. 1 Comparison of equiaxed (left), directionally solidified (center), and single-crystal (right) nickel-base alloy turbine blades for an aircraft engine. Courtesy of Howmet Corporation, Whitehall Casting Division.

Structure and Property Correlations

Cast Nickel. The mechanical property requirements for CZ-100 are listed in Table 3. Cast nickel has excellent toughness, thermal resistance, and heat transfer characteristics.

Table 3 Tensile requirements for cast nickel-base alloys

Alloy	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Hardness, HB
	MPa	ksi	MPa	ksi

Heat-resistant						
HW	415	60	415	60	. . .	. . .
HX	415	60	415	60	. . .	. . .

Nickel-Copper Alloys. Tensile properties of the nickel-copper castings are controlled by the solution-hardening effect of silicon or silicon plus niobium. The tensile properties of M-35-1, M-35-2, and composition A are controlled by a carbon-plus-silicon relationship; composition E and M-30C tensile properties are determined by a silicon-plus-niobium relationship.

At approximately 3.5% Si, an age-hardening effect appears; at approximately 3.8% Si, the solubility of silicon in the nickel-copper matrix is exceeded, and hard, brittle silicides begin to appear. The combination of an aging effect plus silicides in composition D results in an alloy with exceptional resistance to galling. As the silicon content is increased above 3.8%, the amounts of hard, brittle silicides in the tough nickel-copper matrix increase; ductility decreases sharply; and tensile and yield strengths increase. As a result, hardness is the only mechanical property specified for composition D. The toughness of nickel-copper alloys decreases with increasing silicon content, but all grades retain their room-temperature toughness down to at least -195 °C (-320 °F). Tensile requirements for nickel-copper alloys are listed in Table 3.

Nickel-Chromium-Iron Alloys. Minimum mechanical properties for both corrosion-resistant and heat-resistant alloys are given in Table 3. Alloy CY-40 is frequently used for elevated-temperature fittings in conjunction with the wrought alloy of similar base composition. Typical elevated-temperature properties are listed in Table 4. Applications for HW and HX alloys were discussed above.

Table 4 Elevated-temperature mechanical properties of alloy CY-40

Temperature		Tensile strength		Yield strength		Elongation in 25 mm (1 in.), %	Stress to rupture in 100 h	
°C	°F	MPa	ksi	MPa	ksi		MPa	ksi
Room		486	70.5	293	42	16	. . .	. . .
480	900	427	62	. . .	. . .	20	. . .	. . .

650	1200	372	54.5	. . .	. . .	21	165	24
730	1350	314	45.5	. . .	. . .	25	103	15
815	1500	187	27.1	. . .	. . .	34	62	9
925	1700	. . .	. . .	. . .	. . .	. . .	38	5.5

Nickel-Chromium-Molybdenum Alloys. The CW-12MW and CW-7M grades have a relatively high yield strength (Table 3) due to the solution-hardening effects of chromium, molybdenum, and silicon in CW-7M and of tungsten and vanadium in CW-12MW. Ductility is excellent up to the limit of solid solubility. Inadequate heat treatment or improper composition balance, however, may result in the formation of a hard, brittle phase and in a significant loss of ductility. Careful control within the specified composition range is therefore necessary to meet the specified ductility. Carbon and sulfur contents should be kept as low as practicable.

Nickel-Molybdenum Alloys. The N-12MV and N-7M grades have good yield strengths because of the solution-hardening effect of molybdenum (Table 3). Ductility is controlled by the carbon and molybdenum contents. For optimum ductility, carbon content should be as low as practicable, and molybdenum content should be adjusted to avoid the formation of intermetallic phases.

Heat-Resistant Alloys. Nickel-base heat-resistant casting alloys, often referred to as superalloys, generally contain substantial levels of aluminum and titanium (Table 2). These elements strengthen the austenitic matrix through precipitation of $Ni_3(Al,Ti)$, an ordered face-centered cubic (fcc) compound referred to as gamma prime (γ'). Various ratios of aluminum and titanium are used in the different nickel-base heat-resistant alloys; generally, titanium atoms can replace aluminum atoms up to a ratio of 3 Ti to 1 Al without altering the ordered fcc crystallographic structure of γ'. When excess titanium is present, Ni_3Ti, an ordered close-packed hexagonal compound known as eta phase (η), precipitates. Because γ' is coherent with the matrix, precipitation of this phase has a greater strengthening effect than precipitation of η.

In addition to the strengthening imparted by γ' precipitation, solid-solution strengthening is conferred by the addition of refractory elements, and grain-boundary strengthening by additions of boron, zirconium, carbon, and hafnium. Hafnium also enhances grain-boundary ductility. Stress-rupture curves for various nickel-base alloys are shown in Fig. 2.

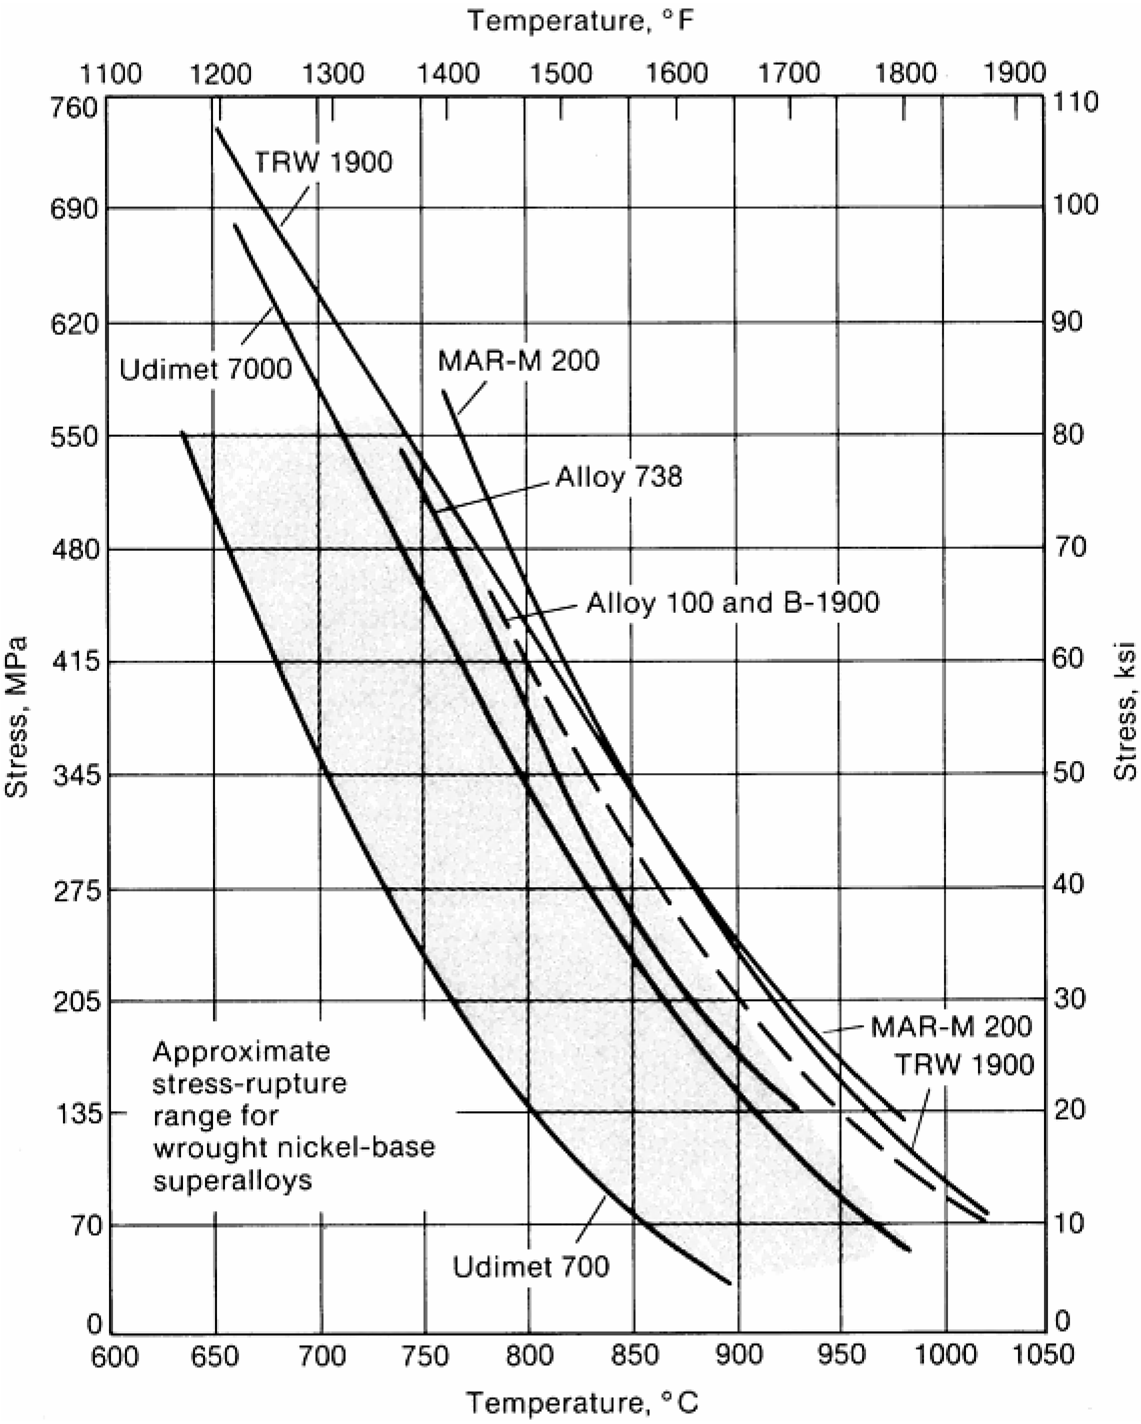

Fig. 2 Stress-rupture curves for 1000-h life of selected cast nickel-base heat-resistant alloys.

The strength of these alloys is complemented by superior corrosion resistance, which is conferred by chromium and aluminum (titanium may be more favorable than aluminum under hot-corrosion conditions). Coatings are used on most nickel alloys for temperatures exceeding about 815 °C (1500 °F) to provide adequate protection from oxidation and corrosion at these temperatures.

Nickel-base heat-resistant alloy castings are produced by investment casting under vacuum, and improvements in properties have been made not only through control of composition but also through more precise control of microstructure. A significant advance in microstructure control was the development of a columnar grain structure produced by directional solidification and single-crystal technology (see discussion below). Extensive use of nickel alloy castings essentially began with Alloy 713, and alloys are available that can be used at temperatures up to about 1040 °C (1900 °F).

In addition to creep strength and corrosion resistance, two other properties--stability, and resistance to thermal fatigue--are important considerations in the selection of nickel-base heat-resistant casting alloys. Thermal-fatigue resistance is partially controlled by composition, but it is also significantly affected by grain-boundary area and alignment relative to applied stresses. The crystallographic orientation of grains also influences thermal stresses because the modulus of elasticity, which directly influences thermal stresses, varies with grain orientation. The stability of property values is directly influenced by metallurgical stability; any microstructural changes that take place during long-term exposure at high temperatures under stress cause attendant changes in properties. For example, if the γ' phase coarsens, strength decreases. Also, potentially deleterious topologically close-packed (tcp) secondary phases, such as σ, Laves, and μ, may form. Coarsening of γ' can be controlled to some degree by adjusting alloy additions. Formation of tcp phases is controlled by adjusting the composition of the matrix to minimize the electron vacancy number, N_v. A high N_v indicates a tendency toward the formation of tcp phases. In general, an N_v value below 2.4 indicates minimal formation of deleterious phases; however, this relationship varies with base-alloy composition. The metallurgical structures of both cast and wrought heat-resistant alloys are discussed in greater detail in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Alloys 713C and 713LC are closely related investment casting alloys used principally for low-pressure turbine airfoils in gas turbines. Intended for operation at intermediate temperatures from 790 to 870 °C (1450 to 1600 °F), these alloys are generally used in uncooled airfoil designs.

Alloy 738X is an investment casting alloy similar in strength to Alloy 713C and Udimet 700 but with outstanding sulfidation resistance. It is used principally for latter-stage turbine airfoils and for hot-corrosion-prone applications such as industrial and marine engines.

Udimet 700, although primarily a wrought alloy, is also used in investment cast high-pressure turbine blades. In cast form, it is similar in strength to Alloy 713C but offers better hot-corrosion resistance. It is designed for operation at intermediate temperatures from 730 to 900 °C (1350 to 1650 °F). A stability-controlled version of U-700 is known as René 77.

Alloy 100 is designed for use at metal temperatures up to about 980 °C (1800 °F) in cooled and uncooled airfoils. A stability-controlled version of Alloy 100 is known as René 100.

B-1900, to which 1% Hf is usually added to improve ductility and thermal-fatigue resistance, is designed for use at metal temperatures up to about 980 °C (1800 °F) in cooled and uncooled airfoils.

René 80 offers excellent corrosion resistance in sulfur-bearing environments. It is designed for use at metal temperatures up to about 950 °C (1750 °F).

Alloy 792 is designed for use in applications similar to those of René 80. It is one of the most sulfidation-resistant nickel alloys available.

MAR-M 246 and MAR-M 247 are designed for use at metal temperatures of about 980 to 1010 °C (1800 to 1850 °F) in cooled and uncooled airfoils and radial and axial wheels (Fig. 3).

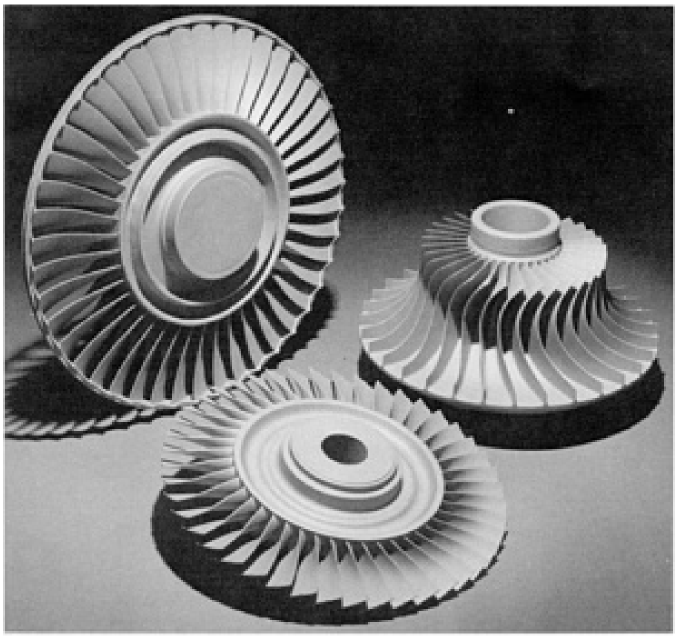

Fig. 3 Various radial and axial turbine wheels made from Mar-M-247 alloy. Courtesy of Howmet Corporation, Whitehall Casting Division.

DS MAR-M 200 + Hf is produced by directional solidification (see discussion below) and is designed for metal temperatures of about 1010 to 1040 °C (1850 to 1900 °F). It is used in cooled airfoils.

Other alloys (such as Udimet 500) are occasionally used in turbine airfoil applications, and Alloy 718 has been cast into large static structures for gas turbines. Additional information on the applications and processing of investment cast nickel-base heat-resistant alloys can be found in the articles "Classification of Processes and Flow Chart of Foundry Operations" and "Investment Casting" in this Volume.

Alloys for directional and single-crystal solidification possess high elevated-temperature strengths. Directionally solidified turbine blades have high strength in the direction of principal stress (the longitudinal direction) because grain boundaries are aligned parallel to this direction. Thus, the effect of grain boundaries on properties is minimized.

Single-crystal alloys have no grain boundaries and therefore require no grain-boundary strengthening elements. For this reason, they can be solution heat treated at higher temperatures than conventional alloys, precipitating a greater amount of the γ' strengthening phase. The lack of grain boundaries also enhances the corrosion resistance of these materials. Table 2 lists several DS/SC alloy compositions. A turbine vane made from CM-247-LC DS alloy is shown in Fig. 4. Properties and performance of DS/SC alloys are detailed in Ref 1, 2, 3, and 4.

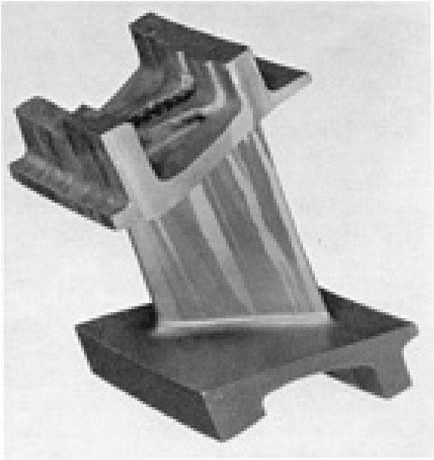

Fig. 4 Directionally solidified turbine vane made from CM-247-LC alloy. Courtesy of Thyssen Guss AG.

Melting Practice

Electric induction furnaces have become the mainstay of the foundry industry for small heat sizes, especially when a number of different alloys are produced. They are also the least expensive of the major furnace types to install. The foundry industry uses these furnaces in sizes ranging from 9 kg to 18 Mg (20 lb to 20 tons); however, most electric induction furnaces are in the 25 to 1350 kg (50 to 3000 lb) range.

Figure 5 shows a cross section of an induction furnace. The furnace shell rests on trunnions, which tilt the furnace during tapping. A copper coil surrounds the furnace lining and the charge materials inside. The metal charge is melted by its resistance to the current induced by a magnetic field when current flows through the coil. More detailed information on induction furnaces can be found in the article "Melting Furnaces: Induction Furnaces" in this Volume.

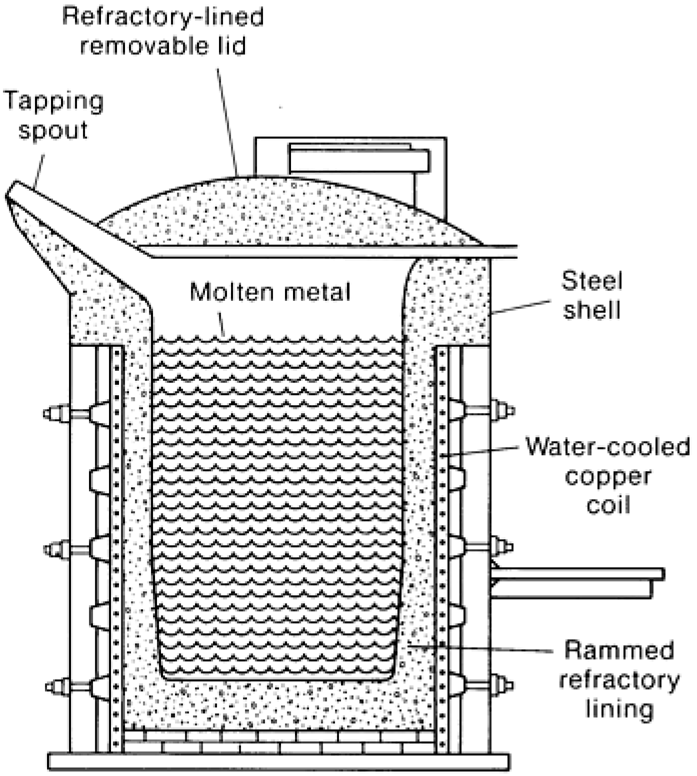

Fig. 5 Cross section of a coreless electric induction furnace.

Vacuum Melting. Nickel-base alloys containing more than about 0.2% of the reactive elements aluminum, titanium, and zirconium are not suitable for melting and casting in oxidizing environments such as air. At the higher alloying levels, these elements readily oxidize, resulting in gross inclusions, oxide laps, and poor composition control. Consequently, such alloys generally require inert gas injection or vacuum melting and casting methods. Extralow gas contents, which can be obtained by vacuum melting, are also required for certain nickel-base alloys. Vacuum melting processes, which are described in the article "Vacuum Melting and Remelting Processes" are always used for directional solidification and single-crystal casting alloys.

Metal Treatment

Argon Oxygen Decarburization (AOD). Some foundries have recently installed AOD units to achieve some of the results that vacuum melting can produce. The AOD unit looks very much like a Bessemer converter with tuyeres in the lower side-walls for the injection of argon or nitrogen and oxygen. These units must be charged with molten metal from an arc or induction furnace. About 20%, but usually less, cold charge consisting of solid virgin material can be added to an AOD unit. The continuous injection of gases causes a violent stirring action and intimate mixing of slag and metal, which can lower sulfur values to below 0.005%. The gas contents (hydrogen, nitrogen, and oxygen) may be even lower than those of vacuum induction melted alloys. More information on AOD processing is available in the section "Argon Oxygen Decarburization" of the article "Degassing Processes (Converter Metallurgy)" in this Volume.

Electroslag remelting furnaces represent another type of equipment that may see some use in the high-alloy foundry in the next decade. Electroslag remelting machines have been used for many years by the wrought steel companies to produce refined ingots. In the Soviet Union, electroslag remelting is being used to cast shapes, and the technology is being evaluated in the United States as well. The process works by taking an ingot (which becomes the electrode), remelting it in stages under molten slag to refine it, and then resolidifying the metal in a water-cooled mold. See the section "Electroslag Remelting (ESR)" in the article "Vacuum Melting and Remelting Processes" in this Volume.

Plasma Refining. Steadily increasing requirements for alloy cleanliness have led producers to adopt several novel refining technologies and process routes, many involving increased use of the ladle as a refining vessel. Such procedures

require longer holding times in the ladle, which necessitate either increased superheats in the furnace or external heating in the ladle to avoid early solidification. Higher superheat, in addition to requiring excessive energy expenditure, can contribute to the problem of melt contamination. The preferred solution is to supply heat to the ladle, maintaining the alloy at minimal superheat during refining. This can be accomplished by the transferred arc plasma torch, with the added benefit of enhanced refining reactions that aid in the production of clean metal with low levels of residual elements. In this work, experiments have been carried out in an induction furnace equipped with a gas-stabilized graphite electrode to investigate the control of oxygen and induction levels and the enhancement of desulfurization afforded by the transferred arc plasma. See the section "Plasma Heating and Degassing" in the article "Degassing Processes (Ladle Metallurgy)" in this Volume.

Foundry Practice

Foundry practice for nickel-base alloys is for the most part similar to that used for cast stainless steels (see the article "High-Alloy Steels" in this Volume). Specific aspects of foundry practice discussed here include pouring, gating and risering, cleaning, welding, and heat treatment of conventional corrosion-resistant nickel-base alloy castings. The processing of investment cast and DS/SC alloys is reviewed in the articles "Investment Casting" and "Directional and Monocrystal Solidification", respectively, in this Volume.

Pouring Practice

Three types of ladles are used for pouring nickel-base castings: bottom pour, teapot, and lip pour. Ladle capacity normally ranges from 45 kg to 36 Mg (100 lb to 40 tons), although ladles having much larger capacities are available.

The bottom-pour ladle has an opening in the bottom that is fitted with a refractory nozzle (Fig. 6). A stopper rod, suspended inside the ladle, pulls the stopper head up from its seat in the nozzle, allowing the molten alloy to flow from the ladle. When the stopper head is returned to the position shown in Fig. 6, the flow is cut off. The position of the stopper head is controlled manually by the slide-and-rack mechanism shown at the left in Fig. 6.

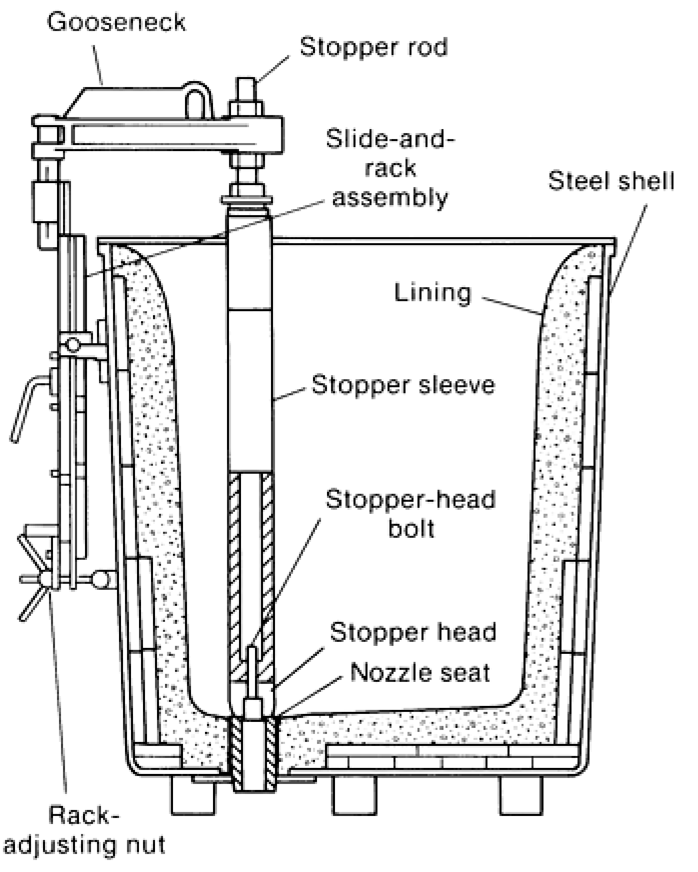

Fig. 6 Typical bottom-pour ladle used to pour large castings.

Bottom pouring is preferred for pouring large castings from large ladles, because it is difficult to tip a large ladle and still control the stream of molten steel. Also, the bottom-pour ladle delivers cleaner metal to the mold. Inclusions, pieces of ladle lining, and slag float to the top of the ladle; thus, bottom pouring greatly reduces the risk of passing nonmetallic particles into the mold cavity.

On the other hand, it is impractical to pour molten metal into small molds from a large bottom-pour ladle. The pressure head created by the metal remaining in the ladle delivers the molten metal too fast. Also, the time required to fill a small mold is short, thus requiring that a large bottom-pour ladle be opened and closed many times in order to empty it. This may cause the ladle to leak, although special nozzles have been developed to minimize leakage. Despite the fact that the size of bottom-pour ladles could be scaled down for pouring smaller castings, this is unnecessary because of the almost equal ability of the teapot ladle to deliver clean metal.

The teapot ladle incorporates a ceramic wall, or baffle, that separates the bowl of the ladle from the spout. The baffle extends almost four-fifths of the distance to the bottom of the ladle (Fig. 7). As the ladle is tipped, hot metal flows from the bottom of the ladle up the spout and over the lip. Because the metal is taken from near the bottom of the ladle, it is

free of slag and pieces of eroded refractory. The teapot design is feasible in various sizes, generally covering the entire range of casting sizes that are below the minimum size for which the bottom-pour ladle is used.

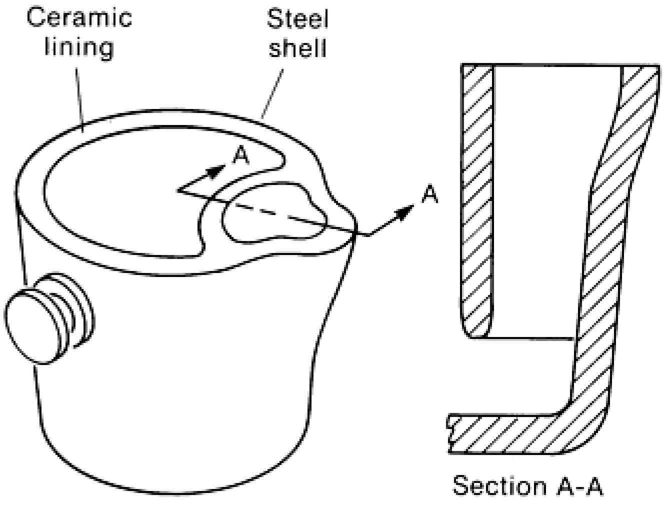

Fig. 7 Typical teapot ladle used to pour small- to medium-size castings.

Lip-pour ladles resemble the teapot type but have no baffles to hold back the slag. Because the hot metal is not taken from the bottom of the ladle, this type of ladle pours a more contaminated metal and is seldom used to pour high-alloy castings. Nevertheless, it is widely used as a tapping ladle (at the melting furnace) and as a transfer ladle to feed smaller ladles of the teapot type.

Pouring Time. Ideally, the optimum pouring time for a given casting would be determined by the weight and shape of the casting, the temperature and solidification characteristics of the molten metal, and the heat transfer and thermal stability characteristics of the mold. However, most foundries are required to pour may different castings from one heat or even from one ladle. Therefore, rather than attempting to control pouring time directly, foundries control the speed with which molten steel enters the mold cavity. This control is achieved through the design of the gating system.

Gating Systems

An effective gating system for pouring nickel-base alloys, as well as other metals, into green sand molds is one that fills the mold as rapidly as possible without developing pronounced turbulence. It is essential that the mold be filled rapidly to minimize temperature variations within the metal; this results in optimized control of solidification.

Turbulent metal flow is harmful because it breaks up the metal stream, exposing more surface area to air and forming metallic oxides. The oxides can rise to the top of the mold cavity, resulting in a rough surface of inclusions in the casting. In addition, turbulent flow erodes the mold material. These eroded particles also float to the top of the mold cavity.

Preferred Metal Flow. According to preferred practice, the pourer directs the metal stream toward the pouring cup at the top of the mold, controlling the pouring rate to keep the cup full of molten metal throughout the pouring cycle. The opening in the bottom of the cup is directly over the sprue, or downgate, which is tapered at the bottom, thus reducing the diameter of the stream of descending metal. The taper prevents the stream from pulling away from the walls and drawing air into the gating system. The descending metal impinges on the sprue well at the bottom of the sprue, and the direction of flow changes from vertical to horizontal, with the metal flowing along runners to gates (ingates), and then to the main body of the casting. A gating system that incorporates these features is shown in Fig. 8.

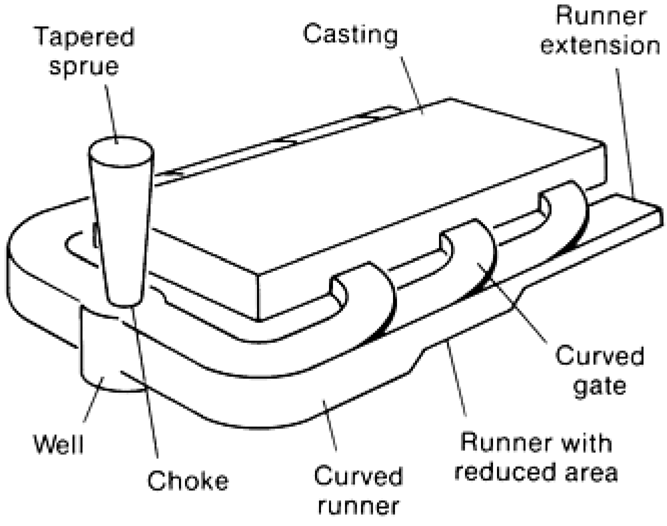

Fig. 8 Gating system for good metal flow.

Gating system design largely determines the manner in which molten metal is fed into the mold, as well as the rate of feeding. The number of gates influences the distribution of the flow between gates. A good design has even distribution between gates both initially and while the mold is filling. The distribution of flow in the gating system affects the type of flow that occurs in the main body of the casting. A large difference in the flow between gates creates a swirl of metal in the mold about a vertical axis, in addition to that occurring about a horizontal axis.

The gating system shown in Fig. 8 is an example of a so-called finger-type parting line system, in which the fingers feed metal to the casting just above the parting line. Other major types of gating systems used in alloy foundries include the bottom gate, which feeds metal to the bottom of the casting, and the step gate, which feeds metal through a number of stepped gates, one above another. In the system shown in Fig. 8, the ratio of the cross-sectional area of the choke of the sprue to that of all of the runners emanating from the sprue basin and to all of the gates is 1:4:4. As shown in Fig. 8, the runner area decreases progressively by an amount equal to the area of each gate it passes. This practice ensures that, once the system is filled with metal, it remains full during the pouring cycle and feeds equally to each gate.

Furthermore, the gates are located in the cope, while the runner, which extends beyond the last gate, is located in the drag. Extension of the runner serves as a trap for the first, and usually the most contaminated, metal to enter the system. The entire runner must fill before the metal will rise to the level of the gates. Thus, each gate begins feeding at the same time. The runners and gates are curved wherever a change in direction occurs. This streamlining reduces turbulence in the metal stream and minimizes mold erosion.

In contrast to the ratio of the system shown in Fig. 8 (1:4:4), if the total cross-sectional area of the gates is less than that of the runners (1:2:1, for example), the result is a pressurized system. The metal squirts into the mold cavity and flows turbulently over the mold bottom, which can cause roughening of the bottom surfaces.

Conversely, if the total cross-sectional area of the gates is significantly greater than that of the runners (1:2:3, for example), the gating system will be incompletely filled, and flow from the gates will be uneven. This condition increases the likelihood of mold erosion. When this type of system is required, complicated additions to gating systems are used, including whirlgates, horn gates, strainer cores, tangential gates, and slit gates. However, any addition to the gating system usually increases the cost of the casting because all gating must be removed. More detailed information on gating practice can be found in the article "Gating Design" in this Volume.

Mold Erosion. In addition to the contribution of gating design to a reduction in mold erosion, further reduction can be achieved by making the gating system out of tile, which is superior to green sand in erosion resistance. However, the use of tile is generally limited to gating systems for large castings, where the quantity and speed of molten metal passing through the gating system would seriously erode green sand and where precise control of the flow rate is less critical. Thus, gating systems for smaller castings are rammed in sand, usually with a semicircular or rectangular cross section for the gates and runners.

Risers

Molten nickel-base alloys contract approximately 0.9% per 55 °C (100 °F) as they cool from the pouring temperature to the solidification temperature. They then undergo solidification contraction of 3% during freezing, and finally the solidified metal contracts 2.2% during cooling to room temperature. Therefore, when casting nickel alloys, an ample supply of molten metal must be available from risers (reservoirs) to compensate for the volume decrease, or shrinkage cavities will develop in the locations that solidify last.

Because feed from the riser occurs by gravity, risers are usually located at the top of the casting. Riser forms are placed on the pattern and molded into the cope half of the mold. The riser cavity is usually open to the top of the mold, although blind risers are sometimes used.

Riser Size and Shape. As described in the article "Riser Design" in this Volume, formulas based on surface area, volume, and freezing time of the casting are used to determine riser size. Most risers are cylindrical in shape, with their heights approximately equal to their diameters. This configuration provides a low ratio of surface area to volume, which prolongs the time the metal in the riser remains liquid.

Placement of a riser, in conjunction with its size, determines its effectiveness. The thicker sections of a casting act as reservoirs for feeding the thinner sections, which solidify first. Thus, risers are placed over thick sections that cannot be fed by other areas of the casting. Demonstrating this principle, the gear blank casting shown in Fig. 9 is provided with a large riser over the central hub and six smaller risers spaced equally around the rim of the gear to ensure adequate feeding. Metal enters the mold at the two gates, which are 180° apart.

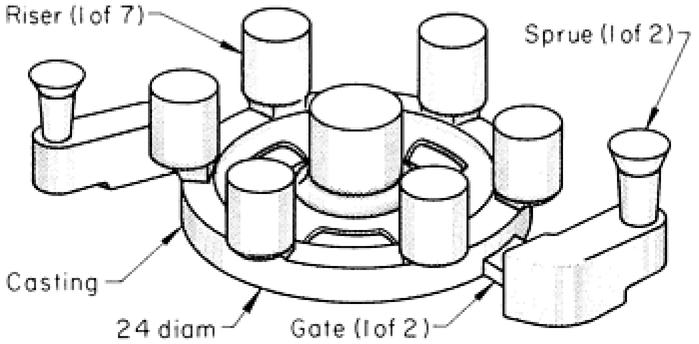

Fig. 9 Gating and feeding system used to cast gear blanks.

Feeding Distance. Castings of uniform thickness present a different problem. Studies have established the feeding distances of a riser for various rectangular shapes in both the horizontal and vertical planes, with and without an end effect (that is, the extra cooling provided by the sand cover of an end surface).

For a uniform section, the maximum feeding distance can be extended by adding a taper. The progressively thicker section solidifies in a progressively longer time, so that a favorable temperature gradient is established from the end of the section to the riser. A tapered pad of exothermic material placed in the mold along the length of the casting will also produce a favorable temperature gradient.

Welding

Cast Nickel. Alloy CZ-100 can be readily repair welded or joined to other castings or to wrought forms by using any of the usual welding processes with suitable nickel rod and wire. Joints or cavities must be carefully prepared for welding because small amounts of sulfur or lead cause weld embrittlement.

Nickel-Copper Alloys. The weldability of the nickel-copper alloys decreases with increasing silicon content, but is adequate up to at least 1.5% Si. Niobium can enhance weldability, particularly when small amounts of low-melting residuals are present. Careful raw material selection and proper foundry practice, however, have largely eliminated any difference in weldability between niobium-containing and niobium-free grades.

The higher-silicon compositions (≥3.5% Si) are not considered weldable. They can be brazed or soldered, as can the lower-silicon grades.

Nickel-Chromium-Iron Alloys. The CY-40 castings can be repair welded or fabrication welded to matching wrought alloys by any of the usual welding processes. Rod and wire of matching nickel-chromium contents are available. Postweld heat treatment is not required after repair welding or fabrication, because the heat-affected zone is not sensitized by the weld heat.

Nickel-Chromium-Molybdenum Alloys. Alloys CW-12MW and CW-7M can be welded by any of the usual welding processes, using wire or rod of matching composition. For optimum weldability, carbon content should be as low as practicable. The usual practice is to solution treat and quench after repair welding. Heat treatment after welding is generally necessary because these alloys are subject to sensitization in the heat-affected zone and because intermetallic precipitates may form in the heat-affected zone.

Nickel-Molybdenum Alloys. Alloys N-12MV and N-7M can be welded by using any of the usual welding processes with wire or rod of matching composition. Postweld heat treatment is usually performed because these alloys are subject to the precipitation of intermetallic compounds in the heat-affected zone.

Heat Treatment

Cast nickel (alloy CZ-100) is used in the as-cast condition. Some other alloys are also used as-cast, but most require some type of thermal treatment to develop optimum properties.

Nickel-copper alloys are used in the as-cast condition. Homogenization at 815 to 925 °C (1500 to 1700 °F) may, under some conditions, improve corrosion resistance slightly, but in most corrosive conditions, alloy performance is not affected by the minor segregation present in the as-cast alloy.

At about 3.5% Si, silicon begins to have an age-hardening effect. The resultant combination of aging and the formation of hard silicides when the silicon content exceeds about 3.8% can cause considerable difficulty in machining. Softening is accomplished by a solution heat treatment, which consists of heating to 900 °C (1650 °F), holding at temperature for 1 h per 25 mm (1 in.) of section thickness, and oil quenching. Maximum softening is obtained by oil quenching from 900 °C (1650 °F), but such treatment is likely to result in quench cracks in castings with complex shapes or varying section thickness.

In the solution heat treatment of complicated or varying-section castings, it is advisable to charge them into a furnace below 315 °C (600 °F) and heat to 900 °C (1650 °F) at a rate that limits the maximum temperature difference within the casting to about 56 °C (100 °F). After being soaked, castings should be transferred to a furnace held at 730 °C (1350 °F), allowed to equalize in temperature, and then oil quenched. Alternatively, the furnace can be rapidly cooled to 730 °C (1350 °F), the casting temperature can be equalized, and the castings can be quenched in oil. Solution heat treated castings are age hardened by placing them in a furnace held at 315 °C (600 °F), heating uniformly to 595 °C (1100 °F), holding at 595 °C (1100 °F) for 4 to 6 h, and air or furnace cooling.

Nickel-Chromium-Iron Alloys. Alloy CY-40 is used in the as-cast condition because it is insensitive to the intergranular attack encountered in as-cast or sensitized stainless steels. A modified cast nickel-chromium-iron alloy for nuclear applications with 0.12% C (max) is usually solution treated as an additional precaution.

Sensitization in the heat-affected zone is not a problem with CY-40. Unless residual stresses pose a problem, postweld heat treatment is therefore not required.

Nickel-Chromium-Molybdenum Alloys. The high chromium and molybdenum contents of CW-12MW and CW-7M result in the precipitation of carbides and intermetallic compounds in the as-cast condition, which can be detrimental to corrosion resistance, ductility, and weldability. These alloys should therefore be solution treated at a temperature of 1175 to 1230 °C (2150 to 2250 °F) and water or spray quenched.

Nickel-Molybdenum Alloys. Slow cooling in the mold is detrimental to the corrosion resistance, ductility, and weldability of N-12MV and N-7M. These alloys should therefore be solution treated at a minimum temperature of 1175 °C (2150 °F) and water quenched.

Specific Applications

Corrosion-resistant nickel-base castings are primarily used in fluid-handling systems with matching wrought alloys; they are also commonly used for pump and valve components or for applications with crevices and velocity effects requiring a superior material in a wrought stainless system. Because of their relatively high cost, nickel-base alloys are usually selected only for severe service conditions in which maintenance of product purity is of great importance and for which less costly stainless steels or other alternative materials are inadequate. Detailed information on the corrosion resistance of nickel-base alloys in aqueous media is available in the article "Corrosion of Nickel-Base Alloys" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

In the application of heat-resistant alloys, considerations include:

- Resistance to corrosion (oxidation) at elevated temperatures
- Stability (resistance to warping, cracking, or thermal fatigue)
- Creep strength (resistance to plastic flow)

Numerous applications of cast heat-resistant nickel-base alloys were discussed earlier in this article. Information on the high-temperature corrosion resistance of these alloys is available in the articles "Fundamentals of Corrosion in Gases," "General Corrosion" (see the section "High-Temperature Corrosion"), and "Corrosion of Metal Processing Equipment" (see the section "Corrosion of Heat-Treating Furnace Accessories") in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Cast Nickel. Nickel castings are most commonly used in the manufacture of caustic soda and in processing with caustic (see the section "Corrosion by Alkalies and Hypochlorite" in the article "Corrosion in the Chemical Processing Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). As the temperature and caustic soda concentration increase, austenitic stainless steels are useful only up to a point. The nickel-copper and nickel-chromium-iron alloys take over as useful alloys under these conditions, while cast nickel is selected for the higher caustic concentrations, including fused anhydrous soda. Minor amounts of such elements as oxygen and sulfur can have profound effects on the corrosion rate of nickel in caustic. Detailed corrosion data should therefore be consulted before making a final alloy selection.

Nickel-Copper Alloys. The principal advantages of the Ni-30Cu alloys are high strength and toughness, coupled with excellent resistance to mineral acids, organic acids, salt solution, food acids, strong alkalies, and marine environments. The most common applications for nickel-copper castings are in the manufacture of, and processing with, hydrofluoric acid and the handling of salt water, neutral and alkaline salt solutions, and reducing acids.

Nickel-chromium-iron alloys are commonly used under oxidizing conditions to handle high-temperature corrosives or corrosive vapors where stainless steels might be subject to intergranular attack or stress-corrosion cracking. In recent years, the CY-40-type alloy has found large-scale application in handling hot boiler feedwater in nuclear plants because of a greater margin of safety over stainless steels. More information on this application is available in the article "Corrosion in the Nuclear Power Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Nickel-chromium-molybdenum alloys are probably the most common materials for upgrading a system in which service conditions are too demanding for either standard or special stainless steels because of severe combinations of acids and elevated temperatures. These cast alloys can be used in conjunction with similar wrought materials, or they can serve to upgrade pump and valve components in a wrought stainless steel system.

Nickel-molybdenum alloys have specialized application areas, primarily in the handling of hydrochloric acid at all temperatures and concentrations. Applications should not be based on upgrading in areas where stainless steels are inadequate, because the nickel-molybdenum alloys are unsuitable for handling most oxidizing solutions for which stainless steels are used.

Alloys for directional and single-crystal solidification are used as blades for aircraft and some land-based turbines (Fig. 1 and 4). Under elevated temperatures, they have very high strength in the direction of primary stress.

Titanium and Titanium Alloys

Jeremy R. Newman, Titech International Inc.; Daniel Eylon, University of Dayton; John K. Thorne, Precision Castparts Corporation

Introduction

SINCE THE INTRODUCTION OF TITANIUM and titanium alloys in the early 1950s, these materials have in a relatively short time become one of the backbone materials for the aerospace, energy, and chemical industries (Ref 1). The combination of high strength-to-weight ratio, excellent mechanical properties, and corrosion resistance makes titanium the best material for many critical applications. Today, titanium alloys are used for static and rotating gas turbine engine components. Some of the most critical and highly stressed civilian and military airframe parts are made of these alloys.

Net Shape Technology Development. The use of titanium has expanded in recent years from applications in nuclear power plants to food processing plants, from oil refinery heat exchangers to marine components and medical prostheses (Ref 2). However, the high cost of titanium alloy components may limit their use to applications for which lower-cost alloys, such as aluminum and stainless steels, cannot be used. The relatively high cost is often the result of the intrinsic raw material cost of the metal, fabricating costs, and, usually most important, the metal removal costs incurred in obtaining the desired end-shape. As a result, in recent years a substantial effort has been focused on the development of net shape or near-net shape technologies to make titanium alloy components more competitive (Ref 3). These titanium net shape technologies include powder metallurgy (PM), superplastic forming (SPF), precision forging, and precision casting. Precision casting is by far the most fully developed and the most widely used net shape technology.

Casting Industry Growth. The annual shipment of titanium castings increased by 240% between 1978 and 1986 (Fig. 1) and titanium casting is the fastest growing segment of titanium technology.

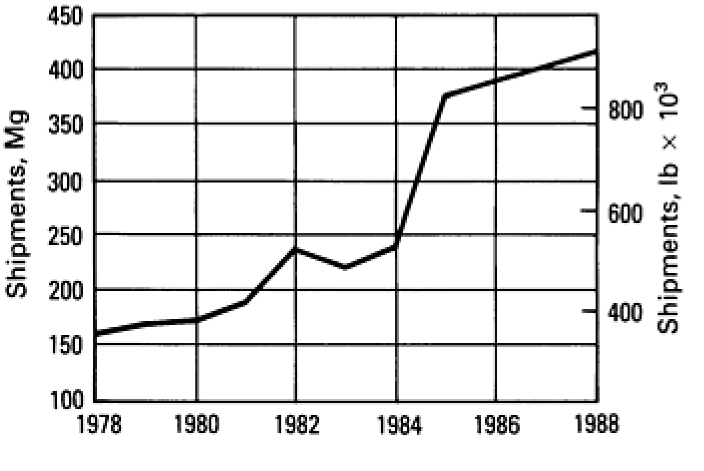

Fig. 1 Growth of 240% in United States titanium casting shipments from 1978 to 1986. Source: Ref 4.

Even at current levels (approaching 450 Mg, or 1 × 10^6 lb, annually), castings still represent less than 2% of total titanium mill product shipments. This is in sharp contrast to the ferrous and aluminum industries, where foundry output is 9% (Ref 5) and 14% (Ref 6) of total output, respectively. This suggests that the growth trend of titanium castings will continue as users become more aware of industry capability, suitability of cast components in a wide variety of applications, and the net shape cost advantages.

Properties Comparable to Wrought. The term castings often connotes products with properties generally inferior to wrought products. This is not true with titanium cast parts. They are generally comparable to wrought products in all respects and quite often superior. Properties associated with crack propagation and creep resistance can be superior to those of wrought products. As a result, titanium castings can be reliably substituted for forged and machined parts in many demanding applications (Ref 7, 8). This is due to several unique properties of titanium alloys. One is the α+ β-to-β allotropic phase transformation at a temperature range of 705 to 1040 °C (1300 to 1900 °F), which is well below the solidification temperature of the alloys. As a result, the cast dendritic β structure is wiped out during the solid state cooling stage, leading to an α+ β platelet structure (Fig. 2a), which is also typical of β processed wrought alloy. Further, the convenient allotropic transformation temperature range of most titanium alloys enables the as-cast microstructure to be improved by means of postcast cooling rate changes and subsequent heat treatment.

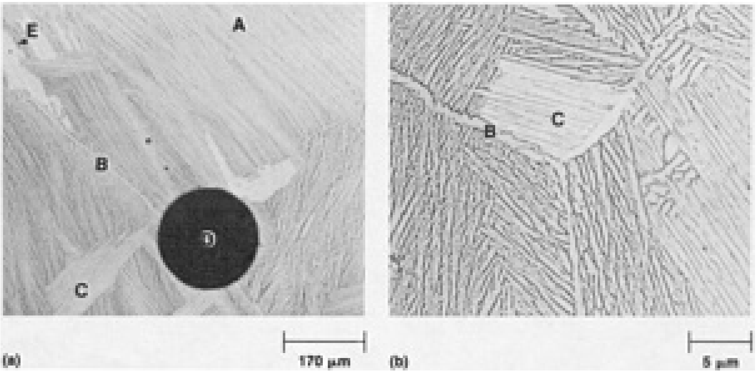

Fig. 2 Comparison of the microstructures of (a) as-cast versus (b) cast + HIP Ti-6Al-4V alloys illustrating lack of porosity in (b). Grain boundary α (B) and α plate colonies (C) are common to both alloys; β grains (A), gas (D), and shrinkage voids (E) are present only in the as-cast alloy.

Reactivity. Another unique property is the high reactivity of titanium at elevated temperatures, leading to an ease of diffusion bonding. As a result, hot isostatic pressing (HIP) of titanium castings yields components with no subsurface porosity. At the HIP temperature range (820 to 980 °C, or 1500 to 1800 °F) titanium dissolves any microconstituents deposited upon internal pore surfaces, leading to complete healing of casting porosity as the pores are collapsed during the pressure and heat cycle. Both the elimination of casting porosity and the promotion of a favorable microstructure improve mechanical properties. However, the high reactivity of titanium, especially in the molten state, presents a special challenge to the foundry. Special, and sometimes relatively expensive, methods of melting (Ref 9), moldmaking, and surface cleaning (Ref 7, 8) may be required to maintain metal integrity. Additional information on HIP of castings may be found in the article "Hot Isostatic Pressing of Castings" in this Volume.

Historical Perspective of Casting Technology

Although titanium is the fourth most abundant structural metal in the earth's crust (0.4 to 0.6 wt%) (Ref 9), it has emerged only recently as a technical metal. This is the result of the high reactivity of titanium, which requires complex methods and high energy input to win the metal from the oxide ores. The required energy per ton is 1.7 times that of aluminum and

16 times that of steel (Ref 10). From 1930 to 1947, metallic titanium extracted from the ore as a powder or sponge form was processed into useful shapes by P/M methods to circumvent the high reactivity in the molten form (Ref 11).

Melting Methods. The melting of small quantities of titanium was first experimented with in 1948 using methods such as resistance heating, induction heating, and tungsten arc melting (Ref 12, 13). However, these methods never developed into industrial processes. The development during the early 1950s of the cold crucible, consumable-electrode vacuum arc melting process, "skull melting," by the U.S. Bureau of Mines (Ref 13, 14) made it possible to melt large quantities of contamination-free titanium into ingots or net shapes. Additional information on numerous melting methods is available in the articles "Melting Furnaces: Electric Arc Furnaces," "Melting Furnaces: Induction Furnaces," "Melting Furnaces: Reverberatory Furnaces and Crucible Furnaces," "Melting Furnaces: Cupolas," and "Vacuum Melting and Remelting Processes" in this Volume.

First Castings. Shape casting of titanium was first demonstrated in the United States in 1954 at the U.S. Bureau of Mines using machined high-density graphite molds (Ref 13, 15). The rammed graphite process developed later, also by the U.S. Bureau of Mines (Ref 16), led to the production of complex shapes. This process, and its derivations, are used today to produce parts for marine and chemical-plant components such as the pump and valve components shown in Fig. 3(a). Some aerospace components such as the aircraft brake torque tubes, landing arrestor hook, and optic housing shown in Fig. 3(b) have also been produced by this method.

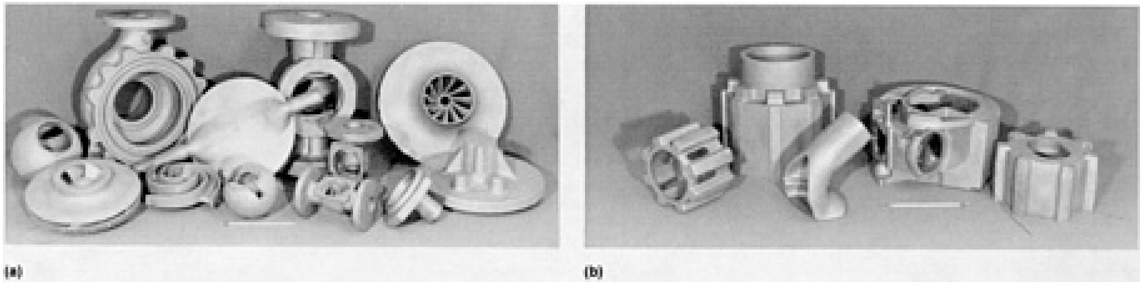

Fig. 3 Typical titanium parts produced by the rammed graphite process. (a) Pump and valve components for marine and chemical-processing applications. (b) Brake torque tubes, landing arrestor hook, and optic housing components used in aerospace applications.

Molding Methods

Rammed Graphite Molding. The traditional rammed graphite molding process uses powdered graphite mixed with organic binders (see the article "Rammed Graphite Molds" in this Volume). Patterns typically are made of wood. The mold material is pneumatically rammed around the pattern and cured at high temperature in a reducing atmosphere to convert the organic binders to pure carbon. The molding process and the tooling are essentially the same as for cope and drag sand molding in ferrous and nonferrous foundries. In the 1970s, derivations of rammed graphite mold materials were developed using components of more traditional sand foundries along with inorganic binders. This resulted in more dimensionally stable and less costly molds that were capable of containing molten titanium without undue metal/mold reaction.

Lost Wax Investment Molding. The principal technology that allowed the proliferation of titanium alloy castings in the aerospace industry was the investment casting method, introduced in the mid-1960s (see the article "Investment Casting" in this Volume). This method, used at the dawn of the metallurgical age for casting copper and bronze tools and ornaments, was later adapted to enable production of high-quality steel and nickel base cast parts. The adaptation of this method to titanium casting technology required the development of ceramic slurry materials with minimum reaction with the extremely reactive molten titanium.

Proprietary lost wax ceramic shell systems have been developed by the several foundries engaged in titanium casting manufacture. Of necessity, these shell systems must be relatively inert to molten titanium and cannot be made with the conventional foundry ceramics used in the ferrous and nonferrous industries. Usually, the face coats are made with special refractory oxides and appropriate binders. After the initial face coat ceramic is applied to the wax pattern, more traditional refractory systems are used to add shell strength from repeated backup ceramic coatings. Regardless of face coat composition, some metal/mold reaction inevitably occurs from titanium reduction of the ceramic oxides. The oxygen-rich surface of the casting stabilizes the α phase, usually forming a metallographically distinct α case layer on the cast surface, which may be removed later by means of chemical milling.

Foundry practice focuses on methods to control both the extent of the metal/mold reaction and the subsequent diffusion of reaction products inward from the cast surface. Diffusion of reaction products into the cast surface is time-at-temperature dependent. Depth of surface contamination can vary from nil on very thin sections to more than 1.5 mm (0.06 in.) on heavy sections. On critical aerospace structures, the brittle α case is removed by chemical milling. The depth of surface contamination must be taken into consideration in the initial wax pattern tool design. Hence, the wax pattern and casting are made slightly oversize, and final dimensions are achieved through careful chemical milling. Metal superheat, mold temperature and thermal conductivity, g force (if centrifugally cast), and rapid postcast heat removal are other key factors in producing a satisfactory product. These parameters are interrelated, that is, a high g force centrifugal pour into cold molds may achieve the same relative fluidity as a static pour into heated molds.

Other Molding Systems. The combination of graphite powder, stucco, and organic binders has also been used as a shell system for the investment casting of titanium. After dewax, the shell is fired in a reducing atmosphere to remove or pyrolyze the binders before casting. This technology has not been promoted as much as the use of refractory oxide shell systems and is presently primarily of historic interest.

In addition to the rammed graphite and investment molding methods, a poured ceramic mold has also been used to produce large parts that require good dimensional accuracy. This method, developed in the late 1970s, was used to a limited extent for several years.

Semipermanent, reusable molds, frequently made from machined graphite, have been used successfully since the earliest U.S. Bureau of Mines work, but only on relatively simple-shaped parts that allow metal volumetric shrinkage to occur without restriction. The method is economical only when reasonably high volumes are required, that is, thousands of parts, because of the high cost of the solid mold material.

Currently, a titanium sand casting technique based on conventional foundry mold-making making practices is under development at the U.S. Bureau of Mines (Ref 17). Because the mold materials are less costly and the cast part is easier to remove from the sand mold than from other methods of titanium casting, this development could lower production costs. However, surface quality problems are restricting the use of this method thus far.

Foundries and Capacities. Table 1 summarizes the use and capacities of the various titanium casting practices by a number of foundries in several countries.

Table 1 Status and capacity of titanium foundries in the United States, Japan, and Western Europe in 1987

Alloys

All production titanium castings to date are based on traditional wrought product compositions. As such, the Ti-6Al-4V alloy dominates structural casting applications. This alloy similarly has dominated wrought industry production since its introduction in the early 1950s, becoming the benchmark alloy against which others are compared. However, other wrought alloys have been developed, for special applications, with better room-temperature or elevated-temperature

strength, creep, or fracture toughness characteristics than those of Ti-6Al-4V. These same alloys are also being cast when net shape casting technology is the most economical method of manufacture. As with Ti-6Al-4V, other cast titanium alloys have properties generally comparable to those of their wrought counterparts.

Chemistry and Demand. Table 2 lists the most prevalent casting alloy chemistries and the most unique attribute of each in comparison with Ti-6Al-4V, plus current approximate market share.

Table 2 Comparison of cast titanium alloys

Alloy	Estimated relative usage of castings	Nominal composition, wt %										Special properties[(a)]
		O	N	H	Al	Fe	V	Cr	Sn	Mo	Zr

(a) Solution-treated and aged (STA) heat treatments may be varied to produce alternate properties.

Specifications. Industry-wide specifications, listed in Table 4 for reference, give more detail on mechanical property guarantees and process control features. In addition, most major aerospace companies have comparable specifications. *MIL Handbook V, Aerospace Design Specifications* does not presently include titanium alloy castings, but it is expected that such information will be incorporated in the near future. As with wrought products, commercially pure titanium castings are used almost entirely in corrosion service. Commercially pure titanium pumps and valves are the principal components made using titanium casting technology for the corrosion resistance field, and are used extensively in chemical and petrochemical plants.

Table 4 Standard industry specifications applicable to titanium castings

MIL-T-81915	Titanium and titanium alloy castings, investment
AMS-4985A	Titanium alloy castings, investment or rammed graphite
AMS-4991	Titanium alloy castings, investment
ASTM B 367	Titanium and titanium alloy castings
MIL-STD-2175	Castings, classification and inspection of
MIL-STD-271	Nondestructive testing requirements for metals

MIL-STD-453	Inspection, radiographic
MIL-Q-9858	Quality program requirement

AMS-4954	Titanium alloy welding wire Ti-6Al-4V
AMS-4956	Titanium alloy welding wire Ti-6Al-4V, extra low interstitial

Newer Alloys. As aircraft engine manufacturers seek to use cast titanium at higher operating temperatures, Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-2Sn-4Zr-6Mo are being specified more frequently. Other titanium alloys for service to 595 °C (1100 °F) are being developed as castings. Extra low interstitial grade Ti-6Al-4V has been used for critical cryogenic space shuttle service where fracture toughness is an important design criteria. The most recent alloys to receive attention in the casting industry are the metastable β alloys Ti-3Al-8V-6Cr-4Zr-4Mo (Beta C) and Ti-15V-3Al-3Cr-3Sn (Ti 15-3). Originally developed as a highly cold-formable and subsequently age-hardened sheet material, these alloys are highly castable and are readily heat treated to an 1170 MPa (170 ksi) strength level, making them serious candidates for the replacement of high-strength precipitation-hardened stainless steels such as 17-4PH. The full density advantage of titanium of about 40% is preserved because strength levels are comparable in both materials. Titanium-aluminide castings are being developed for application in the compressor sections of aircraft gas turbine engines subjected to the highest temperatures. Compositions based upon both the α_2 (Ti_3Al) and γ(TiAl) ordered phases have been cast experimentally, with the former being closer to limited-production status. The low ductility of these alloys at room temperature has been the major producibility challenge. It is anticipated that the service potential for titanium aluminides in the 595 to 925 °C (1100 to 1700 °F) temperature range will eventually be realized. The difficulty in machining shapes in these brittle alloys may increase the advantage of net shape methods such as castings.

Because Ti-6Al-4V dominates the industry, much more metallurgical work has been accomplished with this alloy and is discussed below.

Microstructure of Ti-6Al-4V

Cast Microstructure. To understand the relatively high mechanical property levels of titanium alloy castings and the many improvements made in recent years, it is necessary to understand the microstructures of castings and their influence on the mechanical behavior of titanium. The phase transformation from β to α+ β leads to the elimination of the dendritic cast structure. The existence of such dendrites is evident in the surface morphology of shrinkage pores (Fig. 4). The phase transformation, which in the alloy Ti-6Al-4V is typically initiated at 995 °C (1825 °F), results in the microstructural features shown in Fig. 2(a). This microstructure, which will be discussed in detail, is very similar to a β-processed wrought microstructure and has similar properties. Thus, in the study and development of titanium alloy castings, it is possible to draw much information from conventional ingot metallurgy.

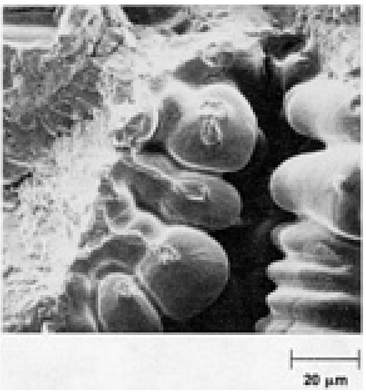

Fig. 4 Dendritic structures present in the surface morphology of an as-cast titanium component.

Hot isostatic pressing is now becoming almost a standard practice for all titanium cast parts produced for the aerospace industry (Table 1). As a result, cast + HIP microstructure also needs to be considered (Fig. 2b). Because the HIP temperature is typically well below the β_t temperature, the as-cast (Fig. 2a) and the cast + HIP microstructures look very much alike, except for the lack of porosity in the latter.

As-Cast and Cast + HIP Microstructures. Because most castings for demanding applications are produced with Ti-6Al-4V alloy (Table 2), only microstructures of this α+ β alloy will be reviewed here.

Beta Grain Size. Beta grains (A, in Fig. 2a) develop during the solid state cooling stage between the solidus/liquidus temperature and the β_t temperature. As a result, large sections, which cool slower, show larger β grains. The size range of the β grains is 0.5 to 5 mm (0.02 to 0.2 in.). As will be further discussed, large β grains may lead to large α plate colonies. This is beneficial for fracture toughness, creep resistance, and fatigue crack propagation resistance (Ref 18, 19) and detrimental for low- and high-cycle fatigue strength (Ref 20, 21).

Grain Boundary α . This α phase (B, in Fig. 2a) is formed along the β grain boundaries when cast material is cooled through the α+ β phase field (in Ti-6Al-4V this is typically from 995 °C, or 1825 °F, down to room temperature). This phase is typically plate shaped and represents the largest α plates in the cast structure. The length of these plates can equal the β grain radius. This has been found to be very detrimental to fatigue crack initiation at room temperature (Ref 22, 23) and at elevated temperatures (Ref 23, 24). Many postcast thermal treatments eliminate this phase to improve fatigue life.

Alpha Plate Colonies. Alpha platelets (C, in Fig. 2a) are the transformation products of the β phase when cooled below the β_t temperature. The hexagonal close-packed (hcp) orientation of these plates is related to the parent body-centered cubic (bcc) β phase orientation through one of the 12 possible variants of the Burgers relationship (Ref 25, 26):

$$\{110\}\beta \parallel (0001)\alpha$$
$$\langle 111\rangle\beta \parallel \langle 1120\rangle\alpha$$

When cooling rates are relatively slow, such as in thick-section castings, many adjacent α platelets transform into the same Burgers variant and form a colony of similarly aligned and crystallographically oriented platelets. The large colonies (like those marked C in Fig. 2a) may be associated with early fatigue crack initiation (Ref 21), the result of heterogeneous basal slip across the plates (Ref 27). At the same time, the large colony structure is beneficial for fatigue crack propagation resistance (Ref 28, 29). Because α platelet colonies cannot grow larger than the β grains, titanium castings with large β grains typically have large colonies. The α platelets are typically 1 to 3 µm (40 to 120 µin.) in thickness and 20 to 100 µm (800 to 4000 µin.) in length (Ref 30, 31), and the typical colony size in castings is 50 to 500 µm (0.002 to 0.02 in.) (Ref 22, 30, 31).

As a general rule, slower cooling rates, such as in thick cast sections, result in microstructures with larger β grains, a longer and thicker grain boundary α phase, thicker α platelets, and larger α platelet colonies.

Porosity. Gas (D, in Fig. 2a) and shrinkage (E) voids are typical phenomena in as-cast titanium products. Hot isostatic pressing, however, closes and heals these pores. This is demonstrated by comparing the as-cast microstructure in Fig. 2(a) with the cast + HIP structure in Fig. 2(b). Hot isostatic pressing also causes a degree of α plate coarsening.

Modification of Microstructure. Virtually all titanium castings produced commercially today are supplied in the annealed condition. However, much microstructural modification development work has recently been done, and it can be expected that solution-treated and aged or other postcast thermal processing will eventually become specified on cast parts requiring certain property enhancement. The following section reviews several of the developmental procedures and their results.

Modification of microstructure is one of the most versatile tools available in metallurgy for improving mechanical properties of alloys. This is commonly achieved through a combination of cold or hot working followed by heat treatment. Net shapes such as castings or P/M products cannot be worked, which limits the options for controlling microstructures. A substantial amount of work has been done in recent years to improve the microstructures of titanium alloy net shape products, with an emphasis on Ti-6Al-4V material. Most treatment schemes can be successfully applied to both cast parts (Ref 8) and P/M compacts (Ref 32, 33). In the case of titanium alloy castings, the main goal has been to eliminate the grain boundary α phase, the large α plate colonies, and the individual α plates. This is accomplished either by solution treatments or by a temporary alloying with hydrogen. In some cases, the hydrogen and solution treatments are combined. The details of these methods, including the appropriate references, are listed in Table 5. The typical resulting microstructures of the α-β solution treatment (ABST), βsolution treatment (BST), broken-up structure (BUS), and high-temperature hydrogenation (HTH) methods are shown in Fig. 5(a), 5(b), 5(c), and 5(d), respectively. As can be seen from the photomicrographs, these treatments are successful in eliminating the large α plate colonies and the grain boundary α phase. As discussed below, a substantial improvement of both tensile and fatigue properties is achieved with these processes.

Table 5 Methods for modifying the microstructure of α+ β titanium alloy net shape products

Method[(a)]	Typical solution treatment	Hydrogenation temperature		Intermediate treatment		Dehydrogenation temperature		Typical annealing or aging treatment	Applied to product forms	Ref

Titanium and Titanium Alloys

Jeremy R. Newman, Titech International Inc.; Daniel Eylon, University of Dayton; John K. Thorne, Precision Castparts Corporation

Mechanical Properties of Ti-6Al-4V

Oxygen Influence. Figure 6 is a frequency distribution of tensile properties from separately cast test bars representing hot isostatic pressed and annealed Ti-6Al-4V castings. Note that oxygen, a carefully controlled alloy addition, is in the 0.16 to 0.20% range, which is common for many aerospace specifications.

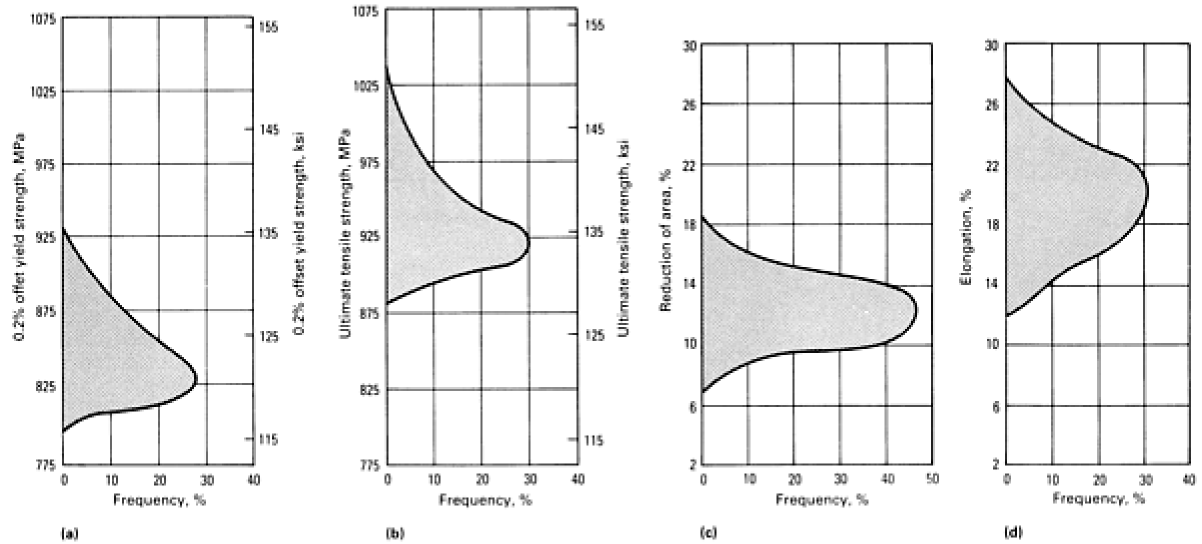

Fig. 6 Frequency distribution of tensile properties of hot isostatically pressed and annealed Ti-6Al-4V casting test bars. Percent frequency is plotted versus (a) 0.2% offset yield strength, (b) ultimate tensile strength, (c) percent reduction of area, and (d) percent elongation. Alloy composition is 0.16 to 0.20% O_2; sample size is

500 heats. Source: Ref 46.

Some specifications allow a 0.25% maximum oxygen content. The resultant properties with oxygen in the 0.20 to 0.25% range are typically about 69 to 83 MPa (10 to 12 ksi) higher than those shown in Fig. 6 with slightly lower ductility levels. In this case, it is possible to guarantee 827 MPa (120 ksi) yield strength and 896 MPa (130 ksi) ultimate tensile strength levels with 6% minimum elongation. This strength level is the same minimum guarantee for wrought-annealed Ti-6Al-4V.

Microstructure Influence. Because the microstructure of titanium alloy cast parts is very similar to β processed wrought or ingot metallurgy (I/M) material, many properties of hot isostatic pressed castings, such as tensile strength, fracture toughness, fatigue crack propagation, and creep, are at the same levels as forged and machined parts. Tensile strength and fracture toughness properties of cast, cast + HIP, and cast + HIP + heat-treated material (Table 5) are compared in Table 6 to wrought β-annealed data. To provide a complete review, properties of castings treated by many of the methods listed in Table 5 are also included. At the present time, fracture toughness data are available for only a few of the conditions. As can be seen, some of the treated conditions present properties in excess of I/M β-annealed material. However, it should be noted that tests were done on relatively small cast coupons. Properties of actual cast parts, especially large components, could be somewhat lower, the result of coarser grain structure or slower quench rates. Of special interest are the hydrogen-treated conditions (such as thermo-chemical treatment, or TCT; constitutional solution treatment, or CST; and HTH, in Table 5) that result in very high tensile strength (as high as 1124 MPa, or 163 ksi) with tensile elongation as high as 8%.

Table 6 Tensile properties and fracture toughness of Ti-6Al-4V cast coupons compared to typical wrought β-annealed material

Material condition[(a)]	Yield strength		Ultimate tensile strength		Elongation, %	Reduction of area, %	K_{Ic}		Ref

(a) All conditions (except as-cast) are cast plus HIP.

(b) See Table 5 for process details.

Fatigue and Fatigue Crack Growth Rate. The fatigue crack growth rate (FCGR) behavior of cast Ti-6Al-4V is also, as expected, very similar to that of β-processed wrought Ti-6Al-4V (Ref 50, 51, 52). This is demonstrated in Fig. 7 in which the scatterband of FCGR of cast and cast-HIP alloy is compared to β-processed I/M (Ref 18, 53).

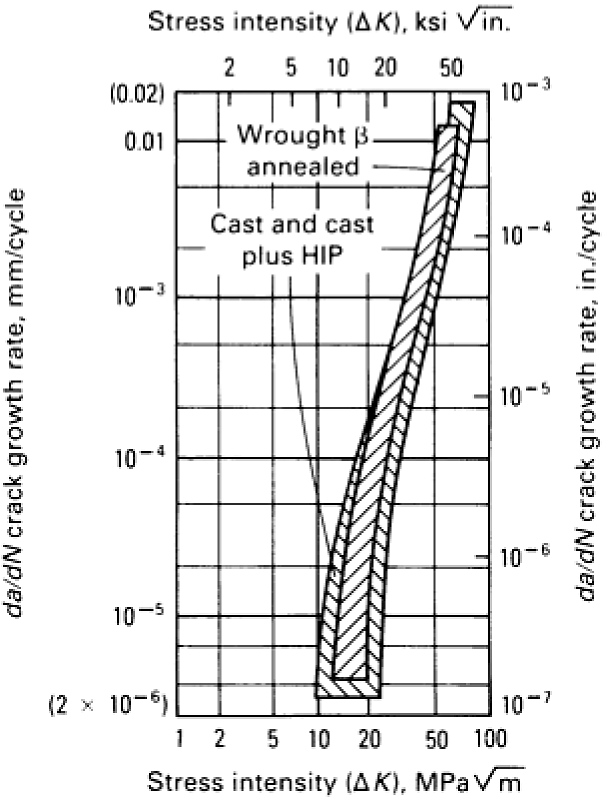

Fig. 7 Scatterband comparison of FCGR behavior of wrought βannealed Ti-6Al-4V to cast and cast HIP Ti-6Al-4V.

The scatterbands of smooth axial fatigue results of cast, cast-HIP (Ref 15, 47, 48, 54, 55, 56, 57), and wrought Ti-6Al-4V are shown in Fig. 8. This figure clearly indicates that the HIP process results in a substantially improved fatigue life well into the wrought-annealed region. The fatigue properties of aerospace quality castings have always been an important issue, because in most other alloy systems this is the property that is most degraded when compared to wrought products. However, because of the complete closure and healing of gas (D, in Fig. 2a) and shrinkage (E, in Fig. 2a) pores by HIP and the β-annealed microstructure, it is possible to get fatigue life comparable to wrought material in premium investment cast and hot isostatic pressed parts. As indicated previously (Table 5), substantial work has been done in recent years to modify the microstructure of cast parts to produce fatigue properties either equivalent or superior to the best wrought-annealed products. Figure 9 compares the smooth fatigue life of Ti-6Al-4V treated by ABST, BST, BUS, CST, Garrett treatment (GTEC), and HTH (Table 5) to wrought material scatterband. As can be seen, all of these treatments were successful in improving fatigue life above wrought levels. The hydrogen treatments (CST and HTH) resulted in the highest improvement in fatigue strength. However, it should be noted that wrought products subjected to the same treatments result in comparable improvements in fatigue strength.

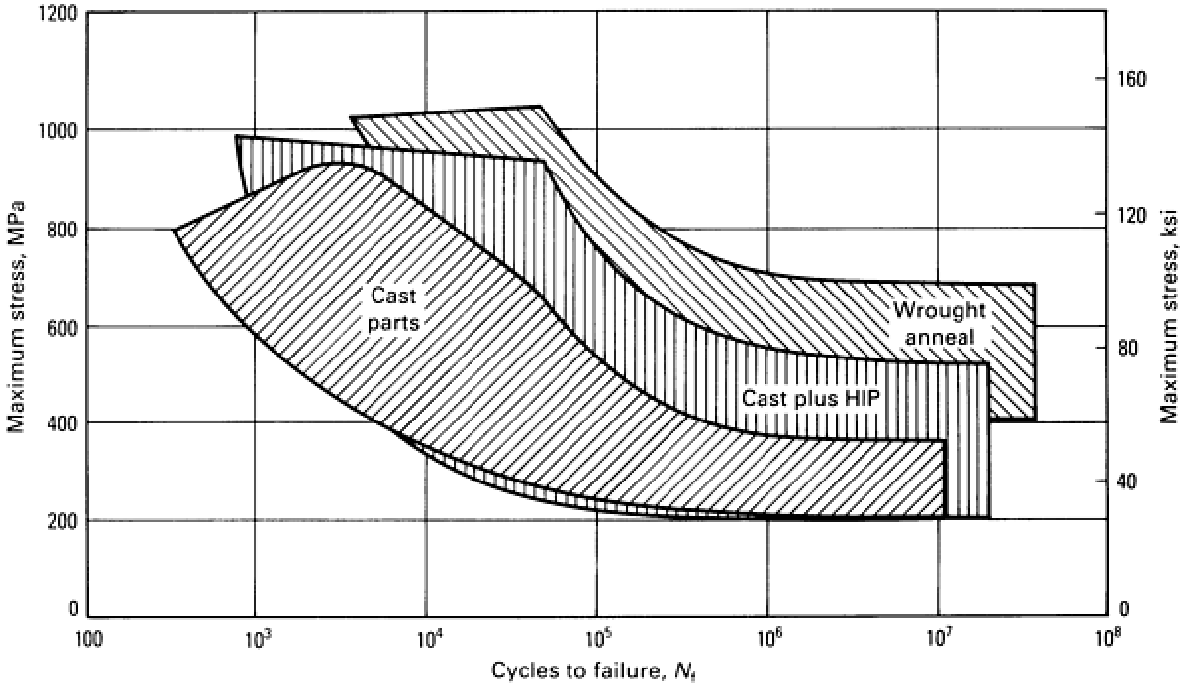

Fig. 8 Comparison of smooth axial fatigue rate in cast and wrought Ti-6Al-4V at room temperature with R = +0.1.

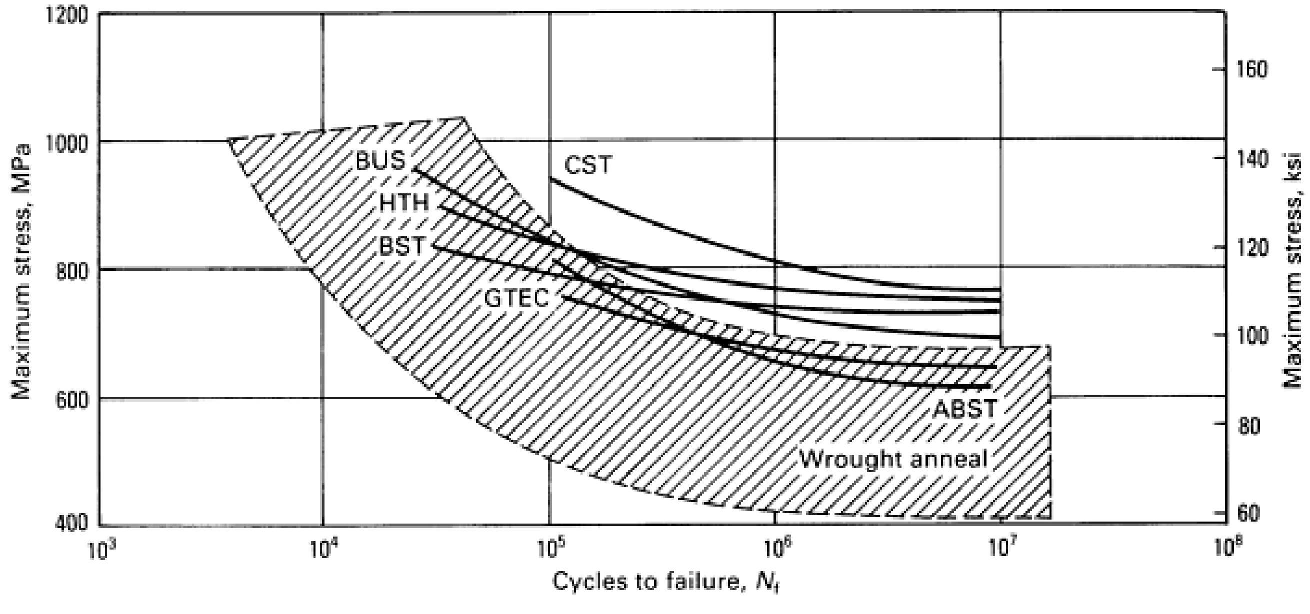

Fig. 9 Comparison of Ti-6Al-4V investment castings subjected to various thermal and hydrogen treatments. Smooth axial fatigue measured at room temperature. R = +0.1; frequency = 5 Hz using triangular wave form.

Casting Design

The best casting design is usually achieved by means of a thorough review by the manufacturer and user when the component is still in the preliminary design stage (see the article "Casting Design" in this Volume). Additional features may be incorporated to reduce machining cost, and components may be integrated to eliminate later fabrication. Specifications and tolerances may be reviewed vis-a-vis foundry capabilities, producibility, and pattern tool concepts to achieve the most practical and cost-effective design (see the articles "Dimensional Tolerances and Allowances" and "Patterns and Patternmaking" in this Volume). When minimum cast part weight is critical, such as in aerospace components, the capability of the foundry to produce varying wall thicknesses, for example, may be beneficial. Often, cast features that cannot be economically duplicated by any other method may be readily produced.

Titanium castings present the designer with few differences in design criteria, compared with other metals. Ideal designs do not contain isolated heavy sections or uniform heavy walls of large area so that centerline shrinkage cavities and regions with a coarse microstructure may be avoided. From a practical sense, however, ideal tapered walls to promote directional solidification are not usually a reality. The advent of hot isostatic pressing to heal internal as-cast shrinkage cavities has offered the designer much more freedom; however, there still is a practical limit to the size of internal cavity that can be healed through hot isostatic pressing without contributing significant surface or structural deformation due to the collapse of internal pores.

The lost wax investment process provides more design freedom for the foundry to properly feed a casting than does the traditional sand or rammed graphite approach. It is normal practice to add a gate and riser to hot isostatic pressed investment castings to achieve reasonably good internal x-ray quality so that hot isostatic pressing will not cause extensive surface or structural deformation.

The usual required minimum practical wall thickness for investment castings is 2.0 mm (0.080 in.); however, sections as small as 1.1 mm (0.045 in.) are routinely made. Even thinner walls may be achieved by chemical milling beyond that required for α case removal; however, as-cast wall variation is not improved and becomes a larger percentage of the resultant wall thickness. Sand or rammed graphite molded castings have a usual minimum wall thickness of 4.75 mm (0.187 in.), although 3.0 mm (0.12 in.) is not unreasonable for short sections.

Fillet radii should be as generous as possible to minimize the occurrence of hot tears. While 0.76 mm (0.030 in.) radii are produced, the preferred minimum is 3.0 mm (0.12 in.). A rule of thumb is that a fillet radius should be 0.5 times the sum of the thicknesses of the two adjoining walls.

With proper tool design, zero draft walls are possible. To promote directional solidification, a 3° included draft angle may be preferred. Hot isostatic pressing will close any centerline shrinkage cavities in zero draft walls, making it unnecessary to provide draft. Draft requirements are also dependent upon foundry practice, with rammed graphite tooling usually requiring draft, and investment casting typically not requiring draft.

Tolerances. Typically, the major area of concern is true position of a thin-section surface with respect to a datum. Surface areas of approximately 129 cm^2 (20 $in.^2$) or greater in sections of less than approximately 5.08 mm (0.200 in.) thickness are susceptible to distortion, depending on adjoining sections. The high strength of titanium compared with aluminum and low elastic modulus compared with steel present challenges in straightening and in maintaining extremely tight, true positions. General tolerance band capabilities for linear dimensions are shown in Table 7.

Table 7 General linear and diametrical tolerance guideline for titanium castings

Size		**Total tolerance band**[(a)]	
mm	**in.**	**Investment cast**	**Rammed graphite process**
25 to <102	1 to <4	0.76 mm (0.030 in.) or 1.0%, whichever is greater	1.52 mm (0.060 in.)
102 to <305	4 to <12	1.02 mm (0.040 in.) or 0.7%, whichever is greater	1.78 mm (0.070 in.) or 1.0%, whichever is greater
305 to <610	12 to <24	1.52 mm (0.060 in.) or 0.6%, whichever is greater	1.0%
≥610	≥24	0.5%	1.0%
Examples			
254 mm (10		1.78 mm (0.070 in.) total tolerance band or ±0.89 mm	2.54 mm (0.100 in.) total tolerance band or ±1.27

in.)		(±0.035 in.)	mm (±0.050 in.)
508 mm (20 in.)		3.05 mm (0.120 in.) total tolerance band or ± 1.52 mm (±0.060 in.)	5.08 mm (0.200 in.) total tolerance band or ±2.54 mm (±0.100 in.)

(a) Improved tolerances may be possible depending on the specific foundry capabilities and overall part-specific requirements.

Hot sizing fixtures have been increasingly used to help control critical casting dimensions. This technique typically involves the use of steel fixtures to "creep" the casting into final tolerances in an anneal or stress relief heat treatment by the weight of the steel or the use of differential thermal expansion of the steel relative to the titanium.

Standard casting industry thickness tolerances of ±0.76 mm (±0.030 in.) for rammed graphite and ±0.25 mm (±0.010 in.) for investment cast walls are more difficult to maintain with titanium primarily because of the influence of chemical milling. As mentioned earlier, for critical applications it is necessary to mill all surfaces chemically to remove the residue α case. This operation is subject to variation because of part geometry and bath variables, and because it is usually manually controlled. Standard industry surface finishes are shown in Table 8.

Table 8 Surface finish of titanium castings

Process	**NAS 823 surface comparator**	RMS equivalent	
		μm	μin.

Titanium and Titanium Alloys

Jeremy R. Newman, Titech International Inc.; Daniel Eylon, University of Dayton; John K. Thorne, Precision Castparts Corporation

Melting and Pouring Practice

Vacuum Consumable Electrode. The dominant, almost universal, method of melting titanium is with a consumable titanium electrode lowered into water-cooled copper crucibles while confined in a vacuum chamber. This skull melting (see the section "Vacuum Arc Skull Melting and Casting" in the article "Vacuum Melting and Remelting Processes" in this Volume) technique prevents the highly reactive liquid titanium from dissolving the crucible because it is contained in a solid "skull" frozen against the water-cooled crucible wall. When an adequate melt quantity has been obtained, the residual electrode is quickly retracted, and the crucible is tilted for pouring into the molds. A "skull" of solid titanium remains in the crucible for reuse in a subsequent pour or for later removal.

Superheating. The consumable electrode practice affords little opportunity for superheating the molten pool because of the cooling effect of the water-cooled crucible. Because of limited superheating, it is common either to pour castings centrifugally, forcing the metal into the mold cavity, or to pour statically into preheated molds to obtain adequate fluidity. Postcast cooling takes place in a vacuum or in an inert gas atmosphere until the molds can be safely removed to air without oxidation of the titanium.

Electrode Composition. Consumable titanium electrodes are either ingot metallurgy forged billet, consolidated revert wrought material, selected foundry returns, or a combination of all of these. Casting specifications or user requirements can dictate the composition of revert materials used in electrode construction. Figure 10 shows a typical centrifugal casting furnace arrangement.

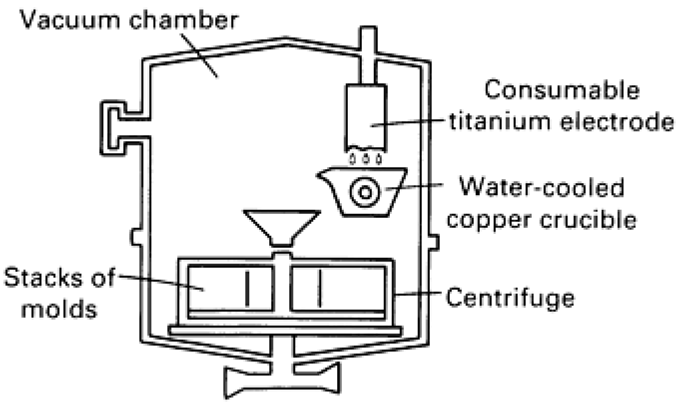

Fig. 10 A centrifugal vacuum casting furnace.

Chemical Milling

Residual surface contamination, or α case, is typically removed from as-cast parts before further processing. This is to eliminate the possibility of diffusion of these contaminants into the part during subsequent HIP or heat treatment. Chemical milling is normally conducted in solutions based on hydrofluoric and nitric acid mixtures plus additives designed to enhance surface finish and control hydrogen pickup. Hydrogen pickup is more likely the greater the β phase content of the alloy and is also influenced by etch rate and bath temperature. Subsequent vacuum anneals may be used to remove hydrogen picked up in chemical milling. The general objective is to remove the entire as-cast surface uniformly to the extent of maximum α case depth, and to retain the dimensional integrity of the part.

Hot Isostatic Pressing

Hot isostatic pressing may be used to ensure complete elimination of internal gas (D, in Fig. 2a) and shrinkage (E, in Fig. 2a) porosity. The cast part is chemically cleaned and typically subjected to argon pressure of 103 MPa (15 ksi) at 900 to 955 °C (1650 to 1750 °F) for a 2 h hold time (Ti-6Al-4V alloy) for void closure and diffusion bonding. This practice has been shown to reduce the scatterband of fatigue property test results and significantly improve fatigue life (Fig. 8). HIP temperature may coarsen the microstructure, causing a slight debit in tensile strength, but the benefits of HIP normally exceed this slight decrease in strength, and the practice is widely used for aerospace titanium alloy cast parts.

Weld Repair

Weld repair of titanium castings is a normal facet of the manufacturing process and is used to eliminate surface-related defects, such as HIP-induced surface depressions. Tungsten inert-gas (TIG) welding practice in argon-filled glove boxes is used with weld filler wire of the same composition as the parent metal. Generally, all weld-repaired castings are stress relief annealed. Excellent quality weld deposits are routinely obtained in proper practice. Weld deposits may have higher strength but lower ductility than the parent metal because of microstructural differences due to the fast cooling rate of the welding process. Those differences may be eliminated by a postweld solution heat treatment, but standard practice is for stress relief or anneal only.

Heat Treatment

Conventional heat treatment of titanium castings is for stress relief anneal after any weld repair. The Ti-6Al-4V alloy is typically heat treated at 730 to 845 °C (1350 to 1550 °F). This is done in a vacuum to ensure removal of any hydrogen pickup from chemical milling and to protect the titanium from oxidation. As with HIP, castings must be chemically clean prior to heat treatment if diffusion of surface contaminants is to be avoided. Alternate heat treatments for property improvement, such as solution-treating and aging of Ti-6Al-4V alloy castings, are available. Numerous other heat treatments are in various stages of development, as discussed in an earlier section (Table 5).

Final Evaluation and Certification

Titanium castings are produced to numerous quality specifications. Typically, these require some type of x-ray and dye penetrant inspection in addition to dimensional checks using layout equipment, dimensional inspection fixtures, and coordinate measuring machines. Metallurgical certifications may include HIP and heat treatment run certifications, and chemistry, tensile properties, and microstructural examination of representative coupons for absence of surface contamination.

In the absence of universally accepted x-ray standards, it is common practice to use steel or aluminum reference radiographs (Table 4). Because internal discontinuities in titanium do not necessarily appear the same as they do in other metals, it is necessary to have an expert evaluation of radiographs for proper interpretation. Currently, an industry task force is working on the development of radiographic standards for titanium castings through the American Society for Testing and Materials (ASTM).

Product Applications

The titanium castings industry is relatively young by most foundry standards. The earliest commercial applications, in the 1960s, were for use in corrosion-resistant service in pump and valve components. These applications continue to dominate the rammed graphite production method; however, in more recent years, some users have justified the expense of lost wax investment tooling for some commercial corrosion-resistant casting applications (see Fig. 11).

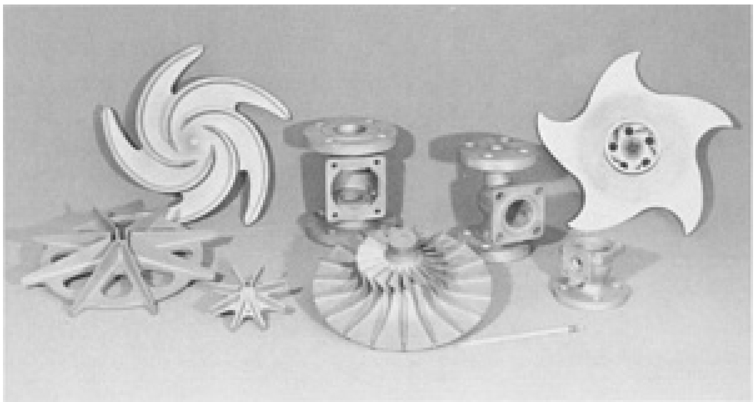

Fig. 11 Investment cast titanium components for use in corrosive environments.

Aerospace use of rammed-graphite-type castings became a production reality in the early 1970s for aircraft brake torque tubes, missile wings, and hot gas nozzles. As the more precise investment casting technology developed and the commercial use of HIP became a reality in the mid-1970s, titanium casting applications quickly expanded into critical airframe (Fig. 12) and gas turbine engine (Fig. 13) components. The first applications were primarily in Ti-6Al-4V, the workhorse alloy for wrought aerospace products, and castings were often substituted for forgings, with the addition of some net shape features; this trend continues. With continuing experience in manufacturing and specifying titanium castings, applications expanded from relatively simple less-critical components for military engines and airframes to large, complex structural shapes for both military and commercial engine and airframe programs. Today, titanium cast parts are routinely produced for critical structural applications such as space shuttle attachment fittings, complex airframe structures, engine mounts, compressor cases and frames of many types, missile bodies and wings, and hydraulic housings (Fig. 14). Quality and dimensional capabilities continue to be advanced. Titanium castings are used for framework for very sensitive optical equipment due to their stiffness and the compatibility of the coefficient of thermal expansion of titanium with that of glass (Fig. 15). Applications evolving for engine airfoil shapes (Fig. 16) include individual vanes and integral vane rings for stators, as well as a few rotating parts that would otherwise be made from wrought product. Growth will continue as users seek to take advantage of the flexibility of design inherent in the investment casting process and the improvement in economics of net and near-net shapes.

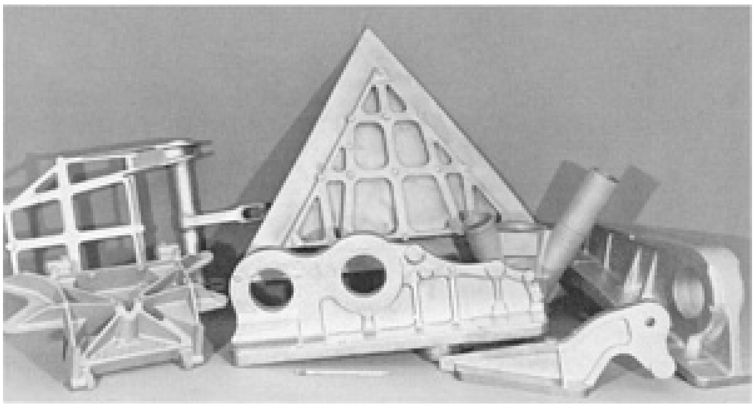

Fig. 12 Investment cast titanium airframe parts.

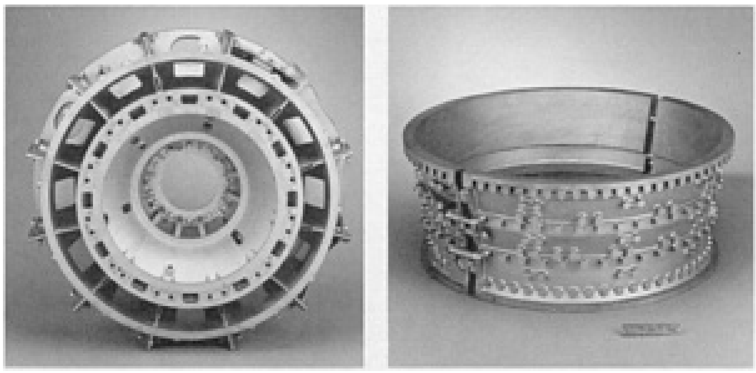

Fig. 13 Typical investment cast titanium components used for gas turbine applications.

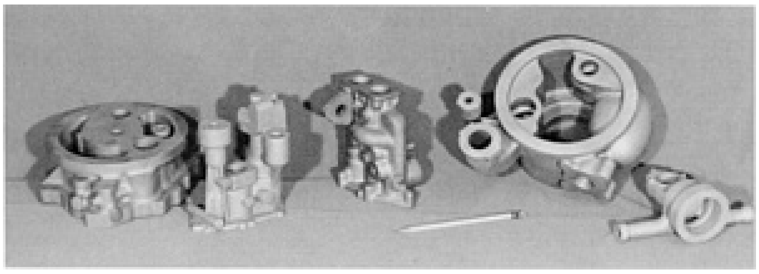

Fig. 14 Titanium hydraulic housings produced by the investment casting process.

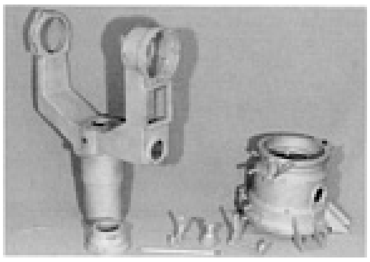

Fig. 15 Titanium housings for military optical applications produced by the investment casting process.

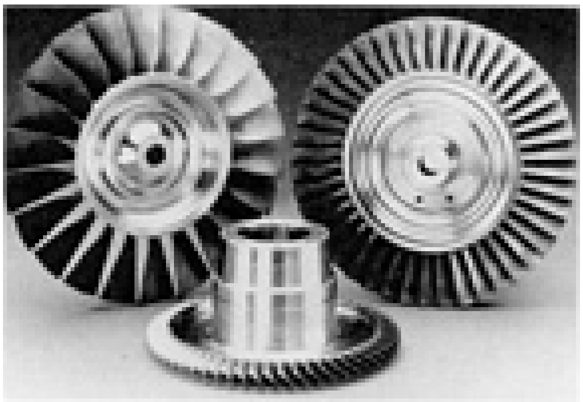

Fig. 16 Investment cast titanium engine airfoil components.

In spite of the wide acceptance of titanium castings for airframe applications, growth has been somewhat hindered because of the lack of an industry-wide data base to establish casting factors accurately, relative to wrought material. Such standards are now being established with probable elimination of design casting factors (Ref 58). Foundry size capabilities are expanding to allow the manufacture of larger airframe and static gas turbine engine structures. Widespread routine use of aerospace titanium castings is anticipated as the titanium foundry industry matches with well-established quality and product standards, and user understanding and confidence continue to be gained from satisfactory product performance.

Concurrent with the above trend, investment cast titanium is increasingly being specified for medical prostheses because of its inertness to body fluids, elastic modulus approaching that of bone, and the net shape design flexibility of the casting process. Custom-designed knee and hip implant components (Fig. 17) are routinely produced in volume. Some of these are subsequently coated with a diffusion bonded porous surface to facilitate bone ingrowth or an eventual fixation of the metal implant with the patient's bone structure.

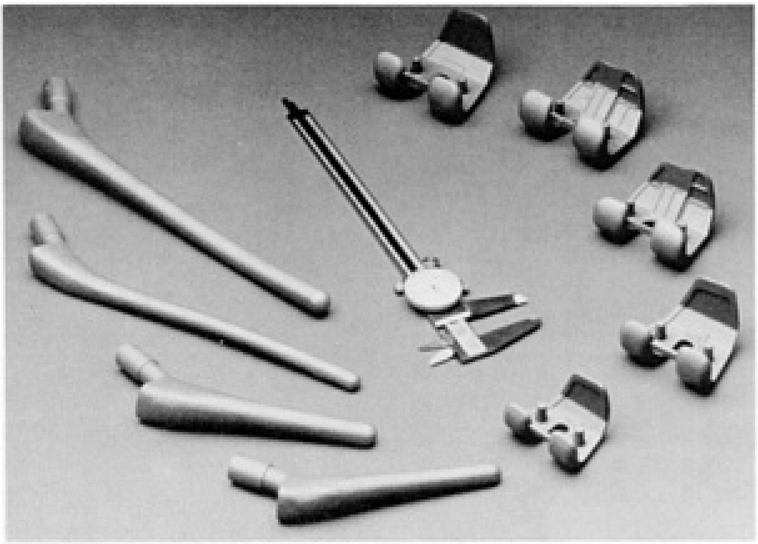

Fig. 17 Titanium knee and hip implant prostheses manufactured by the investment casting process.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Introduction

ZIRCONIUM casting technology was developed at the U.S. Bureau of Mines Albany Research Center in the mid-1950s (Ref 1, 2, 3). The program was sponsored by the Atomic Energy Commission to develop casting technology capable of producing simple shapes that could be substituted for more expensive machined parts in nuclear applications. These researchers were also engaged in the development of titanium casting technology. Because of the similarities between these reactive metals, the molding, melting and casting, and processing technologies produced were identical. These similarities continue today.

No commercial zirconium casting alloys have yet been developed. Existing wrought alloys have been used with allowances for higher interstitial (oxygen, nitrogen, and carbon) and trace element contaminants.

Although the initial usage of zirconium castings was in nuclear applications, zirconium castings are currently used exclusively in the chemical processing industry, where their corrosion properties are utilized. The typical shapes produced are shown in Fig. 1. This article will focus on foundry practices, such as fabricating patterns and molds, as well as the melting, welding, and hot isostatic pressing techniques utilized to produce zirconium and zirconium alloy castings.

Patterns

A variety of patterns can be used to produce molds for the casting of zirconium. The molding system will determine the usable pattern type. With rammed graphite systems, match plate patterns, cope and drag patterns, core boxes, and loose patterns can be utilized, with the same pattern being used to produce zirconium, titanium, and other alloys. Wax patterns are used with refractory/ceramic shell molds. Permanent molds are compatible with zirconium casting, but they are not in use at this time. Shell molds are produced with gates and risers as integral components of the mold. Graphite molds are rammed without gates and risers. The gates and risers are cut in when the molds are assembled. Compared to other reactive metals, zirconium has very poor fluidity. Many large gates must be provided when gating a mold.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Molds

As with other reactive metals, zirconium must be handled very carefully when in the molten state. It will react with all conventional molding media. The extent of the mold-metal reaction depends on several factors:

- Size and configuration of the casting
- Mass of the casting
- Mold media
- Surface roughness of the mold

The first commercial zirconium casting utilized a machined graphite mold with a rammed graphite core.

Sand Systems. Although machined graphite is still used for base plates and spacers, most castings utilize a granular graphite sand with a hydrocarbon binder consisting of corn syrup, starch, and powdered pitch. The molds are rammed up by hand and allowed to set for several hours to develop an acceptable green strength. The mold is dried at 200 °C (390 °F) to remove moisture and then fired at 900 °C (1650 °F), under a reducing atmosphere, to carburize the binder constituents. Typical mold shrinkage is 16 to 26 mm/m ($\frac{3}{16}$ to $\frac{5}{16}$ in./ft). Care must be taken to provide a smooth surface for the mold/molten metal interface. Rough-surfaced molds will allow greater reaction between the mold and the metal. Graphite, however, has a good chilling effect on molten zirconium, and in general only internal core areas are susceptible to metal-mold reactions.

The typical reaction surface is 0.000 to 0.13 mm (0.000 to 0.005 in.) thick, but large masses of metal will be prone to greater metal-mold reaction. After casting, the graphite mold is physically broken off from the casting and recycled, with only minimal losses from fines generated in the regrinding. Cast zirconium is not a forging material, and care must be used when removing mold and core. One misplaced hammer blow can ruin a casting. Castings with thicknesses as great as 127 mm (5 in.) have been produced commercially with the rammed graphite mold system.

Two other sand systems have been identified as having potential use as mold media for zirconium (Ref 4, 5). The first is zircon sand/waterglass utilizing zirconium silicate sand and sodium silicate as the binder. The advantage of this system is reduced shrinkage of the mold to provide a more precise casting and a no-fire binder (200 °C, or 390 °F, cure), which would eliminate the multiple-stage firing process needed for graphite. This mold system requires a zirconia mold wash to protect the molten metal from reaction with the sand. Castings of a commercial size (23 kg, or 50 lb) were poured in 1979 with moderate success. The casting surface was rougher than with graphite molds, and the cores showed higher metal reaction. The second system, an olivine sand/bentonite binder, also requires the use of a zirconia mold wash to minimize the mold-metal reaction. No commercial-size castings have been produced with this system.

Shell Molds. For investment castings, shell molds are produced from wax patterns dipped in slurried ceramic, and a suitably strong shell is manufactured by repeated buildup of refractory layers. Upon curing of the molds, the wax is melted out and the shell is ready for pouring. Although shell mold systems are proprietary and may vary from foundry to foundry, zirconium is being successfully cast into shells produced from zirconia inner layers and aluminum silicate outer layers. Casting thicknesses as great as 25 mm (1 in.) have been successfully poured. Exact mold reaction layers have not been determined, but because zirconium is more reactive in the molten state than titanium, it is anticipated that the reaction layer of investment cast zirconium will be at least equal to that experienced in titanium.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Melting

Zirconium casting utilizes two melting methods: vacuum arc skull melting and vacuum induction melting. Both furnace systems are capable of melting all reactive alloys.

Vacuum arc skull melting furnaces use consumable electrodes melting into water-cooled copper crucibles. When sufficient metal has been melted, the crucible is tipped and the metal is poured into the mold positioned below. Skull

melting furnaces are capable of using all types of mold systems and are limited only by the weight of the melted metal and the size constraint of the furnace. Zirconium melts of 955 kg (2100 lb) have been poured, yielding finished castings as large as 635 kg (1400 lb).

Castings can be produced with the receiving molds in a static mode as well as by centrifugal casting. Centrifugal casting is accomplished by mounting the molds on a turntable. This setup utilizes a center sprue with a runner system to feed from the outside of the mold in. The mold is filled against the centrifugal forces, allowing a slower fill rate and reducing the potential for entrapped gases in the casting. There are limitations for centrifugal casting in a vacuum arc skull melt furnace. The pour must have a balanced setup, that is, molds equally spaced around the center sprue. The mold media and mold design must be strong enough to support the forces exerted on the setup by the molten metal.

Vacuum induction melting (VIM) is used to produce small casting pours. The current furnace design utilizes a split copper crucible with a melting capacity of approximately 27 kg (60 lb). The advantage of a VIM system is the ability to pour small single casting pours with minimal skull losses. As with skull melting, VIM furnaces have the capacity to use all types of molding systems (Ref 6).

Processing

After knockout, gates and risers are removed by abrasive cutoff or by oxyacetylene torch. If torch cutting is used, the slag area and subslag-contaminated material must be removed by grinding.

All metal surfaces in contact with the mold will have a contaminated layer. For graphite systems, it is a carbon-stabilized layer; for refractory systems, oxygen stabilized. Depending on the application, this hard, brittle layer should be removed from the surface because it may be a source of contaminants during any subsequent weld repair and it may adversely affect the mechanical properties of the casting. In some applications, corrosion resistance may be affected.

Abrasive grit or shotblasting can be used to remove most of this contaminated layer.

Chemical Milling. For internal surfaces or blind areas, chemical milling is more efficient than abrasive grit or shotblasting and is the preferred method. Chemical milling solutions are of the following general chemical composition: 25 to 50% nitric acid, 3 to 10% hydrofluoric acid, and the remainder water. Temperature for the solution should be kept below 55 °C (130 °F) to minimize hydrogen pickup.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Weld Repair of Casting Defects

Casting Defects. As-cast zirconium typically has three types of casting defects: gas hole porosity, cold shuts (or surface laps), and shrinkage cavities.

Gas hole porosity is generated from the metal-mold reaction and the evolution of gases from the mold. This type of defect can be minimized by proper firing of the mold, but certain portions of a casting may still contain these small spherical voids.

Cold Shunts. Because of the high melting point of zirconium (1850 °C, or 3360 °F) and the chilling effect the mold media has on the metal, zirconium will exhibit more cold shunts than titanium or other castings. However, these defects are surface phenomena only and, depending on application, may be left in with no detrimental effect.

Shrinkage Cavities. Zirconium has less fluidity than titanium, which is the only material to compare zirconium to for melting parameters and mold material. This low fluidity will result in shrinkage cavities forming in areas of a casting where flow conditions are upset. Therefore, zirconium requires larger or greater numbers of metal distribution gates to provide castings with minimum shrinkage.

Weld Repair. It is probable that all castings will have some shrinkage, and unless a given casting is designed for use with shrinkage, it will be necessary to remove the voids. Suitable excavation and weld repair then become necessary steps in the production of zirconium castings. Weld repair is performed using gas tungsten arc welding. Welding can be done on a bench setup with sufficient inert-gas protection, but for production it is best to perform the weld repair in a weld chamber. Zirconium is extremely reactive to atmospheric gases, and if contaminated, the weld will be embrittled, will possess adverse mechanical properties, and will perhaps exhibit reduced corrosion resistance.

Preparation of the weld area is necessary for sound welds. The area must be cleaned of any residual grease or oil. The filler rod should also be degreased before use. For repair of internal defects, the defect is exposed, usually by drilling or machining. This should be done without lubricants or coolants in order to minimize contamination of the weld area; the surrounding area must be cleaned after the machining operation. The cavity itself need not be cleaned. After placing the casting in the weld chamber, either a vacuum pumpdown followed by backfilling with inert gas or a flow-through purge of inert gas is required to protect the metal during welding. It is also advisable to getter the weld chamber by striking an arc on a sacrificial plate or piece of scrap before working on the part. The getter pool should be held until the resultant weld bead is bright with no sign of discoloration. Filler metal should be of the same nominal composition as the casting.

Postweld stress relieving, if necessary, will be carried out in the 535 to 595 °C (1000 to 1100 °F) temperature range. Some specific applications, such as high sulfuric acid concentrations, may require a 745 °C (1375 °F) stress-relief temperature for optimum corrosion resistance properties.

John P. Laughlin, Oregon Metallurgical Corporation

Hot Isostatic Pressing

Hot isostatic pressing (HIP) has been used as an alternative to weld repair for improving internal integrity. A HIP schedule has been developed for zirconium; zirconium has been included in the same HIP load with titanium, and acceptable results have been obtained. Castings should be x-rayed before hot isostatic pressing to evaluate the location of shrink voids for possible distortion or warpage.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Machining

Cast zirconium has machining characteristics similar to those of the wrought product. As with any zirconium machining, care should be taken in the handling and storage of turnings and dust because of their pyrophoric nature.

Zirconium and Zirconium Alloys

John P. Laughlin, Oregon Metallurgical Corporation

Structure and Properties

All zirconium initially solidifies into a body-centered cubic structure and then, upon further cooling, transforms into a hexagonal close-packed Widmanstätten α phase (Fig. 2). Cast zirconium alloys are equal in strength to wrought alloys of the same composition. Ductilities, however, are below typical values for comparable wrought alloys. Table 1 lists the minimum room-temperature tensile properties of cast zirconium alloys (Ref 7). Table 2 lists typical room-temperature tensile properties for commercially pure zirconium (grade 702). There are no data for the typical properties for Alloys 704 and 705. Figure 3 shows typical elevated-temperature tensile properties for cast Alloy 702. Impact strength is not a property that is normally tested for. However, cast zirconium has been tested infrequently for Charpy V-notch impact strengths with average values of 9.5 J (7 ft · lbf) with a range of 5.4 to 15 J (4 to 11 ft · lbf). Wrought Alloy 702 tested in the longitudinal direction produces a typical Charpy value of 35 J (26 ft · lbf) (Ref 8).

Table 1 Minimum room-temperature properties of cast zirconium alloys

Cast Metal-Matrix Composites

Pradeep Rohatgi, The University of Wisconsin--Milwaukee

Introduction

METAL-MATRIX COMPOSITES (MMCs) are engineered combinations of two or more materials (one of which is a metal) in which tailored properties are achieved by systematic combinations of different constituents. Conventional monolithic materials have limitations in terms of achievable combinations of strength, stiffness, coefficient of expansion, and density. Engineered MMCs consisting of continuous or discontinuous fibers (designated by an f), whiskers (w), or particles in a metal result in combinations of very high specific strength and specific modulus (Table 1). Furthermore, systematic design and synthesis procedures can be developed to achieve unique combinations of engineering properties, such as high elevated-temperature strengths, fatigue strength, damping properties, electrical conductivity, thermal conductivity, and coefficient of thermal expansion. In a broader sense, several cast materials with two-phase microstructures in which the volume and shape of the phases are governed by phase diagrams (that is, cast iron and aluminum-silicon alloys) have long been produced in foundries. Modern cast MMCs differ from these older materials in that any selected volume, shape, and size of reinforcement can be introduced into the matrix (Table 2); these tailored materials represent a new product opportunity for foundrymen.

A variety of methods for producing MMCs, including foundry techniques, have recently become available. The potential advantage of preparing these composite materials by foundry techniques is near-net shape fabrication in a simple and cost-effective manner. In addition, foundry processes lend themselves to the manufacture of large numbers of complexly shaped components at high production rates, which is required by automotive and other consumer-oriented industries.

Structurally, cast MMCs consist of continuous or discontinuous fibers, whiskers, or particles in an alloy matrix that solidifies in the restricted spaces between the reinforcing phase to form the bulk of the matrix. By carefully controlling the relative amounts and distributions of the ingredients constituting a composite and by controlling the solidification conditions, MMCs can be imparted a tailored set of useful engineering properties that cannot be realized with conventional monolithic materials. In addition, the solidification microstructure of the matrix is refined and modified because of the fibers and particles, indicating the possibility of controlling microsegregation, macrosegregation, and grain size in the matrix. This represents an opportunity to develop new matrix alloys.

From the standpoint of property-performance relationships and from the viewpoint of ease of processing and manufacturing, the interface between the matrix and the reinforcing phase (fiber or particle) is of central importance. Improvements in wetting between the matrix and the reinforcing phase in MMCs are an important goal of surface engineering. Other interrelated goals of surface engineering are control of fracture path (toughness), protection of filaments, and their role as nucleation catalysts to control the matrix microstructure. The solidification processing of MMCs in a foundry allows tailoring of the interface between the matrix and the fiber in order to suit specific property-

performance requirements. The cost of producing cast MMCs has decreased rapidly, especially with the use of low cost particulate reinforcements such as graphite and silicon carbide. Low cost composites such as metal-silicon carbide (SiC) particle and metal-graphite particle are commercially available.

Cast Metal-Matrix Composites

Pradeep Rohatgi, The University of Wisconsin--Milwaukee

Fiber-Metal Wettability and Its Effect on Casting Quality

Cast MMCs are made by introducing fibers or particles into molten or partially solidified metals, followed by casting of these slurries in molds. Alternatively, a preform of fibers or a prepacked bed of particles is made and infiltrated by molten alloys, which then freeze in the interfiber spaces to form the composite. In both these processes, mixing and wetting between molten alloys and dispersoids are desirable in terms of ease of fabrication and ultimate distribution of particulates and fibers (Ref 1, 2).

Graphite/magnesium, graphite/aluminum, and several other fiber-reinforced metals are valuable structural materials because they combine high specific strength and stiffness with a near-zero coefficient of thermal expansion and high electrical and thermal conductivities. The primary difficulty in fabricating these fiber-reinforced metals is poor wetting and bonding between fibers and metals (Ref 3). However, compatibility and bonding between the fiber and the metal in these systems are induced by the chemical vapor deposition of a thin layer of titanium and boron onto the fibers to achieve wetting. These coated fibers are air-unstable because the titanium-boron coating is rapidly oxidized when exposed to air and because molten metal does not wet the fiber. To circumvent this difficulty, air-stable coatings of silicon dioxide that are wetted by magnesium have been used for graphite fibers (Ref 4).

These coatings are deposited on the fiber surfaces using silicon-base organometallic compounds. The fibers are simply passed through the organometallic solution, which is then chemically converted by either hydrolysis or pyrolysis to form the silicon dioxide coating. The flexible coated fibers can then be wound or laid-up and held in place with a removable binder for selective reinforcement. They are then incorporated into magnesium near-net shape structures by the pressure infiltration of magnesium. Complex structural components with high volume fractions of carbon fibers can be fabricated in this manner in a foundry. High-strength high stiffness 100% polycrystalline α-alumina (Al_2O_3)/magnesium composites containing up to 70 vol% Al_2O_3 have been prepared by a pressure infiltration process (described later in this article).

For nonwetting metals, the α-Al_2O_3 is coated with the metal by vapor deposition or by electroless plating before infiltration. Titanium-boron coatings have also been used for graphite/aluminum, Al_2O_3/aluminum, and Al_2O_3/lead MMCs (Ref 5). However, in terms of ease of fabrication and cost, modification of the matrix alloy by the addition of small amounts of reactive elements such as magnesium, calcium, lithium, or sodium is preferred. Alumina-reinforced aluminum, copper, lead, and zinc composites, as well as several particle-filled MMCs, have been synthesized by using

reactive agents (Ref 1, 6). Careful control of reactions at the fiber/metal interface is required for improving the wettability and bonding between the two, without causing excessive degradation of the fiber surface. The formation of brittle intermetallic compounds at the interface (for example, carbides in graphite/aluminum and silicon carbide/aluminum composites) during processing can cause degradation of fibers and loss of strength in the longitudinal direction (Ref 7, 8).

Improved wettability and bonding at the interface can be achieved in some systems by a chemical reaction that forms spinels or oxides isostructural with spinels ($MgAl_2O_4$). Spinel promotes bonding at the interface because it forms strong bonds with metals and ceramics. The thickness and uniformity of the interfacial reaction layer (Fig. 1) can be controlled by optimizing melt temperature, residence time of particles or fibers in the melt (Fig. 2), and the degree of melt agitation (Ref 9). Continuous adherent metallic coatings (for example, copper and nickel) on several nonwetting particles such as graphite, shell char, and mica improve the melt-particle wettability and allow high percentages of these particles to be recovered in the solidified castings (Ref 10, 11).

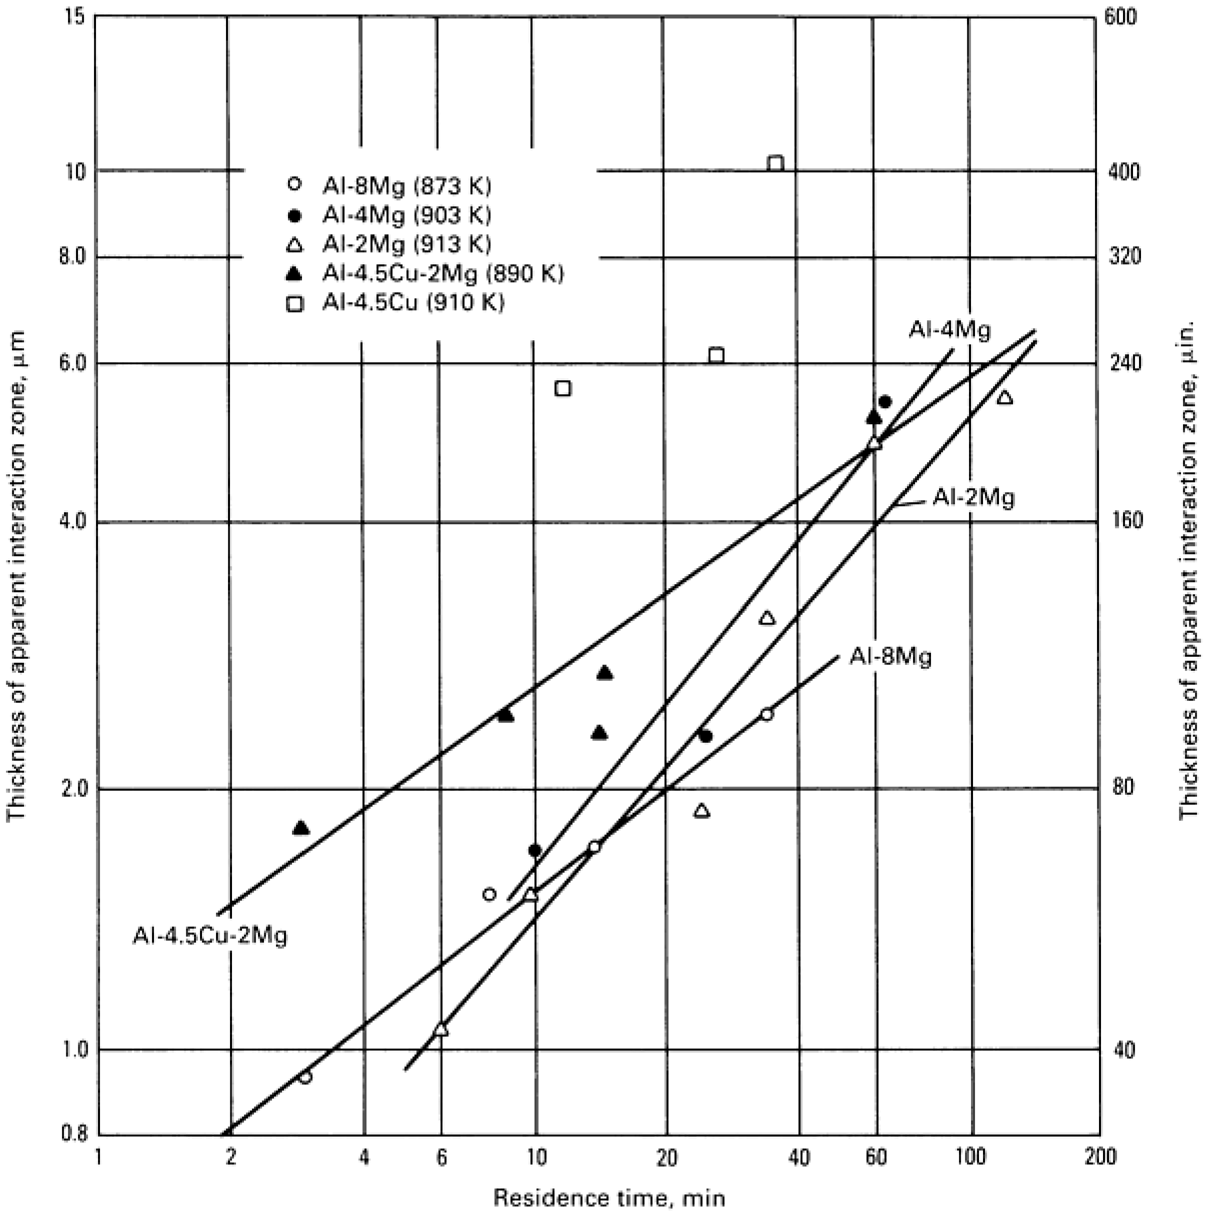

Fig. 2 Average thickness of apparent interaction zone as a function of residence time of Al_2O_3 fibers in various aluminum alloy slurries.

The wetting properties of ceramics by liquid metals are governed by a number of variables, including heat of formation, stoichiometry, valence electron concentration in the ceramic phase, interfacial chemical reactions, temperature, and contact time (Ref 12). The work of adhesion between a ceramic and a melt decreases with increasing heat of formation of carbides. The high energy of formation of a stable carbide implies strong interatomic bonds and correspondingly weak interaction with melts. This leads to a high interfacial energy and a small work of immersion, resulting in poor wetting. The wetting angles of copper and the carbides of group IVA metals (titanium and zirconium) decrease with increasing carbon content, indicating the influence of stoichiometry on the surface energies that govern wetting behavior.

High valence electron concentration generally implies lower stability of carbides and improved wettability between ceramics and metals. High temperature and long contact times promote melt-ceramic wettability due to reactions at the melt/ceramic interface, resulting in reduced contact angle. Figure 3 shows the dependence of contact angle on temperature in the Al_2O_3/aluminum and carbon/aluminum systems.

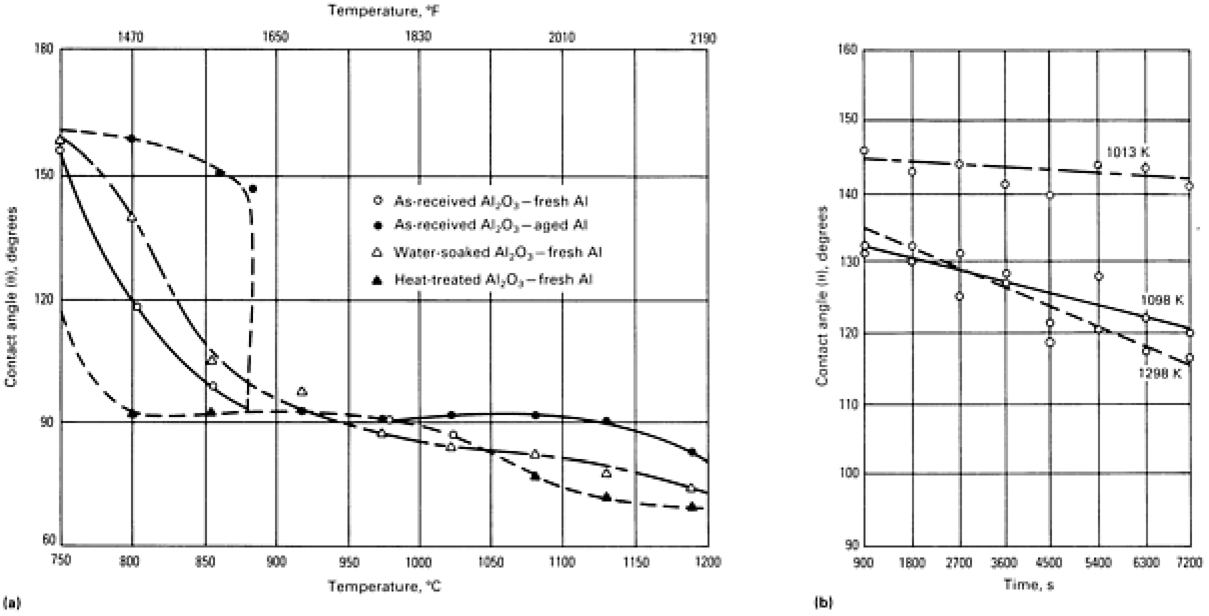

Fig. 3 Contact angle (a) in Al_2O_3/Al composite as a function of temperature. (b) Contact angle in aluminum/graphite composite as a function of time.

Therefore, although MMCs are not restricted by phase diagram considerations (fixed proportions, chemistry, and morphology of solidifying phases), thermodynamic free energy and kinetic barriers still exist in their processing in the form of poor wettability and rates of mixing, and they must be addressed in the production of these composites (Ref 1, 2).

Cast Metal-Matrix Composites

Pradeep Rohatgi, The University of Wisconsin--Milwaukee

Casting Techniques

A basic requirement of the foundry processing of MMCs is the initial intimate contact and the intimate bonding between the ceramic phase and the molten alloy. This is achieved either by mixing the ceramic dispersoids into molten alloys or by pressure infiltration of molten alloys into preforms of the ceramic phase. As mentioned earlier, because of the poor wettability of most ceramics by molten metals, intimate contact between fiber and alloy can be promoted only by artificially inducing wettability or by using external forces to overcome the thermodynamic surface energy barrier and viscous drag. Mixing techniques generally used for introducing and homogeneously dispersing a discontinuous phase in a melt are:

- Addition of particles to a vigorously agitated fully or partially molten alloy (Ref 13, 14, 15, 16). Figure 4 shows a schematic of an agitation vessel
- Injection of discontinuous phase into the melt with an injection gun (Ref 17)
- Dispersion of pellets or briquettes, formed by compressing powders of base alloys and the ceramic phase, into a mildly agitated melt (Ref 18)
- Addition of powders to an ultrasonically irradiated melt. The pressure gradients caused by cavitation phenomena promote homogeneous mixing of ceramics in metallic melts
- Addition of powders to an electromagnetically stirred melt. The turbulent flow caused by electromagnetic stirring is used to obtain a uniform suspension
- Centrifugal dispersion of particles in a melt. This technique has been used for carbon microballoons

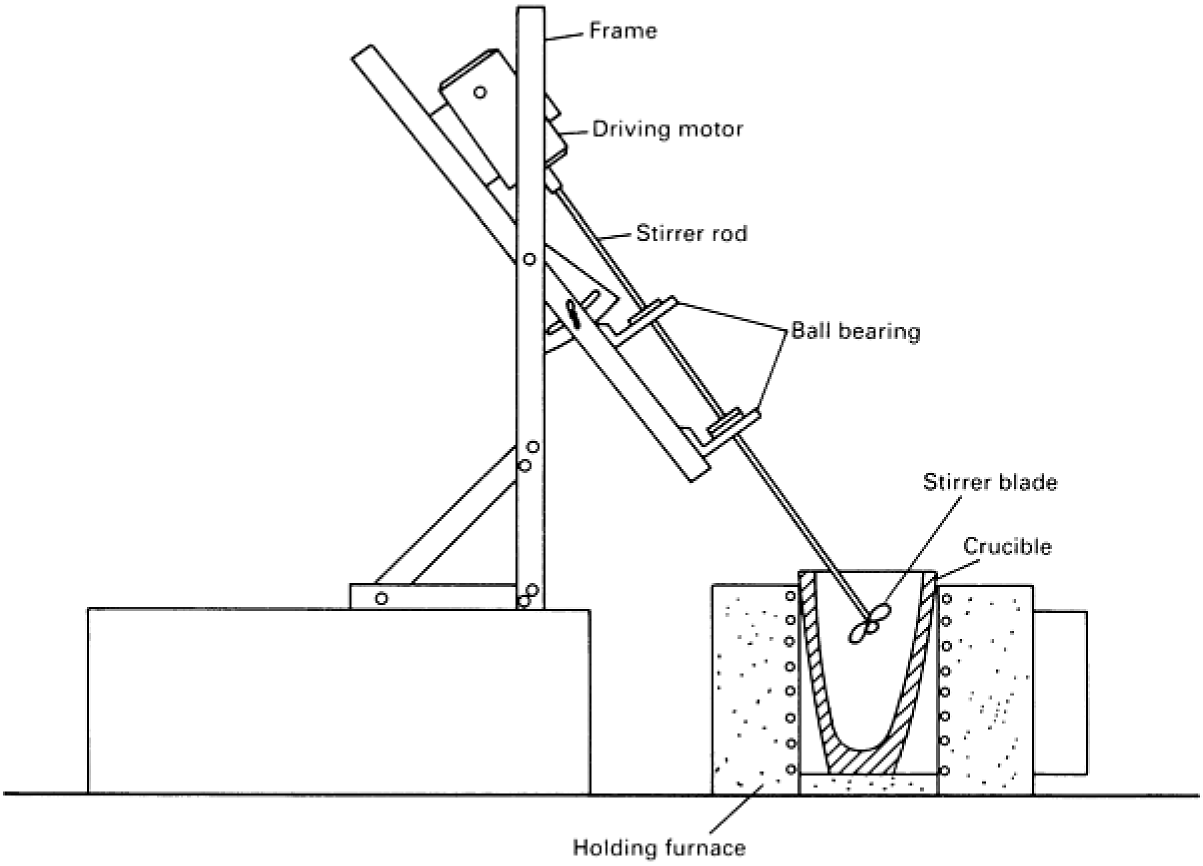

Fig. 4 Schematic showing the mechanical stirring device used in the vortex technique of dispersing particles in melts.

In all the above techniques, external force is used to transfer a nonwettable ceramic phase into a melt and to create a homogeneous suspension of the ceramic in the melt. The uniformity of particle dispersion in a melt before solidification is controlled by the dynamics of particle movement in agitated vessels. Because of the inherent complexity of dispersion, it is difficult to optimize the initial processing conditions to achieve a specific particle distribution in the cast matrix. Visual observations on transparent models of agitated melt-particle systems have been found to provide useful guidelines for systematic design of processing schedules.

The melt-particle slurry can be cast either by conventional foundry techniques, such as gravity, pressure die, or centrifugal casting, or by novel techniques such as squeeze casting (liquid-forging), spray codeposition, melt spinning, or laser melt-particle injection. The choice of casting technique and mold configuration is of central importance to the quality (soundness, particle distribution) of a composite casting because the suspended particles experience buoyancy-driven movement in the solidifying melt until they are encapsulated in the solidifying structure by crystallizing phases. Particles such as graphite, mica, talc, porous alumina, and hollow microballoons are lighter than most aluminum alloys and tend to segregate near the top portion of gravity castings, leaving behind a particle-impoverished region near the bottom of the casting. Similarly, heavier particles such as zircon, glass, SiC, SiO_2, TiO_2, and ZrO_2 tend to settle and segregate near the bottom portion of the gravity castings (Ref 1).

The spatial arrangement of the discontinuous ceramic phase in the cast structure principally determines the properties of the cast composite. The distribution of phases depends on the quality of melt-particle slurry prior to casting and the following additional variables:

- Cooling rate
- Viscosity of the solidifying melt
- Shape, size, and volume fraction of particles
- Particle and melt specific gravities

- Thermal properties of particles and matrix alloy
- Chemistry and morphology of crystallizing phases and their interactions with particles, nucleation of primary phases on ceramics, entrapment or pushing of particles by solidifying interfaces
- The flocculation (clustering) of particles
- The presence of any external forces during solidification

The various techniques used to solidify melt-particle slurries are discussed below.

Sand Casting. The slow solidification rates obtained in insulating sand molds permit considerable buoyancy-driven segregation of particles. Depending on the intrinsic hardness of the dispersed particles, high particle volume fraction surfaces can serve as selectively reinforced surfaces--for example, tailor-made lubricating or abrasion-resistant contacting surfaces for various tribological applications. Thin sections of sand cast composites or the codispersion of ceramic particles and a suitable micro-chill powder (normally the same as base alloy) reduce particle segregation in specific areas by decreasing solidification time.

Die Casting. The relatively rapid solidification rates in metallic molds generally give rise to a more homogeneous distribution of particles in the cast matrix (Ref 1, 19). Figure 5 shows microstructures of the permanent mold gravity die casting of aluminum alloys containing dispersions of graphite, zircon, and talc particles. Figure 6 shows frequency distributions of interparticle spacing and particle size in a gravity die cast graphite/aluminum MMC. These measurements were made across three different sections of the composite ingot (top, middle, and bottom) for two pourings during a batch process. The computed mean particle size and spacing are very close to the corresponding value for maximum frequency, indicating in statistical terms an absence of appreciable clustering or segregation of particles in the permanent mold casting of particle composites (Ref 20). Further improvements in particle distribution can be achieved by using water-cooled molds, copper chills, and other agitation techniques.

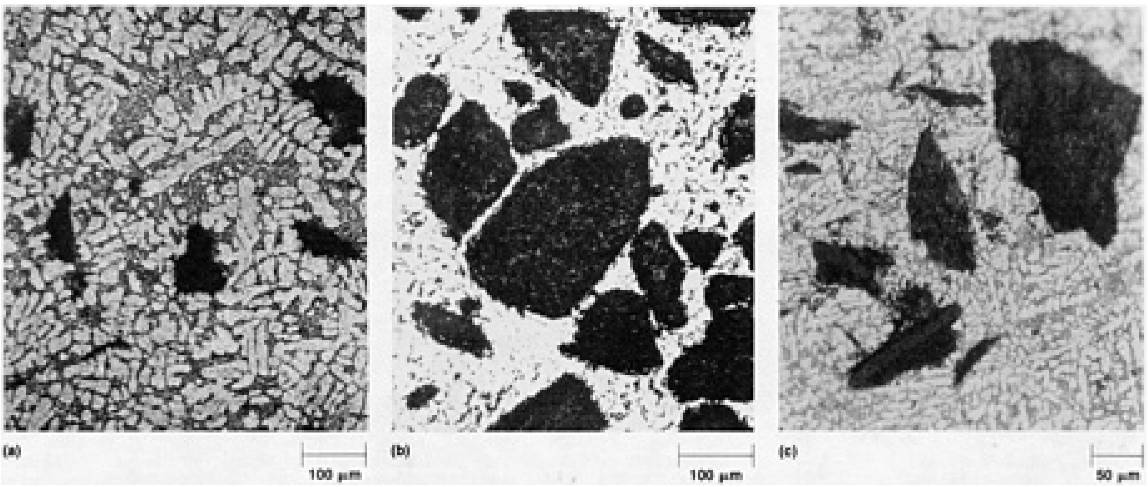

Fig. 5 Micrographs showing the uniform particle distribution obtained in the permanent mold casting of MMCs. (a) Graphite particles in aluminum-silicon alloy matrix. (b) Zircon particles in aluminum-silicon alloy matrix. (c) Talc in aluminum-silicon alloy matrix.

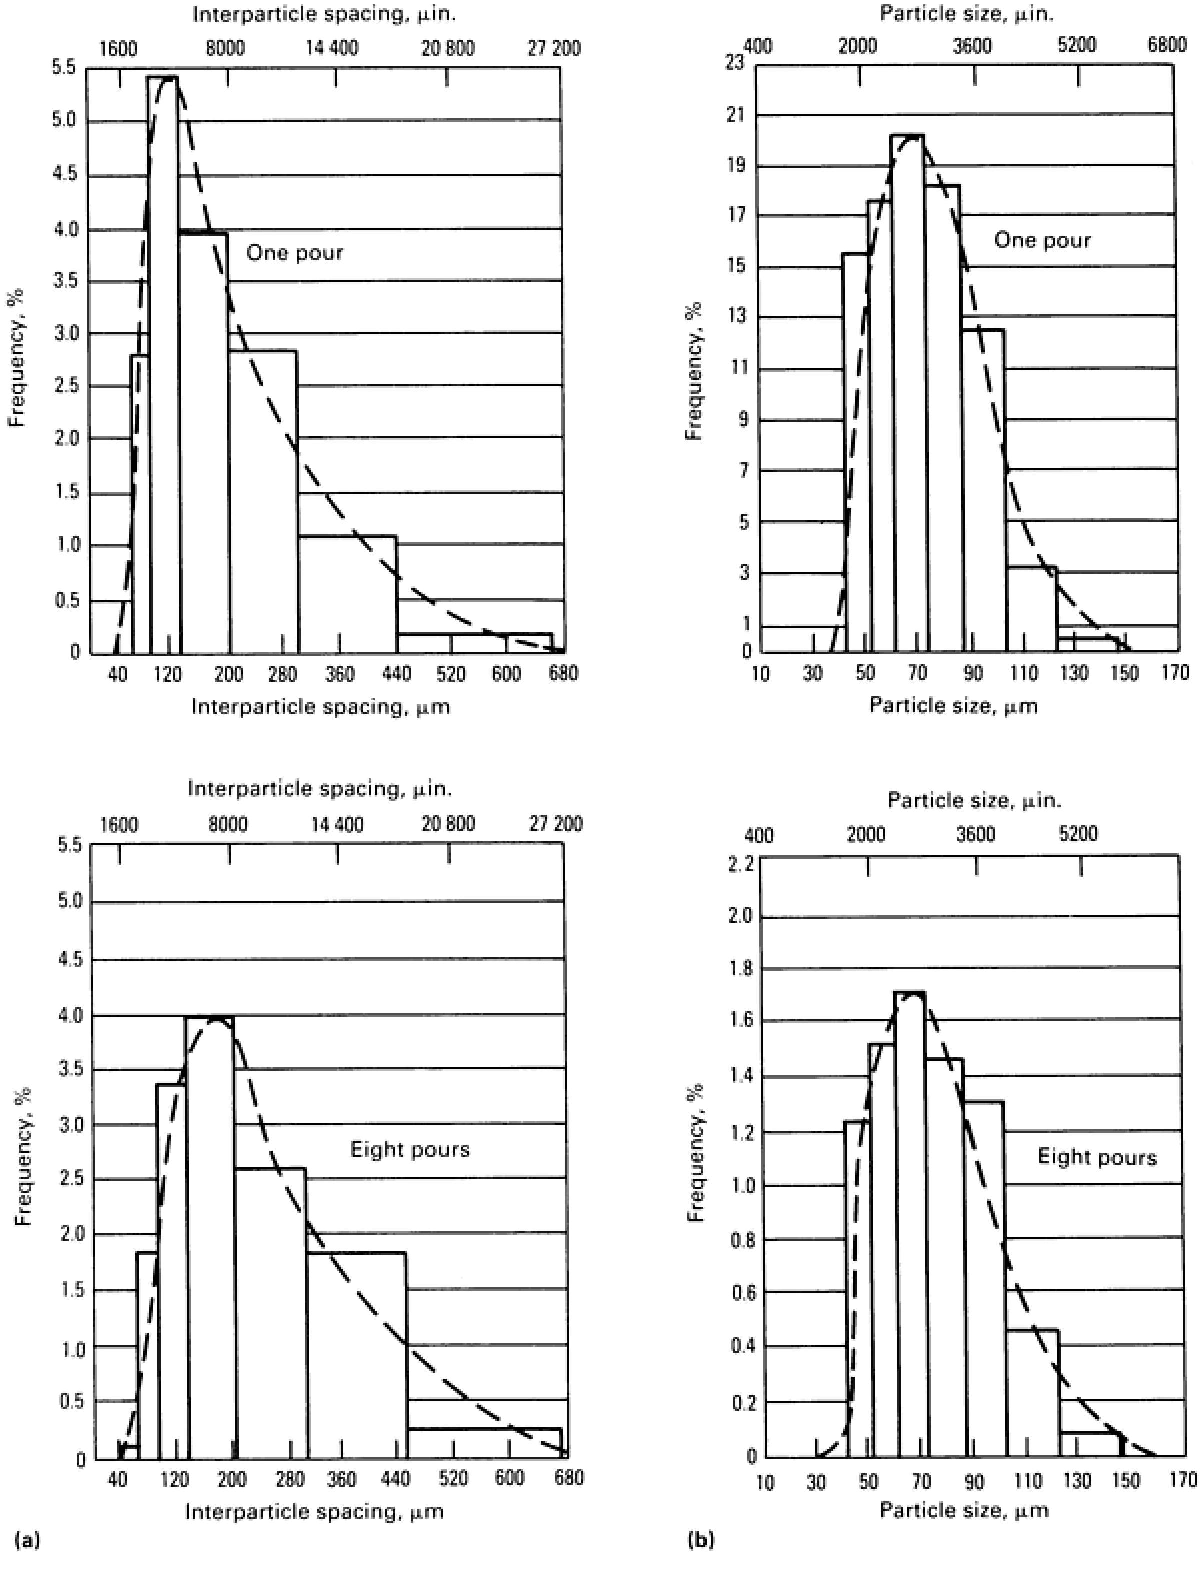

Fig. 6 Histograms showing graphite particle spacing and size distribution in aluminum alloy/graphite composites made in permanent molds after one and eight pours in the same mold. (a) Particle spacing. (b) Particle size distribution.

Centrifugal casting of composite melts containing particle dispersions results in the formation of two distinct zones in the solidified material: a particle-rich zone and a particle-impoverished zone. If the particles are lighter than the melt (for example, graphite, mica, or carbon microballoons in aluminum), the particle-rich zone forms at the inner circumference. The outer zone is particle rich if the particles are denser than the melt (for example, zircon or silicon carbide in aluminum).

Centrifugal acceleration in the rotating mold causes the lighter graphite, mica, or carbon to segregate near the axis of rotation, producing high particle volume fraction surfaces for bearing applications. The thickness of these particle-rich zones decreases with increasing pouring temperature and speed of rotation, but remains adequate for machining. Up to 8% by weight mica and graphite and up to 30% by weight zircon particles can be incorporated into selected zones of an aluminum alloy by this technique. Figure 7 shows sections of typical centrifugal castings of aluminum/zircon (Fig. 7a) and aluminum/graphite (Fig. 7b) composites. In Fig. 7(a), the heavier zircon segregates near the outer circumference, producing hard, abrasion-resistant surfaces; in Fig. 7(b), the lighter graphite concentrates near the inner periphery, producing wear-resistant, solid-lubricated surfaces for such antifriction applications as bearings or cylinder liners.

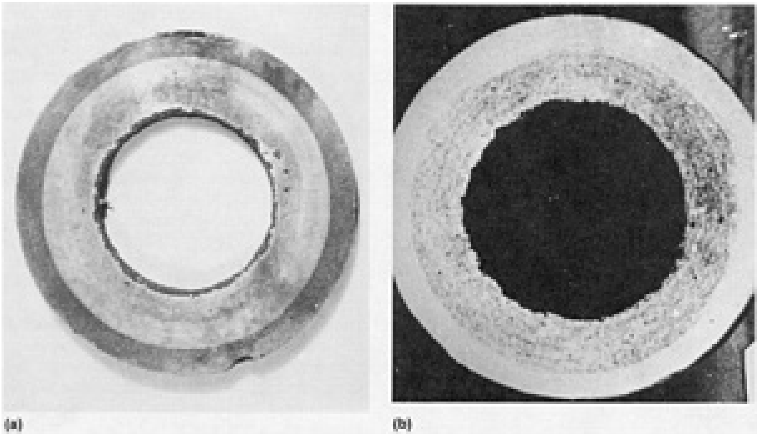

Fig. 7 Centrifugally cast MMCs showing segregation of particles caused by centrifugal force. (a) Aluminum/zircon composite with zircon particles segregated at outer periphery. (b) Aluminum/graphite particle composite with segregation of graphite particles at inner rim.

Compocasting. Particles and discontinuous fibers of SiC, Al_2O_3, TiC, silicon nitride, graphite, mica, glass, slag, MgO, and boron carbide have been incorporated into vigorously agitated, partially solidified aluminum alloy slurries by the compocasting technique (Ref 1, 9). The discontinuous ceramic phase is mechanically entrapped between the proeutectic phase present in the alloy slurry, which is held between its liquidus and solidus temperatures. Under mechanical agitation, such an alloy slurry exhibits thixotropy in that the viscosity decreases with increasing shear rate. This effect appears to be time dependent and reversible. Increasing the particle residence time in the slurry promotes wetting and bond formation due to chemical reactions at the interface, as shown in Fig. 2 and discussed in the section "Fiber-Metal Wettability and Its Effect on Casting Quality" in this article. This semifusion process allows near-net shape fabrication by extrusion or forging because deformation resistance is considerably reduced due to the semifused state of the composite slurry.

Aluminum-silicon alloys (4 to 16% Si) containing 2.8 wt% graphite particles prepared by compocasting followed by squeeze casting show better particle distribution in hypoeutectic alloys (<12.6 wt% Si) than in near-eutectic and hypereutectic alloys. The last two alloys show some evidence of graphite clustering. Apparently, the significantly higher proportion of the proeutectic solid present in the hypoeutectic alloy slurries aids the separation and dispersion of particles.

Compocasting generally results in significant fiber breakage because of the grinding effect of the stirrer and the partially solid alloy slurry. This can be avoided by first mixing the discontinuous fibers in fully liquid alloy, followed by solidification, remelting, and squeeze filtering of the composite melt in a porous ceramic filter using a set of forging dies. This process can remove up to 70% excess melt, depending on squeeze conditions, and it allows a high volume fraction of fibers having random-planar alignment (Fig. 8) to be obtained. However, the chances of fiber breakage and degradation of properties of the composites because of the squeezing operation could offset its advantages at high volume fractions of fibers.

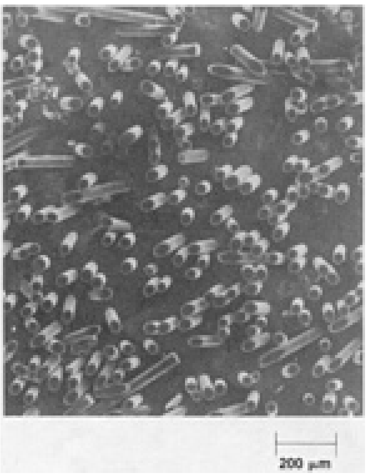

Fig. 8 SEM micrograph of electrochemically etched vertical section of cast Al-4Mg/23 vol% alumina fiber composite showing random planar orientation of fibers. Courtesy of R. Mehrabian.

Pressure die casting of composites allows larger and more intricate component shapes to be produced rapidly at relatively low pressures (≤15 MPa, or 2.2 ksi) and equivalent capital expenditure. Pressurized gas and hydraulic ram in a die casting machine have been employed to synthesize porosity-free fiber and particle composites. It has been reported that high pressures, short infiltration paths, and columnar solidification toward the gate produce void-free composite castings. The pressure die cast particle composites exhibit lower bulk and interfacial porosities, more uniform particle distribution, less agglomeration of particles, and occasional exfoliation and/or fragmentation of soft particles (for example, graphite in aluminum alloy), with the melt penetrating into fine exfoliation cleavages (Ref 21). High concentrations (60 wt% or more) of zircon ($ZrSiO_4$) particles can be uniformly dispersed in pressure die cast aluminum-silicon-magnesium alloys. Pressure die castings of Al-12Si-1Cu-1Mg-1.5Ni-0.8Fe-0.5Mn/7 wt% graphite and Al-8Si-0.75Mg/Al_2O_3 particle composites showed considerable improvement in particle distribution, good particle-matrix bonding, and elimination of porosity, as confirmed by scanning electron microscopy and ultrasonic velocity measurements.

Squeeze casting or liquid forging of MMCs is a recent development that involves unidirectional pressure infiltration of fiber preforms or powder beds in order to produce void-free, near-net shape castings of composites. Aluminosilicate fiber reinforced aluminum alloy pistons made by a Japanese automaker have been in use in heavy diesel engines for some years, and a considerable amount of work has been done on the pressure casting of ceramic particle and fiber-reinforced MMCs for industrial applications (Ref 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32). The fibers or particles exert a considerable influence on grain size, coarsening kinetics, and microsegregation in the matrix alloy. The fundamental phenomena involved are surface thermodynamics, surface chemistry, fluid dynamics, and heat and solute transport. The processing variables governing the evolution of microstructures in squeeze cast MMCs, in decreasing order of importance, are (Ref 31, 33):

- Fiber preheat temperature
- Interfiber spacing
- Infiltration pressure
- Infiltration speed
- Metal-superheat temperature

If the metal or fiber temperature is too low, poorly infiltrated or very porous castings will be produced. If the temperatures are too high, excessive fiber/metal reaction will degrade casting properties. Finally, if the plunger speed is too fast, the preform can be deformed on infiltration. A threshold pressure is required to initiate liquid-metal flow through a fibrous preform or powder bed. This pressure begins in the thermodynamic surface energy barrier because of nonwetting, as discussed earlier. Because wetting is a function of time, the threshold pressure increases with increasing infiltration rates (Ref 33). Table 3 lists some experimental results on the pressure infiltration of B_4C particles and SiC fibers by aluminum alloys.

Table 3 Wetting characteristics and threshold infiltration pressures for aluminum/SiC and aluminum/B_4C systems

The squeeze casting of composite melts into finished shapes promotes a fine, equiaxed grain structure because of large undercoolings and rapid heat extraction. Preheated particles or fiber preforms are inserted into a metal die and infiltrated with molten metal under high pressure (70 to 200 MPa, or 10 to 29 ksi), followed by solidification under pressure. Alternatively, whiskers or particles can be mixed with molten metal before squeeze casting. Aluminum alloy composites containing SiC and Al_2O_3 powders, aluminosilicate fibers, and silicon nitride whiskers have been fabricated by squeeze casting. These ceramic particles and fibers are poorly wetted by metallic alloys (contact angle > 90°), and their infiltration requires considerable hydrostatic pressure to overcome the capillarity pressure.

Further, frictional forces arising from the viscosity of the melt tend to oppose fluid flow through interfiber channels or interparticle corridors. Additional pressure is therefore required to overcome the viscous friction. Several theoretical analyses for modeling and analyzing the frictional forces have been proposed (Ref 24, 28, 31). These relate the infiltration velocity to applied pressure, capillarity, viscosity, and interfiber spacing as well as to fiber preform permeability and the change of permeability due to concurrent solidification in preforms preheated to below the melting point of the metal (Ref 33).

Freeze choking is an important aspect to be considered during the pressure infiltration of fiber preforms or powder beds. Freeze choking depends on the melt superheat, die temperature, and fiber temperature. Initially, a layer of metal solidifies on the prepacked fiber surface, which is of sufficient thickness to bring the fiber temperature to the melting point of the metal as a result of latent heat evolution. This results in an increase in the effective fiber diameter and volume fraction and a concomitant reduction in the permeability of the preform. The infiltration process ceases when the liquid front advances through the interfiber channels slowly enough to enable the fibers to extract latent heat with sufficient rapidity, leading to near-complete freezing of the front. This results in metal-starved regions in the composite and the formation of porosity.

In earlier studies on the squeeze casting of premixed ceramic-melt slurries, the wettability problem was overcome by codispersing SiC whiskers and aluminum alloy powder in an aqueous solution of isopropyl alcohol, followed by infiltration, compaction into small briquettes, and vacuum degassing. These briquettes were then disintegrated into a mechanically stirred base alloy melt, followed by squeeze casting under a pressure of 207 MPa (30 ksi). The resultant strengthening effects of composites are attributable to several factors, including fine grain size, elimination of bulk and interfacial porosities, increased solid solubility due to hydrostatic pressure, and the presence of high-strength SiC whiskers. Figure 9 shows a schematic illustrating the principle of squeeze casting for particle composites. The threshold pressures, P_{th} obtained experimentally for SiC fiber reinforced and B_4C particle filled aluminum alloys are given in Table 3. Combinations of compocasting and squeeze casting have been used to produce aluminum/SiC particle composites containing 20 wt% SiC (Ref 36) and aluminum/graphite particle composites containing 8 wt% particles (Ref 37).

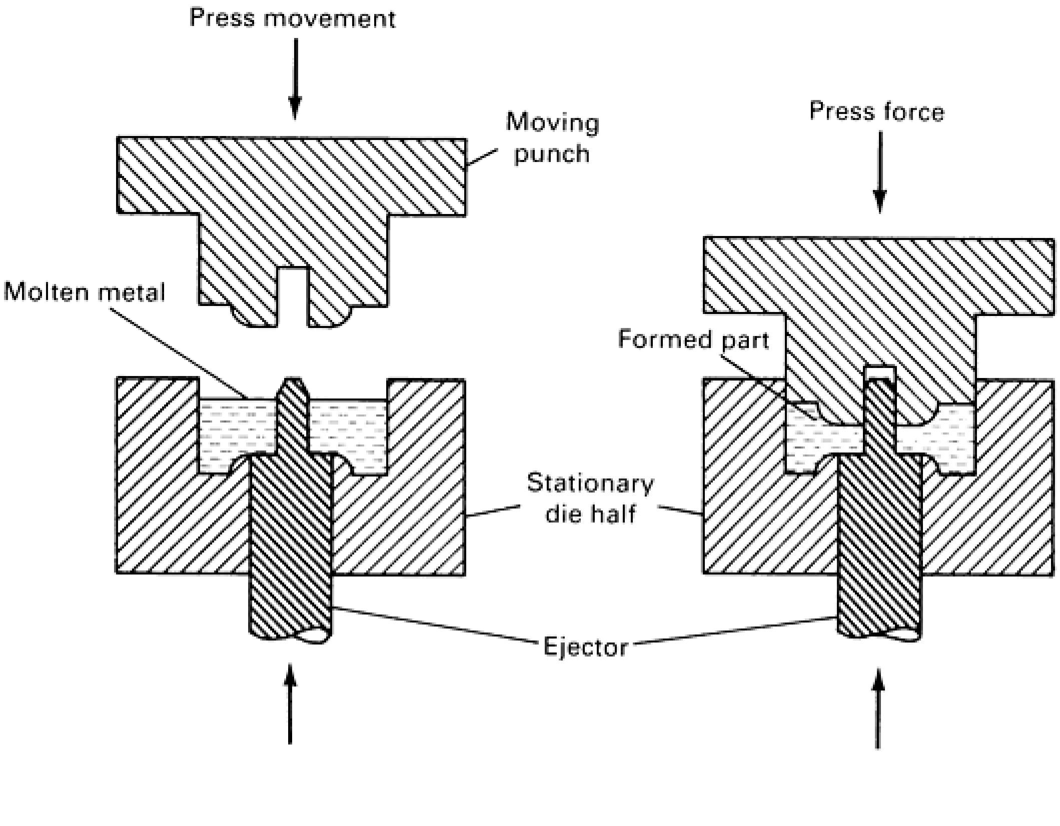

Fig. 9 Schematic of the squeeze casting process for synthesizing MMCs.

Packed beds or aggregates of single or hybrid particles kept inside a mold can be pressure infiltrated to produce cast metal-hybrid particle composites. The particles must be preheated to a temperature equal to or greater than critical preheating temperature (cpt) in order to avoid freeze choking. For hybrid particle systems (for example, glass, carbon, aluminum, or copper particles in tin), cpt is given by (Ref 26):

$$cpt = T_E - \frac{(1-V_V^{mix})D^M N^M [1-(L_m)^{mix}]}{V_V^{mix} \sum X^i D^i C^i} \quad \textbf{(Eq 1)}$$

where T_E, D^M, and N^M are the melting point, density, and latent heat of the melt infiltrated; L_m is the critical liquid fraction; V_v^{nix} is the packing density of particles; and X^i, D^i, and C^i are the volume fraction, density, and specific heat of particle i in the hybrid particle assembly.

For single-particle systems, cpt is expressed as (Ref 24):

$$cpt = T_E - \left(\frac{0.233 D^M N^M}{V_V^P D^P C^P} \right) \quad \textbf{(Eq 2)}$$

where V_V^P, D^P, and C^P are the packing density, the density, and the specific heat of the particles, respectively. For composite systems using particles smaller than a critical value, cpt does exist; however, for systems using particles larger than that size, the identification of cpt becomes difficult with increasing sizes of particles. Systems using angular particles have cpt lower than that of spherical particle systems because the packing density of particles in the former system is lower than that of the latter. The pressure applied to the melt, as well as the melt superheat, does not influence the cpt of the particles. Similar observations on the effect of metal superheat on the sound composite lengths in pressure-infiltrated fiber-reinforced metals are discussed in the section "Fluidity of Composites" in this article (Ref 33).

Plate and tubular composites of aluminum alloys containing continuous or discontinuous SiC fibers can be synthesized by squeeze casting (Ref 25). The SiC yarn, consisting of about 500 monofilaments (average diameter: 13 μm, or 510 μin.), is mechanically wound around a steel frame or aligned unidirectionally in an aluminum vessel. In the case of discontinuous SiC fibers, fiber can be chopped and packed in the vessel. The vessel with fiber is preheated in air for good penetration of the molten metal matrix into the interfiber space. The vessel is then placed into the mold, which is preheated to 500 to 700 K. The fiber volume fraction of composites is controlled by selecting the winding conditions (for continuous fiber) or packing conditions (for discontinuous fibers) before casting. Typical casting conditions for plate-type SiC fiber-reinforced aluminum alloy composites are given in Table 4.

Table 4 Typical casting conditions for SiC fiber-reinforced aluminum and aluminum alloy (Al-4.5Cu, Al-11.8Si, and Al-4.8Mg) composites

Type of composite	**Metal mold temperature, K**	**Time between pouring and pressurizing, s**	**Applied pressure**		**Pressure time, s**	Casting temperature, K
			MPa	**ksi**		
Plate type	573	10	49	7.1	90	**1073**

Source: Ref 25

With the above casting conditions and fiber-matrix combinations, high moduli and strengths (both room temperature and high temperature) of SiC fiber-reinforced MMCs can be obtained. Elastic moduli of plate-shaped MMCs produced in this manner are given in Table 5.

Table 5 Elastic moduli of SiC fiber-reinforced plate-shaped MMCs produced by squeeze casting

Type of MMC	**Fiber packing density V_f**	Elastic modulus GPa psi × 10^3	
Aluminum matrix	0	3.79	**0.55**
Al-4.5Cu/continuous SiC fiber	0.35	10.85	**1.57**
Al-11.8Si/continuous SiC fiber	0.35	10.50	**1.52**
Al-4.8Mg/continuous SiC fiber	0.35	10.25	**1.49**
Aluminum/discontinuous SiC fiber	**0.44**	**11.6**	**1.68**

Source: Ref 25

During the fabrication of fiber-reinforced MMCs, the fibers are exposed to several environments that may cause thermal, chemical, or mechanical degradation of the fibers. This could alter the tensile characteristics and fracture mode of MMCs. Isothermal heating at elevated temperatures (up to 700 °C, or 1290 °F, for 110 h), hydrostatic pressurizing (in oil at 49 or 196 MPa, or 7 or 28 ksi, for 10 min), and chemical vapor deposited aluminum coatings on fibers, followed by isothermal heating (700 °C, or 1290 °F, for 10 min), do not cause fiber degradation in the first two treatments. However, the fibers decrease in average strength and coefficient of variation with exposure time after exposure to liquid aluminum. Aluminum-treated fibers fracture because of the formation of reaction layers, leading to a decrease in tensile strength. As-received fibers fracture because of inner defects or surface flaws; fibers failing from inner defects have the highest strength, followed by those failing from surface defects and those failing from the formation of reaction layers, in that order.

Vacuum Infiltration. Several fiber-reinforced metals are prepared by the vacuum infiltration process. In the first step, the fiber yarn is made into an easy-to-handle tape with a fugitive binder in a manner similar to that used to produce a resin-matrix composite prepreg. Fiber tapes are then laid out in the desired orientation, fiber volume fraction, and shape, and they are inserted into a suitable casting mold. The fugitive organic binder is burned away, and the mold is infiltrated with molten matrix metal. The best castings in terms of soundness (voids, porosity, distribution of fibers) and mechanical properties are obtained if the mold assembly is heated and evacuated before introducing the liquid metal. In the case of α-Al_2O_3 reinforced aluminum-lithium alloys prepared using steel molds, it has been found that thin (0.13 mm, or 0.005 in.) rupturable steel membranes attached ahead of the mold gating system provide considerable flexibility for infiltration through direct immersion of the mold in the melt or through piping the melt to the mold assembly.

The liquid infiltration process used for making aluminum/graphite composites differs from the above process for preparing α-Al_2O_3/aluminum composites. Graphite fibers are first surface treated and then infiltrated with molten metal in the form of wires. These coated graphite wires are then diffusion bonded together to form larger sections.

In the case in which a wetting agent such as lithium or magnesium is used to promote wetting during liquid-metal infiltration, careful control of the concentration of additive/time/temperature and other process parameters is required to prevent excessive fiber reaction and the resulting strength degradation. The best mechanical performance of MMCs is achieved by optimizing the concentration of wetting agents to obtain fully wetted (low-porosity) composites while

maintaining a minimum amount of reaction with the fibers. In the case of α-Al_2O_3/aluminum-lithium composites, lithium concentrations in excess of approximately 3.5 to 4.0 wt% significantly reduce tensile strength. Composites with 3.3 wt% Li, however, show significant retention of strength after 10 min of contact time with molten metal at an infiltration temperature of 700 °C (1290 °F).

The α-Al_2O_3 fibers extracted from vacuum-infiltrated aluminum-lithium composites are gray rather than the original white color, and the intensity of the color increases with increasing reaction time. The fiber-matrix reaction products contain aluminum as an oxygen-deficient suboxide (lithium can reduce Al_2O_3). The extracted gray fibers change back to their original color (white) when heated in air, which is consistent with the reoxidation of the reduced fiber surface to Al_2O_3. The reaction product in these MMCs is the compound $LiAlO_2$ (Ref 5).

The secondary ion mass spectroscopy of α-Al_2O_3 extracted from an Al-1.7Li matrix shows the presence of lithium to depths greater than 8 nm (80 $\overset{0}{A}$) in the fiber. Electron diffraction analysis has shown the presence of $Li_2O{\cdot}5Al_2O_3$ spinel as well as a second unidentified phase. Further, the thin (~5 nm, or 50 $\overset{0}{A}$) silica coating applied to the fiber surface before fabrication is mostly removed during infiltration with aluminum-lithium alloy.

Investment casting of MMCs uses the filament-winding of prepreg-handling procedures developed for fiber-reinforced plastics to position and orient the proper volume fraction of continuous fibers within the casting. The layers of reinforcing fibers are glued together with an appropriate plastic adhesive (fugitive binder), which burns away without contaminating either the matrix or the fiber/matrix interface. These layers are stacked in the proper sequence and orientation, and the fiber preform thus produced is either infiltrated under pressure or by creating vacuum in the permeable preform.

The advantage of investment casting of composites is that a machine mold capable of withstanding high temperatures can be dispensed with because the fiber preform becomes the basic pattern for the component. Continuous graphite fiber-reinforced magnesium has been produced by this method (Ref 38, 39, 40, 41).

Effects of Remelting and Degassing

Many of the studies on the remelting and degassing of MMCs have been reported for aluminum/graphite particle composites (Ref 42). No noticeable loss of graphite occurs as a result of remelting and degassing aluminum-graphite particle composites with nitrogen (Fig. 10), and graphite distribution remains reasonably uniform even after three remelts. This occurs for both uncoated and nickel- or copper-coated graphite particles in aluminum. However, degassing with chlorine or chlorine-bearing compounds such as hexachloroethane adversely affects the recovery and distribution of particles in the casting, because chlorine presumably impairs the wetting between graphite and aluminum.

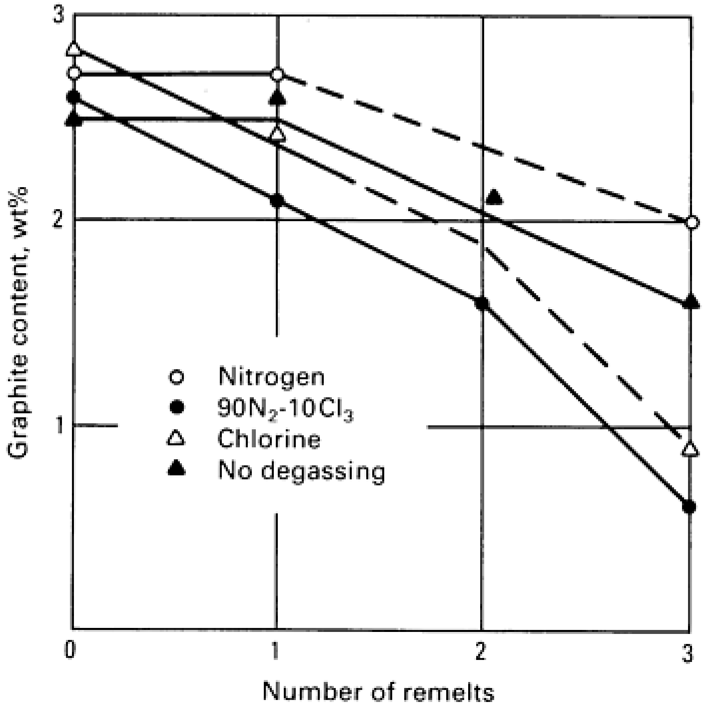

Fig. 10 Graphite loss in an Al-12Si-2.7Ni/graphite composite as a function of remelting and degassing.

The addition of modifiers such as sodium or sodium-bearing compounds to aluminum-silicon alloy melts containing graphite does not adversely affect the process of graphite dispersion in the melt when these modifiers are added before the addition of graphite. However, the addition of compound modifiers that release chlorine after graphite dispersion causes rejection of all graphite particles. The presence of graphite leads to partial refinement and modification of silicon in aluminum-silicon alloys, reducing the amount of sodium or phosphorus required for modification (Ref 43).

The hot tearing tendency of aluminum/graphite composite alloys is not increased by the presence of graphite particles (Ref 42). The Al-11.8Si alloy is inherently resistant to hot tearing, and the addition of up to 4 wt% Cu coated graphite particles (equivalent alloy composition: Al-11.8Si-2.75Cu) does not increase susceptibility to hot tearing in testpieces of up to 200 mm (8 in.) in length.

Fluidity of Composites

Discontinuous Fibers and Particles. The dispersion of discontinuous fibers and particles into metallic melts imparts viscous, slurrylike characteristics to the latter and therefore affects their flowability or fluidity (Ref 1). Additions of discontinuous particles such as alumina, graphite, mica, and other ceramic particles to aluminum alloys cause a reduction in spiral fluidity, which is measured as the distance from the center of a standard spiral plate mold that a liquid front from a given quantity of melt flows before freezing. The spiral fluidity of these alloys decreases linearly with increasing particle surface area per unit weight, as shown in Fig. 11(a). This occurs presumably because of the progressive increase in effective viscosity of the suspension with increasing particle volume fraction.

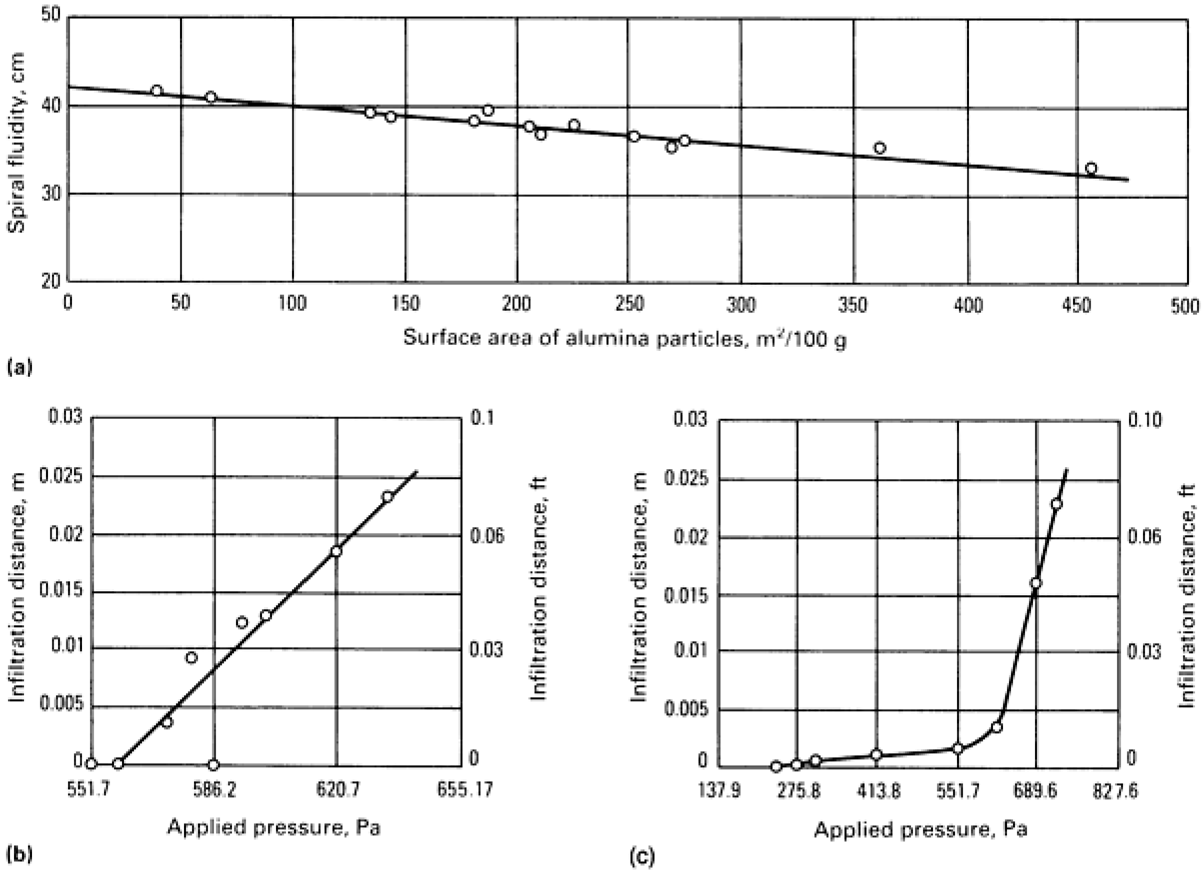

Fig. 11 Spiral fluidity (a) of aluminum-silicon alloy as a function of surface area per unit weight of Al_2O_3 particles. (b) Infiltration distance as a function of applied pressure for an Al-2Cu/SiC fiber composite. (c) Infiltration distance as a function of applied pressure for an Al-2Mg/boron carbide particle composite. Data in (b) and (c) supplied by J.A. Cornie, Massachusetts Institute of Technology.

The casting fluidity of aluminum alloys containing suspended particles decreases with a decrease in melt temperature in a manner similar to the fluidity of alloys without particles. The fluidity of composite slurries is extremely sensitive to the

variations in volume fraction of dispersed particles, and it decreases sharply with progressive additions of particles. The fluidity of composite melts also depends on the shape, size, flocculation, and segregation of particles in a melt. For example, the spiral fluidity of an Al-11.8Si alloy containing dispersions of Al_2O_3 particles decreases with decreasing size of Al_2O_3 at constant weight percent of particles (Fig. 12). Figure 12 also shows that the spiral fluidity of composite slurry decreases with decreasing pouring temperature for constant particle size and weight percentage. Reciprocal relationships between fluidity and the apparent viscosity of melt-particle suspensions have been noted in aluminum-silicon alloys, iron-carbon-sulfur alloys, and Al-4.5Cu-1.5Mg alloy/2.5 wt% flaky mica composites. The fluidity values of particle-filled composite melts are adequate for making gravity cast composites at low volume fraction of particles.

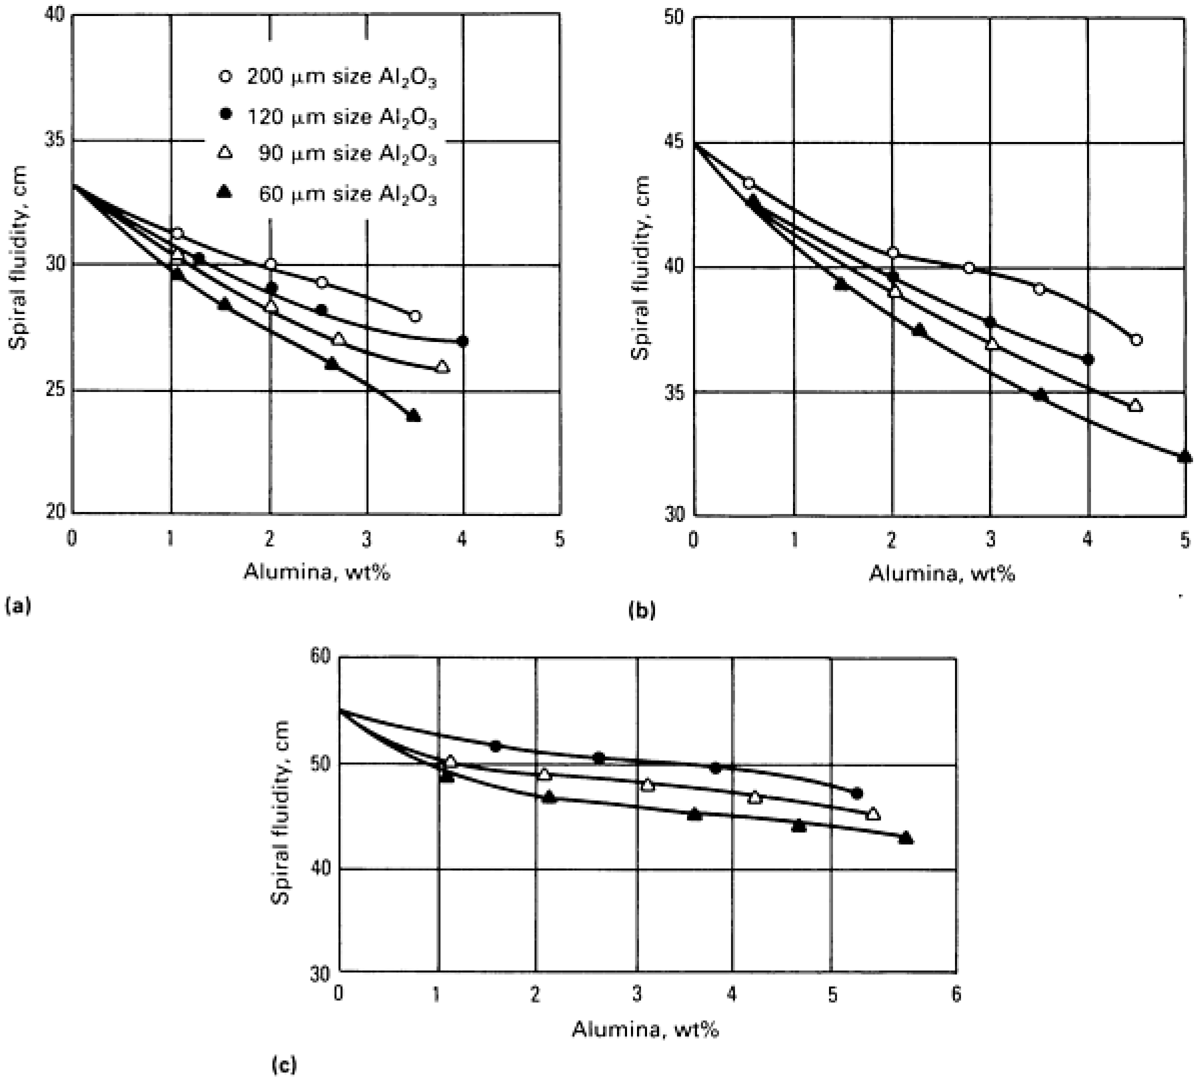

Fig. 12 Effect of particle size and pouring temperature on the spiral fluidity of Al-11.8Si/Al_2O_3 MMCs. (a) Pouring temperature: 680 °C (1255 °F). (b) Pouring temperature: 700 °C (1290 °F). (c) Pouring temperature: 740 °C (1365 °F).

Continuous Fibers. In MMCs reinforced with continuous fibers, infiltration length and preform permeability are indicators of fluidity. Experiments show a strong dependence of permeability and infiltration length on fiber volume fraction and fiber temperature, and a weaker dependence on metal temperature. Figure 11(b) and (c) show the influence of applied pressure on infiltration lengths in SiC fiber-reinforced Al-2Cu alloy and in B_4C particle filled Al-2Mg alloy, respectively; a threshold pressure (Table 3) is required to initiate infiltration in both cases. The infiltration distance increases with increasing applied pressure, with B_4C particle reinforced alloys showing a slow initial increase. This effect is apparently due to greater tortuosity and greater fluid drag in the packed bed of particles compared to the continuous-fiber preforms.

The relative magnitudes of fiber preheat temperature and metal preheat temperature can significantly influence the infiltration behavior of fiber preforms by a pure metal (Ref 33). In the presence of metal superheat, the solid metal sheath initially formed around cold fibers (fiber temperature below the melting point of the metal) remelts, and the length of the remelted region always remains a fixed fraction of the total infiltration length for the case of constant applied pressure, no external heat extraction, and instantaneous heat transfer between metal and fiber. For the case of preheated fibers (fiber temperature greater than the melting point of the metal) under identical conditions, metal flow continues indefinitely unless external heat extraction causes cessation of flow to the point where the flow channel closes due to solidification from an external heat sink.

Impurity content in the metal significantly affects infiltration length. For example, a decrease in the purity of aluminum from 99.999% to 99.9% results in a decrease of 50% in infiltration length through alumino-silicate fibers. This is presumably due to a breakdown of the planar solid/liquid interfaces in the presence of impurities, which create greater drag on fluid flow.

Microstructures

Aluminum-silicon and aluminum-copper alloys have been primarily used as matrix materials in a wide variety of cast MMCs containing graphite and ceramic particles, carbon and glass microballoons, and discontinuous or continuous ceramic fibers (Ref 44). The microstructures of these MMCs show that primary aluminum in hypoeutectic alloys tends to avoid the discontinuous ceramic phase (SiC, alumina, graphite, mica, and so on) and nucleates in the interstices between particles or fibers unless special surface modification techniques are used to promote heterogeneous nucleation on the fiber surface. Primary aluminum crystallizing from the melt does not nucleate on the particle or fiber surface, because of surface thermodynamics and solute and thermal fields in the finite spaces between solidifying interfaces and the constraining second phase. The primary solid (α-aluminum) grows by rejecting solute in the melt, while the discontinuous ceramic phase tends to restrict diffusion and fluid flow; therefore, α-aluminum tends to avoid it, as shown in Fig. 13. Primary silicon and the eutectic in aluminum-silicon alloys tend to concentrate on the particle or fiber surface (Ref 1).

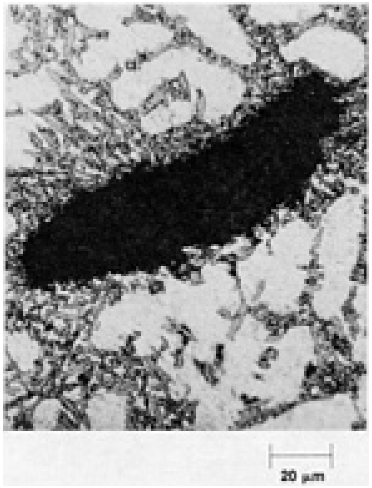

Fig. 13 Micrograph showing a graphite particle in the last freezing interdendritic liquid in an aluminum-silicon alloy.

A closely related feature of these microstructures is the phenomenon of second-phase avoidance in MMCs, which is exemplified by unidirectional solidification experiments in which solidifying interfaces tend to push a freely suspended ceramic particle in a melt. These experiments show the existence of a minimum critical growth velocity of the front that must be exceeded to attain engulfment of the ceramic particle by the growth front.

The discontinuous ceramic phase also tends to modify or refine the structure; for example, eutectic silicon in aluminum-silicon alloys is modified, while primary silicon is refined when solidification occurs in the presence of a high volume fraction of ceramic phase. Figure 14 shows modification of eutectic silicon due to the presence of graphite particles in aluminum-silicon alloys (Ref 19, 42).

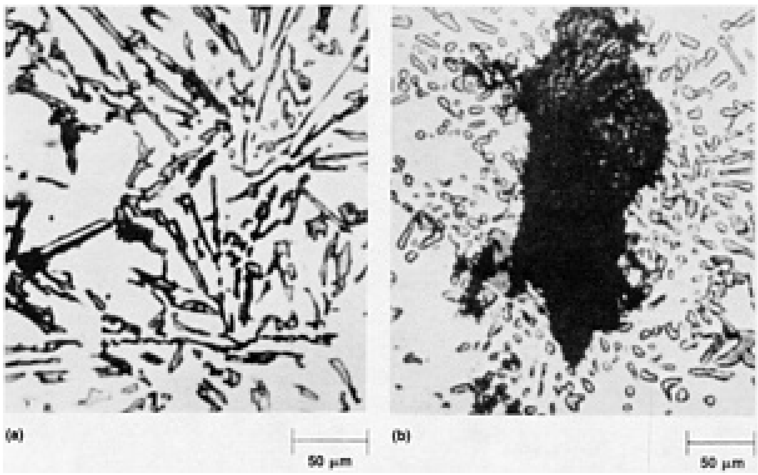

Fig. 14 Effect of graphite on the eutectic phase in aluminum-silicon alloys. (a) Needlelike eutectic silicon in as-cast alloy. (b) As-cast alloy with graphite particles; note shape modification of the eutectic.

Microstructures in fiber-reinforced MMCs can be modulated in a predetermined manner by controlling interfiber spacing and cooling rate. If the cooling rate is sufficiently high or if fiber volume fraction is sufficiently low, the matrix alloy solidifies uninfluenced by the fibers. At sufficiently slow cooling rates, when the secondary dendrite arm spacing in the unreinforced alloy is comparable to interfiber spacing, the grain size becomes large compared to interfiber spacing. In this case, fibers do not enhance the nucleation of the solid phase. With further decrease in the cooling rates, the extent of microsegregation is reduced, and at sufficiently slow cooling rates, the matrix can be rendered free of microsegregation. The underlying mechanisms range from restricted diffusion in the solid state to dendrite coalescence during solidification (Ref 29, 30, 31, 32).

Most of the above results are based on studies of two common alloy matrices: aluminum-copper and aluminum-silicon. The Al-4.5Cu alloy is well characterized and undergoes dendritic solidification in normal unreinforced castings, with coring and some second-phase $CuAl_2$ between dendrite arms. Aluminum-silicon alloys do not show microsegregation patterns in normal castings.

Properties and Applications

Modern fiber-reinforced or particle-filled MMCs produced by foundry techniques find a wide variety of applications (Table 6) because of the low cost of their fabrication and the specificity of achievable engineering properties (Ref 39, 40, 41, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57). Some of these properties are high longitudinal and transverse strengths at normal and elevated temperatures; near-zero coefficients of thermal expansion; good electrical and thermal conductivities; and excellent antifriction, antiabrasion, damping, and machinability properties.

Table 6 Selected potential applications of cast metal-matrix composites

Composite	**Applications**	Special features
Aluminum/graphite	Bearings	**Cheaper, lighter, self-lubricating, conserve Cu, Pb, Sn, Zn, etc.**
Aluminum/graphite, aluminum/α-Al_2O_3, aluminum/SiC-Al_2O_3	Automobile pistons, cylinder liners, piston rings, connecting rods	**Reduced wear, antiseizing, cold start, lighter, conserves fuel, improved efficiency**
Copper/graphite	Sliding electrical contacts	**Excellent conductivity and antiseizing properties**
Aluminum/SiC	Turbocharger impellers	**High-temperature use**

Aluminum/glass or carbon microballoons	. . .	**Ultralight materials**
Magnesium/carbon fiber	Tubular composites for space structures	**Zero thermal expansion, High-temperature strength, good specific strength and specific stiffness**
Aluminum/zircon, aluminum/SiC, aluminum/silica	Cutting tools, machine shrouds, impellers	**Hard, abrasion-resistant materials**
Aluminum/char, aluminum/clay	**Low-cost, low-energy materials**	**. . .**

Several generalized theoretical models predicting the properties of MMCs are available, although simple equations and rules of thumb often give excellent results (Ref 48, 49). The tensile strengths, elastic moduli, and densities of MMCs can generally be estimated from a rule of mixture. The rule of mixture for elastic modulus, for example, is a simple superposition of the effective contributions of the constituent phases to the overall property:

$$E_c = E_m \cdot V_m + E_f \cdot V_f \qquad \textbf{(Eq 3)}$$

where V_m and V_f, are the volume fractions of the matrix and the fibers or particles, respectively, and E_c, E_m, and E_f represent the elastic moduli of the composite, matrix, and fiber, respectively. Similar relationships hold for the tensile strength of α-Al_2O_3 reinforced aluminum-lithium alloys, zircon particle dispersed aluminum-silicon alloys, and many other systems. Equation 3 holds along the longitudinal (fiber) direction. The composite modulus along the transverse direction in fiber composites follows (Ref 49):

$$\frac{1}{E_T} = \frac{V_f}{E_f} + \frac{(1-V_f)}{E_m} \qquad \textbf{(Eq 4)}$$

The composite strength σ_L along the fiber direction can be calculated using Eq 5:

$$s_L = s_{fu}\left\{\left[\frac{(K_o-1)}{K_o} - \frac{S_c}{2S}\right]V_f + \frac{1}{K_o}\right\} \qquad \textbf{(Eq 5)}$$

where σ_{fu} is the ultimate tensile strength of the fiber, S is half of the fiber length-to-diameter ratio ($L/2d$), $S_c = \sigma_{fu}/2\,\tau_i$ (τ_i is interfacial shear stress between fiber and matrix), and $K_0 = E_f/E_m$.

Equation 5 is applicable to MMCs with relatively long fibers ($S \geq S_c$). For short fiber ($S < S_c$) reinforced MMCs, the yield strength σ_{Ly} of composite along longitudinal direction is given by:

$$\sigma_{Ly} = V_f\, S\, \tau_i + (1 - V_f)\,\sigma_{my} \qquad \textbf{(Eq 6)}$$

where σ_{my} is the yield strength of the matrix material. For imperfectly bonded MMCs, transverse yield strength σ_{Ty} is expressed as:

$$\sigma_{Ty} = V_f\sigma_i + (1 - V_f)\,\sigma_m \qquad \textbf{(Eq 7)}$$

where σ_i is the interfacial tensile strength of the composite and σ_m is the tensile strength of the matrix.

The coefficient of thermal expansion of an MMC along longitudinal and transverse directions are given by Eq 8 and 9, respectively (Ref 49):

$$a_L = \frac{a_f V_f K_0 + a_m (1 - V_f)}{(K_0 - 1)V_f + 1} \quad \textbf{(Eq 8)}$$

$$a_T = \frac{a_{Tf} V_f + (1 - V_f) a_{Tm} + V_f (1 - V_f)(v_f E_m - v_m E_f)}{V_f E_f + (1 - V_f) E_m (a_{Lf} - a_{Lm})} \quad \textbf{(Eq 9)}$$

where α_{Tf} and α_{Tm} are thermal expansion coefficients of fiber and matrix along transverse directions and ν_f and ν_m are Poissons ratios for fiber and matrix, respectively. The coefficient of thermal expansion of composites is an important property for various structural applications, such as aerospace, in which dimensional integrity over a wide temperature range is important. Modern fiber-reinforced metals such as magnesium/graphite can achieve zero thermal expansion coefficient until very high temperatures and are therefore ideally suited to various structural applications in space.

The mechanical strength of many MMCs reinforced with continuous fibers is anisotropic as well as extremely sensitive to changes in volume fraction of ceramic phase. The high-temperature strength of MMCs is enhanced by reinforcements, such as SiC whiskers or continuous Borsic (boron fibers coated with SiC) fibers. Aluminum/silicon carbide composites have excellent high-temperature strength up to 500 °C (930 °F); above this temperature, however, debonding and decohesion between fibers and matrix cause fiber pullout and failure of material. Aluminum/carbon MMCs combine very high stiffness with very low thermal expansion due to the almost zero expansion coefficient of carbon fibers in the longitudinal direction. Magnesium/carbon composites also have nearly zero expansion coefficients (Ref 39, 41).

In the case of particle-filled MMCs, the mechanical properties are not as significantly altered (as in continuous-fiber composites), but tribological properties (wear, friction, galling) show marked improvements. Soft, solid lubricant particles such as graphite and mica improve the antiseizing properties of aluminum alloys, while hard particles such as SiC, Al_2O_3, WC, TiC, zircon, silica, and boron carbide greatly improve the resistance to abrasion of aluminum alloys (Ref 51). Particle additions can also give rise to better damping and conductivity of the matrix alloy. For example, the damping capacity of aluminum and copper alloys is considerably enhanced when graphite powder is dispersed in them. A Japanese company has produced a high-damping MMC of aluminum or copper and 20% graphite. The damping capacity of the composite is considerably more stable at high temperature than conventional vibration-insulating alloys, including cast irons (Ref 58). Sliding electrical contacts made from the Cu/20 graphite alloy perform better than the sintered materials generally used, because the alloy combines excellent resistance to seizure with high electrical conductivity.

Selective reinforcement of metals with ceramic fibers (for example, SiC or Al_2O_3 in aluminum) is used in automotive parts such as diesel engines (Ref 53). Enhanced wear resistance and higher use temperature at equivalent cost have made such selectively reinforced MMCs a potentially very useful class of modern composite materials. Figure 15(a) shows an automotive piston selectively reinforced with Al_2O_3 fibers and produced by squeeze infiltrating a fiber assembly with molten aluminum alloy (Ref 46, 47). Other automotive applications are also shown in Fig. 15. Figures 16 and 17 show bearing-type and wear-resistant applications for graphite-containing composites. Connecting rods have been made from α-Al_2O_3/aluminum-silicon carbide composites by casting techniques (Ref 49). In all these cases, graphite particles were stirred in molten aluminum alloys, followed by the solidification of suspensions using conventional foundry techniques. The use of graphite in automobile engine parts considerably reduces the wear of the cylinder liner and improves fuel efficiency and engine horsepower at equivalent cost (Ref 45, 46, 50, 52, 53, 59).

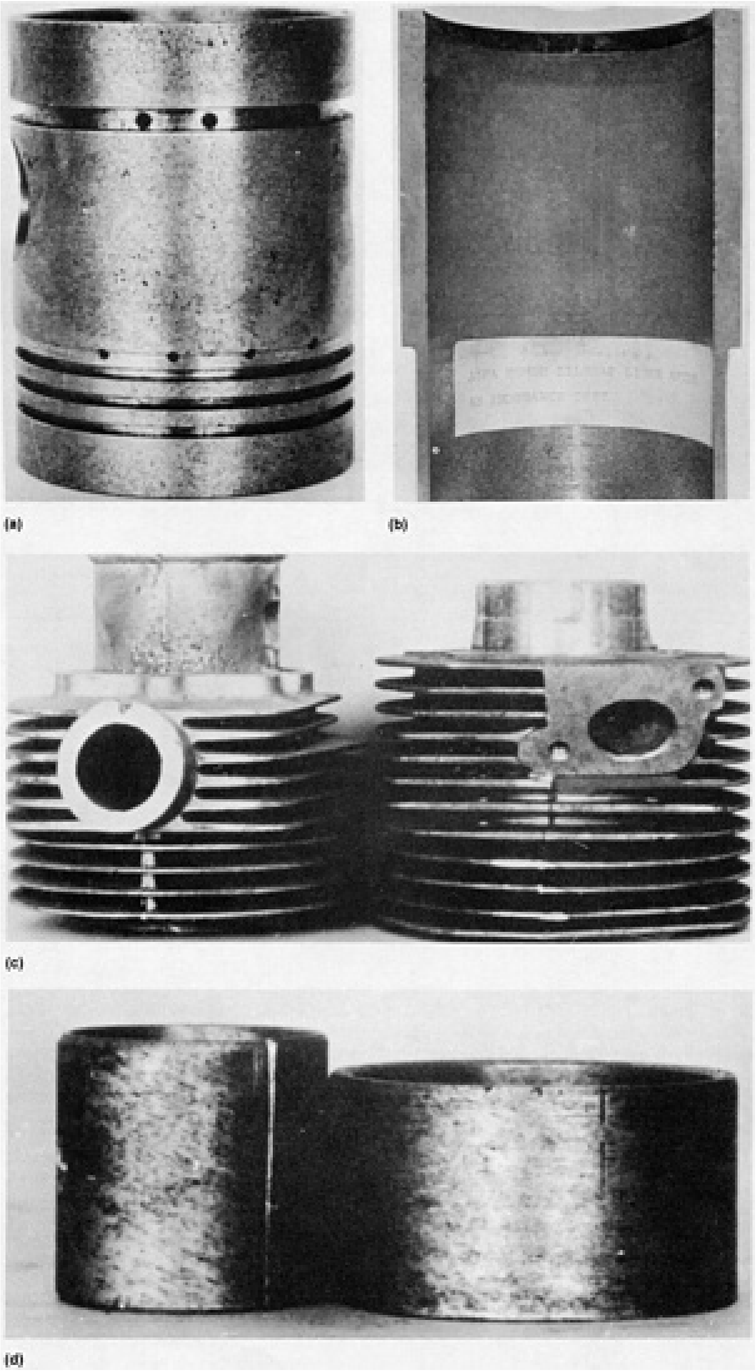

Fig. 15 Automotive applications for cast aluminum/graphite MMCs. (a) Piston. (b) Bearing surface of cylinder after wear testing. (c) Cylinder block. (d) Journal bearings.

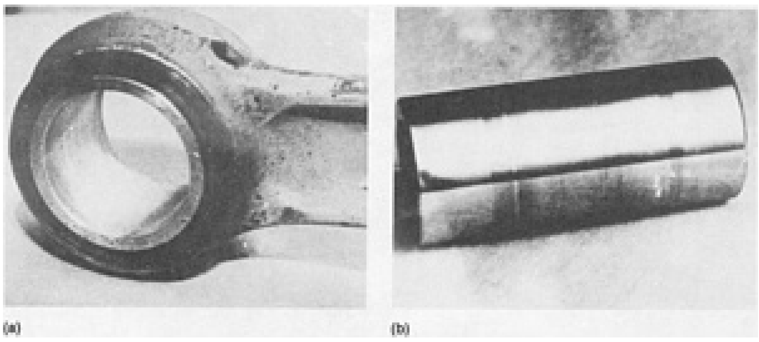

Fig. 16 Al-4.5Cu/graphite bearing (a) in connecting rod and corresponding pin (b) showing surface scoring after 100 h of testing.

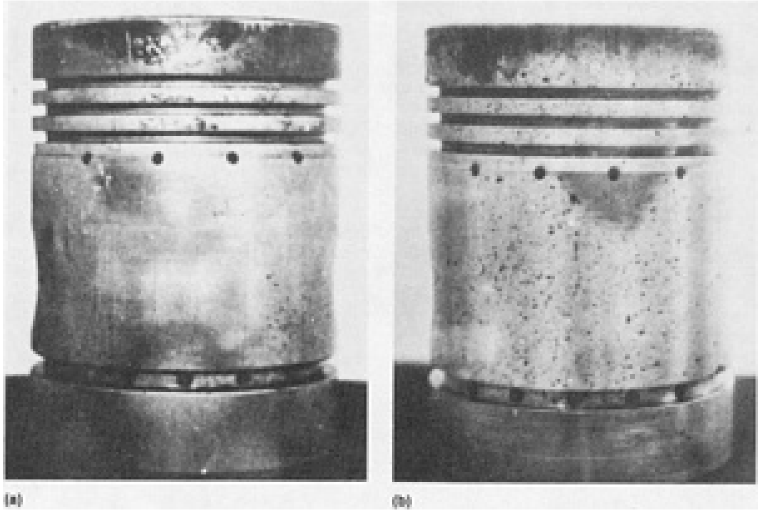

Fig. 17 Comparison of wear of standard piston after a 30 h run (a) and aluminum alloy/graphite piston after a 60 h run (b).

The most promising application for cast aluminum/graphite particle composite alloys is for bearings, which would be less expensive, lighter, and self-lubricating, compared to the bearings currently being made out of copper-, lead-, tin-, and cadmium-containing alloys. Cast aluminum-graphite fan bushings experience considerably lower wear as well as reduced temperature rise during trials at 1400 rpm for 1500 h.

Cast aluminum-graphite alloy pistons used in single-cylinder diesel engines with a cast iron bore reduce fuel consumption and frictional horsepower losses. Because of their lower density, aluminum/graphite composites reduce the overall weight of internal combustion engines. Such an engine will not seize during cold start or failure of lubricant, because of the excellent antiseizing properties of aluminum/graphite MMCs (Ref 46, 47, 48, 49, 50). In the Brazilian Gran Prix 42-lap race in 1975, a racing car with a cast aluminum/graphite particle composite engine liner won the race even though the radiator broke and cooling fluid was completely lost after 27 laps (Ref 56).

Alloys with a dispersed ceramic phase are finding application in impellers and other tribological systems that operate at high temperatures where there is a possibility of liquid lubricant failure. A proprietary process has been developed for producing cast aluminum/SiC MMCs that shows acceptably uniform particle distribution, high strength, and high stiffness (Ref 60, 61). Cast aluminum alloys reinforced with ceramic phase are being proposed for use as turbocharger impellers, which run at high temperatures. Figure 18 shows an investment cast aluminum alloy A357/SiC composite cast to the net shape of a prototype turbocharger impeller (Ref 54). Figure 19 shows cast magnesium/graphite composite tubes produced for space structure applications.

Introduction to Computer Applications in Metal Casting

John T. Berry, University of Alabama

THE ARTICLES in this Section describe some of the developments taking place in the field of computer development in casting technology. Computers are being increasingly applied for design of patterns and castings and for other tasks in the casting industry, but these applications are discussed in another part of this Volume (see the Sections "Patterns" and "Design Considerations"). The focus of this Section will be the computer modeling of phenomena associated with the solidification of molten metals.

The first article in this Section, "Modeling of Solidification Heat Transfer," describes the increase in computer applications to what is now termed the macroscopic scale of modeling casting solidification, that is, the movement of freezing fronts. The last article, "Modeling of Microstructural Evolution," looks at a different, more recently developed aspect--macro-microscopic modeling--from which the evolution of microstructure can be deduced.

As the art and science of solidification modeling has progressed, however, it has become clear that neither macroscopic nor microscopic aspects of solidification can be studied in all potential applications without consideration of the free and forced convection phenomena in zones of liquid or partially liquid metal. For this reason, investigators have been looking more carefully into the question of modeling the flow of molten metal in the casting/rigging system and into the heat exchange taking place during both forced and free convection. Thus, the second article in this Section, "Modeling of Fluid Flow," describes how the computer can be applied to study the flow of metal through the gating system into the casting mold cavity.

The third article, "Modeling of Combined Fluid Flow and Heat/Mass Transfer," explains how the combined action of the fluid flow and heat/mass transfer that occurs during the pouring and filling of the castings can affect the initial temperature distribution of the molten metal.

The methods currently used in all of these types of analyses generally require considerable time to set up and run, but this is largely a function of the computing power of currently available machines. Because this field is one that continues to develop, the authors have not been unduly harnessed in their thinking with regard to what is currently economically feasible. Rather, they have felt encouraged to look toward a near-term future of increasingly efficient methods and means of computation and information processing. Each author has emphasized the basic principles and results of the technique in question rather than presenting a rigorous treatment of the details of the analysis and associated theory; the latter can be found in the references provided with each article.

Advantages of Computer Modeling. Computer-aided design (CAD), computer-aided manufacturing (CAM), and computer-aided engineering (CAE) offer a number of advantages for castings. These include:

- Increased casting yield per pound of metal poured
- Improved casting quality (absence of unsoundness)
- Enhanced productivity of casting system
- Geometric models provide casting volume, weight, and surface area data, allowing rapid cost-estimating and permitting efficient rigging design
- Automated enmeshment for general purpose heat transfer simulators permits shorter design time
- Automated machining of patterns, which in turn reduces costs
- Fewer prototypes to be experimentally evaluated; shorter lead times from design concept to product
- Easier implementation and evaluation of engineering changes
- Enhanced ability to deal with batch production of castings of different design

Issues still to be resolved involve:

- Combination of fluid flow/solidification modeling in three dimensions for limited computer capacities
- Enhancement of user friendliness of modeling and simulating systems

- Closure of feedback loop in control of the casting process

Modeling of Solidification Heat Transfer

John T. Berry, University of Alabama; Robert D. Pehlke, University of Michigan

Introduction

THE DIGITAL COMPUTER has had a singularly important impact on the engineering design of complex, multicomponent, high value-added products (for example, aerospace structures). Since the early 1960s, applications of this device to stress analysis and heat transfer problems have spread to many other industries, ranging from those involved in naval architecture, offshore structures, and pressure vessel fabrication through to metalworking and machine tools and on to automobile component design and performance.

The application of this device to process engineering, in particular to casting production, has not been as pervasive, being confined to a limited number of large metal casting organizations around the world. In many ways, this is surprising because the potential power of computing machinery was much in evidence as early as the 1940s, when under the sponsorship of the American Foundrymen's Society the classic papers of Paschkis describing studies employing the analog computer to predict freezing patterns in castings appeared (Ref 1). It is difficult to determine why this work was not held in higher esteem by practicing foundrymen, although it clearly would have been quite impractical to simulate the freezing of castings of any complexity with the large networks of resistors and capacitors involved in the analog technique.

The first published reference (1962) to the use of the digital computer in a foundry-related application is undoubtedly that of Fursund (Ref 2) in Denmark, who studied the diffusion of heat into foundry sands as it affected surface finish problems in steel castings. Application to the prediction of freezing patterns appeared slightly later (1965). Using the Transient Heat Transfer program developed previously for the U.S. space program, Henzel and Keverian (Ref 3, 4) discussed the successful application of a finite-difference method (FDM) to heavy steel casting production.

The Heat Transfer Committee of the American Foundrymen's Society sought to encourage further research in the area of computer applications during the late 1960s. Sponsorship of research at the University of Michigan resulted in several important publications (Ref 5). Castings simulated by Pehlke, Wilkes *et al.* were poured in a variety of materials (carbon steel, aluminum, and silicon and leaded brasses). All the configurations were sand castings. An important conclusion drawn at the time was that the predictions of the FDM program concerned were strictly limited by the thermophysical properties of the molding and casting media.

Contemporary with this research, the Norwegian group of Davies *et al.* extended their 1973 FDM work on aluminum sand cast bars (Ref 6) to cover permanent mold (gravity die) and low-pressure die casting (Ref 7). A comprehensive review of the developments during this period until 1983 is provided in Ref 8, which, together with Ref 9 and 10, describes most of the important work in the area of solidification modeling using the computer.

Since the early 1980s, there has been a significant growth in the number of publications in this area. Many of these publications are produced by research groups formed specifically for the purpose of studying the techniques of computer simulation and implementing its use in metal casting production around the world. Notable among the sustained research efforts have been several research collaborations, such as those of Sahm, Hansen, and coworkers in Europe; Ohnaka, Aizawa, and colleagues in Japan; and Desai and the present authors in the United States. The proceedings of a recent international conference include brief reports of progress from most of the groups currently active in solidification modeling (Ref 11). More extensive accounts of progress in this area and in the parallel field of weldment simulation can be found in the published proceedings of successive conferences on the modeling of castings and weldments held under the sponsorship of the Engineering Foundation (Ref 12, 13, 14, and 15).

Modeling of Solidification Heat Transfer

John T. Berry, University of Alabama; Robert D. Pehlke, University of Michigan

Geometric Description and Discretization

The form of the differential equations describing the diffusion of heat into the mold, together with the progress of freezing within the casting, is given in the article "Modeling of Microstructural Evolution" in this Volume. To predict freezing history in complex industrial castings, the three-dimensional form must be provided and the correct boundary conditions specified. Even prior to this, there are several valid reasons for defining accurately and unambiguously the geometry and topography of the casting and its rigging:

- Performing the analysis to generate preliminary rigging design
- Estimating the overall costs for casting production for the purpose of quotation
- Defining the melting capacity and molding equipment needs within the casting plant
- Generating the tapes or other information storage forms required to drive machine tools needed for the fabrication of patterns and core boxes and the sinking of wax pattern, permanent mold, and die casting dies

The need to provide this geometric representation and to link the chosen form of representation with the process of discretization, that is, the breaking up of the whole into discrete elements, has been recognized as being of prime importance by only a limited number of research groups (Ref 16, 17). Turning first to the problem of overall geometry, much can be gained by examining the capabilities of the many geometric modelers now available. The three most established types of geometric representation are (Fig. 1):

- Constructive solid geometry (csg)
- Boundary re presentation (b-rep)
- Wireframe (wf)

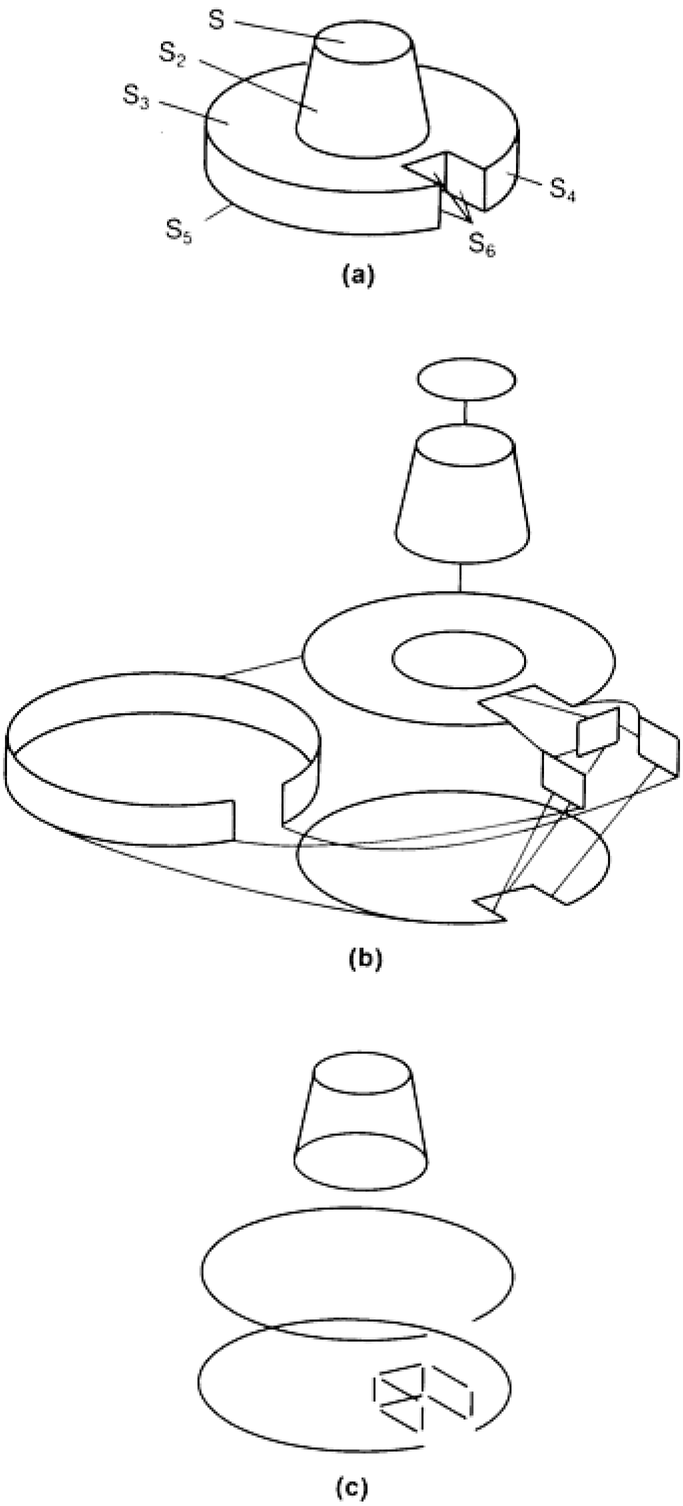

Fig. 1 Three types of three-dimensional geometric representation of a simple casting. (a) Constructive solid

geometry. (b) Boundary representation. (c) Wireframe. Source: Ref 18

The wireframe is not a true solid modeler, but because it normally forms an important part of many preprocessing packages for commercial finite-element method (FEM) computational codes, it is sometimes listed as a form of geometric modeling. The csg and b-rep approaches are both often incorporated into commercially developed computer-aided design (CAD) packages. Figure 2 shows a csg-based model for a partial section of a casting in the form of a thick-wall cylinder together with its rigging. Many contemporary modeling routines permit not only hidden-line removal but also the use of color and shading. Figure 3 shows such a representation of a small aerospace casting. Perhaps the true test of the utility of a geometric modeling package lies in its ability to represent the full range of complex shapes involved in commercial casting. A particular feature, which is likely to appear in most common casting configurations, is that of fillets, which are a necessary patternmaking expedient and something seen when one solid intersects another (Fig. 4).

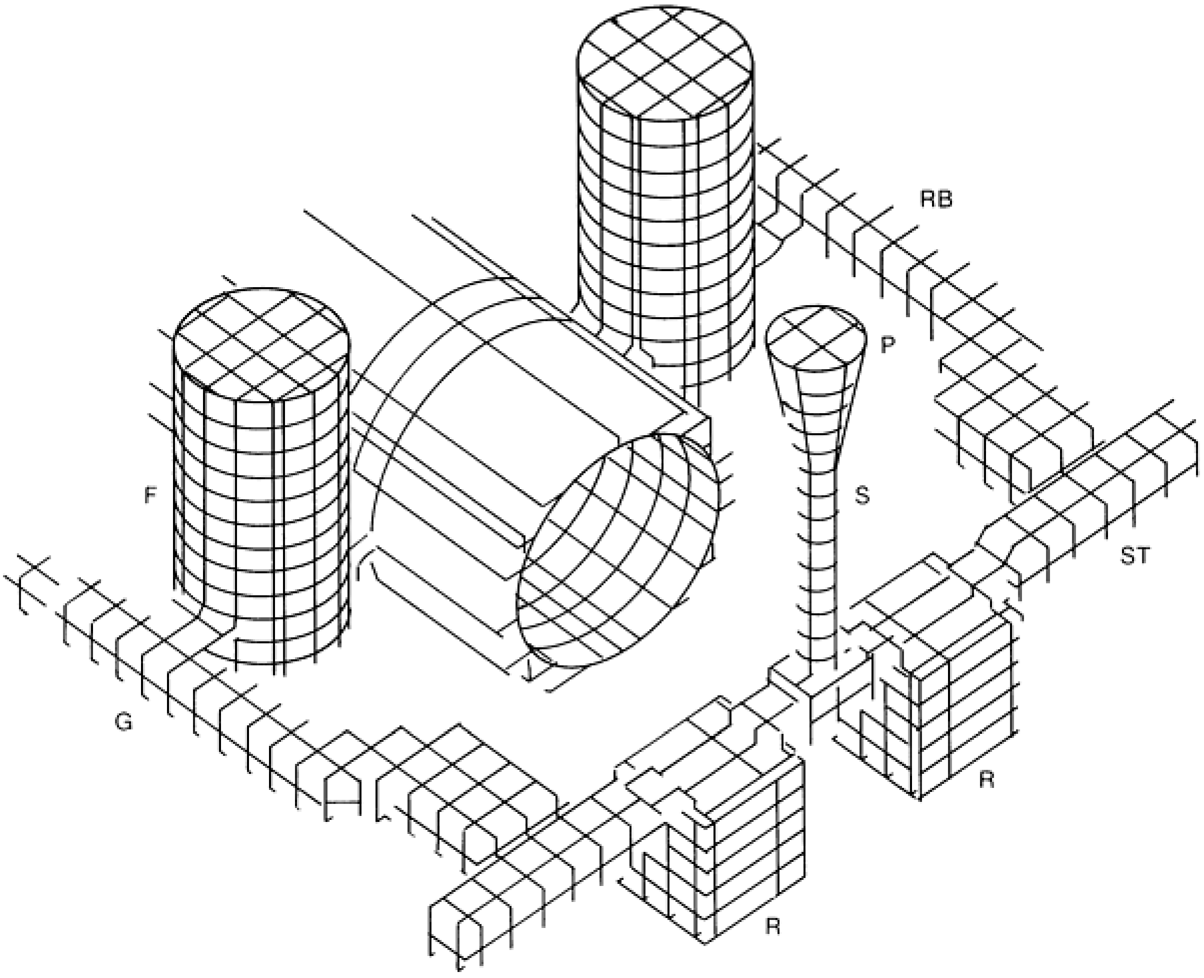

Fig. 2 Portion of a geometric model of a casting with rigging, constructed using a csg geometric modeler. F, feeder or riser; G, ingate location; P, pouring basin; R, reaction chamber; RB, runner bar; S, sprue; ST, slag trap. Source: Ref 19

(b)

Fig. 4 Blending together of surfaces using fillets in preparation of models for patternmaking or for simulation studies. (a) Normal blend with edge limits. (b) Constant-radius blend. Source: Ref 20

Although the surface-modeling technique does not provide a complete geometric description of an object, it has been the basis of one of the most successful attempts thus far to link together computer-aided design and manufacture in the metal casting industry. The DUCT program, which originated at Cambridge University (Ref 20) is able to produce a surface model from a given spine and an orthogonal section set (Fig. 5). Such information can then be conveyed to patternmaking and core box fabricating machinery on a routine basis.

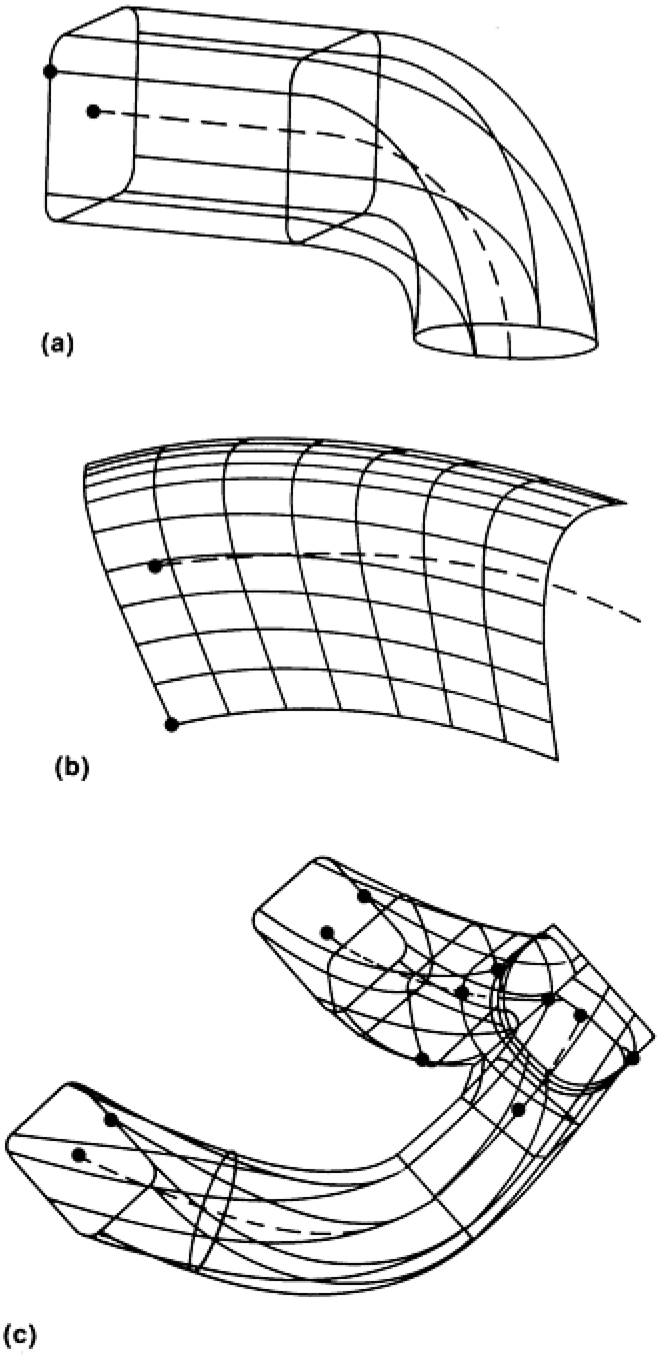

Fig. 5 Method by which a surface-modeling program (DUCT, Ref 20) is used to build a model from a spine (dotted line) and a series of orthogonal sections. The sections are joined by Bezier curves. This technique has been used in the production of automobile manifolds. (a) Single closed DUCT. (b) Single open DUCT. (c) Combination of several closed DUCTs

Before a model of any description can be built and a freezing simulation entered into, the foundry methods engineer must have a reasonably accurate picture of the location and dimensioning of the various components of the rigging system (the gating and risering subsystems) that are to be employed during casting. Two approaches are being followed as alternatives to the age-old art of cut and try. These techniques are both computer based, and one in particular uses (most effectively) the readily available personal computer rather than the mainframe machine demanded by both geometric representational (csg, b-rep, etc.) and numerical computational (FDM, FEM, etc.) programs. The techniques can be referred to as:

- Special-purpose foundry rigging engineering programs
- Knowledge-based expert systems programs

Special-Purpose Programs. Many programs fall under the category of special-purpose programs (Ref 21, 22, 23). One of the most versatile, the Novacast program (Ref 23), determines riser sizes by using the well-known Chvorinov rule (Ref 24) and locates them by using various other empirically derived feeding range rules. The program will also approximate the geometric features of the gating system using the Bernoulli approximation, together with other empirical axioms. This type of program has met with relatively wide acceptance in foundries around the world. In the United States, the AFSoftware programs and other routines prepared at the University of Wisconsin are in widespread use (Ref 21).

Knowledge-Based Expert Systems. Microcomputer programs such as those discussed above are often sufficient for designing the rigging of castings of a less critical nature. However, for those cast components that form parts of aerospace systems or for the safety features of pressure vessels, and so on, further engineering measures are often necessary.

In such cases, the need arises for a knowledge-based expert system and its associated data base. In any particular organization, a vast amount of the expertise involved in the art of foundry practice often disappears with the retirement of certain employees. Although there is no unique solution to the problem of rigging a particular casting, there are many valuable, although sometimes conflicting, opinions available for consideration. Discussions are beginning to appear in the literature on this approach to preparing a rigging system design that will later be tested by simulation (Ref 25). It is expected that this technique will grow extensively over the next 10 years.

FEM Software. Turning to the question of discretization of space within and around the casting (the mold cavity and the mold itself), a number of commercial FEM packages are associated with preprocessing routines that perform the subdivision involved, together with the parallel preparation of files describing that discretization (numbering of elements and nodes, and so on). The principles involved in this important phase of modeling are discussed in Ref 26. More sophisticated enmeshment schemes, now commercially available, will allow the application of higher mesh density to regions where the temperature gradients are expected to be steep. A simple example of the enmeshment of both mold cavity and the mold itself is shown in Fig. 6. No special attempt was made to vary mesh density in particular locations. It should also be mentioned that the configuration shown in Fig. 6 represents a two-dimensional object. Nonetheless, Fig. 6 serves to indicate how rapidly the file-keeping capacity of the computer system will be occupied as the complexity of component design increases.

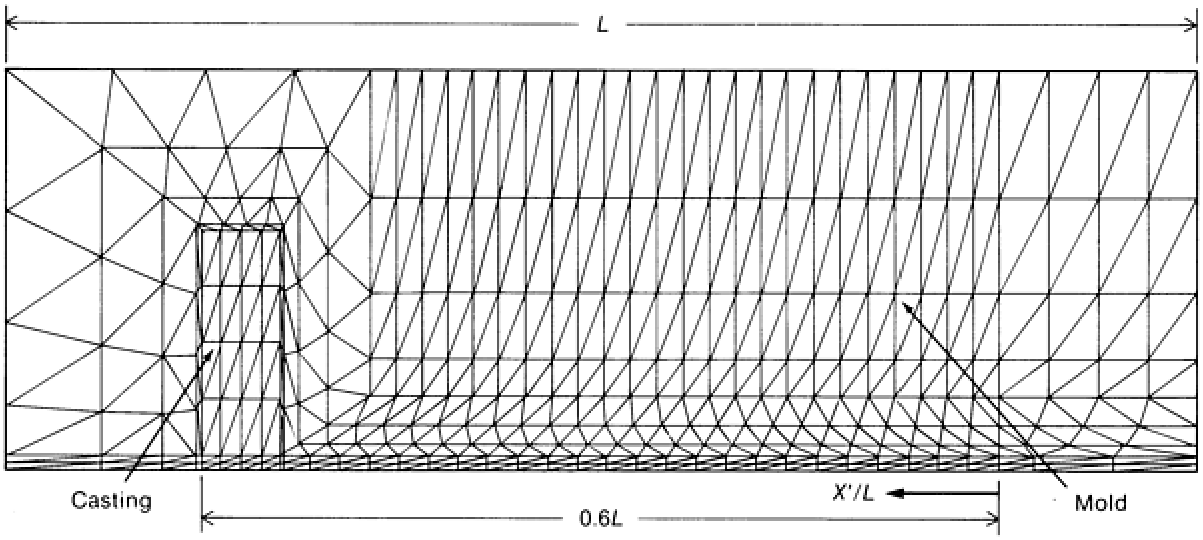

Fig. 6 Discretization (enmeshment) of a plate casting and riser, together with the mold into which they are to be cast

Figure 6 also shows that a preponderance of elements (or nodes) exists within the mold, per force of its enveloping nature with respect to the casting. This will be discussed in the section "The Data Base."

The Computational System

Many successful casting simulations have employed large-scale commercially available, general-purpose programs. The pitfalls of this approach are discussed in Ref 27. Table 1 lists the attributes of certain large-scale programs in the context of their use in solving heat transfer problems. In view of these limitations, some research groups have chosen to build their own simulation programs or solvers. The development of such a program, a dedicated special-purpose FEM code, is discussed in Ref 28. This particular system--The Michigan Solidification Simulator (MSS)--was written exclusively for modeling the general problems of steady-state or transient energy transfer with nonlinear material properties, phase change, and imposed bulk-flow velocity fields. Two-dimensional Cartesian and cylindrical, three-dimensional Cartesian

element types (including interfacial contact resistance elements), totaling three coordinate systems and ten element types, can be supported. In solving the basic governing equations, the simulator permits the use of the following boundary conditions:

1. Temperature specified
2. Heat flux specified
3. Radiative heat transfer specified
4. Convection heat transfer specified

Table 1 Comparison of ANSYS, MARC, and MITAS-II with the ideal goal for metalcasting simulation software

Feature	**Ideal**	**ANSYS**	**MARC**	**MITAS-II**
Ease of setup and use	Easy	Difficult	Moderately difficult	Moderately difficult
Running cost	Low	High	High	Moderate
Ability to account directly for latent heat	Yes	No	Yes	Yes
Dedicated heat transfer code	Yes	No	No	Yes
Accuracy	Good	Very good	Very good	Very good
Pre- and postprocessing capabilities	Good	Good	Good	Poor

Source: Ref 27

Because heat transfer expressions for the third and fourth conditions have the same mathematical form, only three expressions are required to represent all four boundary conditions. Currently, a uniform initial temperature field must also be specified. The computations involve the use of the Galerkin method of weighted residuals. The discretization of the geometry involved in the simulation uses triangles, distorted bricks, and distorted rectangles according to whether two- or three-dimensional castings are to be modeled. At present, the division of a particular domain is undertaken manually. The validation of the program has been performed, first, using cases where analytical solutions exist, principally for one-, two-, and three-dimensional transient heat transfer with various boundary conditions but without solidification; second, for a case involving a latent heat source term but zero superheat, for which an analytical solution exists; and finally, for a variety of axisymmetric and three-dimensional examples involving the actual solidification of metals, where validation was undertaken experimentally from thermocouple measurements or sectioning (Ref 28).

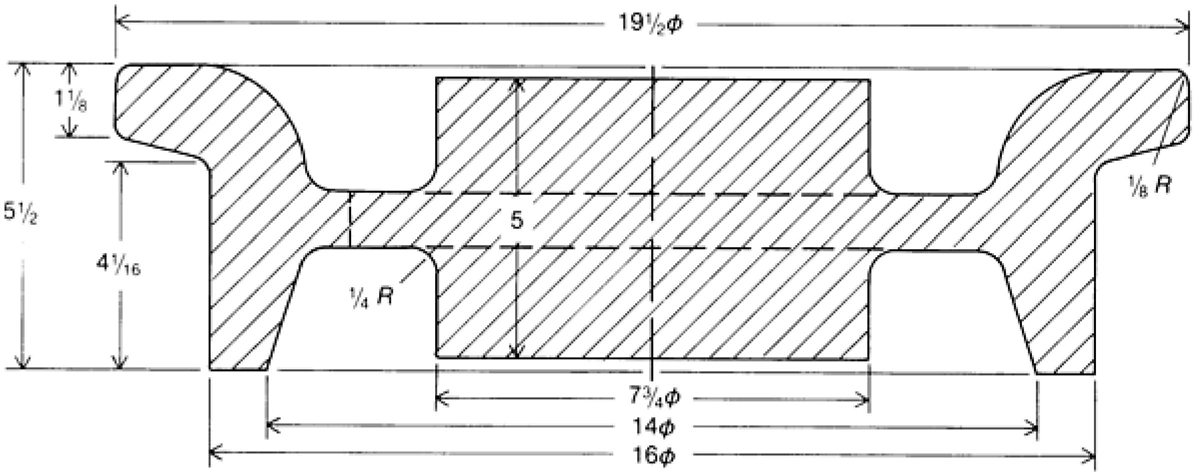
The actual castings simulated were:

- A cylindrical gray iron casting poured in dry sand
- A cylindrical Al-13Si casting poured in dry sand
- A carbon steel railwheel casting
- An investment cast Alloy IN-100 plate

In the first three cases, very good agreement was obtained between simulation and experiment.

The railwheel casting was chosen as an example of an industrial casting (Ref 29). There are no experimental thermocouple data available, but radiographs and casting sections allow inference of cooling patterns and analysis of defects.

Seven different casting configurations were investigated (Ref 29). For the present article, two (casting shapes C and F; see Fig. 7) were selected that are the best documented. The railwheel casting is shown in Fig. 7. Casting F has a web portion padded with 13 mm ($\frac{1}{2}$ in.) of extra metal on both sides.



Details of test wheel castings

Casting	Riser diameter		Riser height		Pouring temperature		Special features
	mm	in.	mm	in.	°C	°F	
A	190	7.5	165	6.5	1675	3050	. . .
B	215	8.5	180	7.0	1675	3050	. . .
C	190	7.5	230	9.0	1610	2930	. . .
D	150	6.0	230	9.0	1610	2930	25 mm (1 in.) thick riser sleeve
E	190	7.5	230	9.0	1610	2930	75 mm (3 in.) thick chromite sand facing around rim and flange
F	190	7.5	230	9.0	1605	2920	Metal padding web thickness of 50 mm (2 in.)

Fig. 7 Cross sectional view of a railwheel casting, with dimensions given in inches. The casting was poured in plain carbon steel. The table details the various riser configurations used in pouring. See also Fig. 8 and 9. Source: Ref 28, 29

The finite-element results for casting C are plotted as isotherms in Fig. 8. The isotherms are the liquidus (1515 °C, or 2760 °F) and the solidus (1485 °C, or 2075 °F). The flange region has a pool of liquid metal that is cut off from the riser by the solidified web. One would expect to see defects in the sectioned casting near this point, and in fact there are defects in this region, as predicted by the numerical simulation (Ref 28, 29).

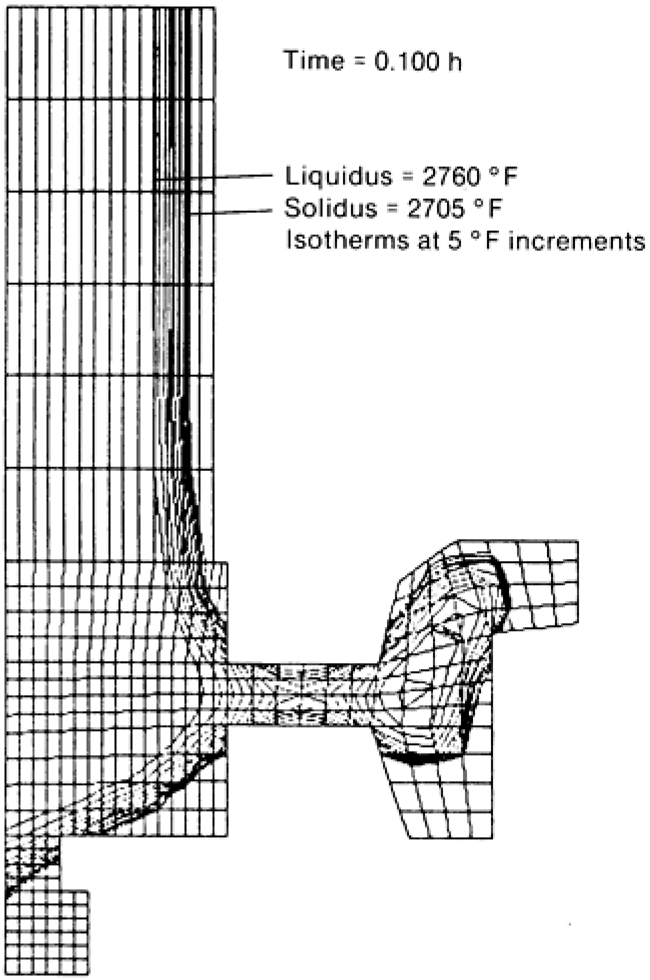


Fig. 8 Results of FEM simulation of railwheel casting using configuration C for riser (see Fig. 7). Pattern of liquidus and solidus isotherms suggests that shrinkage will occur in the rim. Source: Ref 28, 29

The same simulation was run for casting geometry F, which has 13 mm ($\frac{1}{2}$ in.) of additional metal padding on each side of the web. Isotherms from that simulation are shown in Fig. 9 and indicate that the casting should be sound due to the directional solidification. Actual casting sections of casting F showed no shrinkage defects, thus validating the simulation.

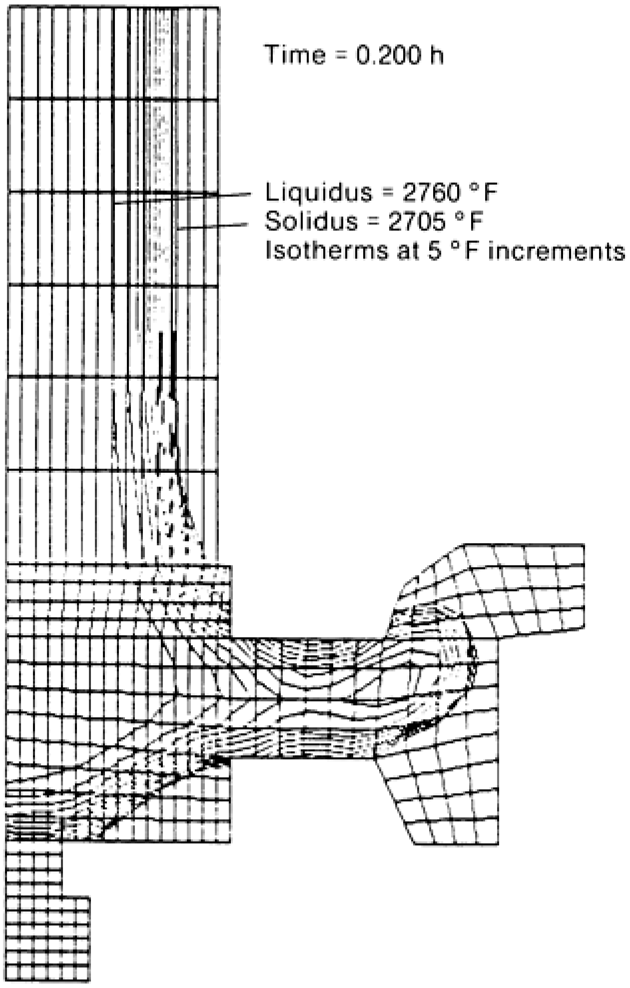

Fig. 9 Results of FEM simulation of railwheel casting using configuration F for riser (see Fig. 7). Web between hub and rim has also been thickened. Isotherms suggest that the casting should be sound. Source: Ref 28, 29

The investment cast plate proved to be more complex to simulate because the surroundings of the investment play an important role. In this case, the agreement was found to depend on the condition assumed for radiation exchange between the investment shell/kaowool wrap and the surrounding environment (an evacuated furnace). In particular, the radiation view factors were seen to be important (Ref 30).

The finite-element method is not the only system in use for performing simulations of shaped casting solidification. Many previous models have been successfully run using the finite-difference method, while more recently publications have appeared describing the use of the boundary-element method, the control volume method, and new developments of the finite-difference method (Ref 31, 32, 33, 34, and 35). At this time, the FEM-based techniques still possess the greatest all-around flexibility.

Nonetheless, the reader should examine carefully publications describing these new and alternative computational approaches. Particular attention should be paid to the:

- Ability to handle complexities of external shape
- Ability to handle totally enclosed portions of the mold, such as coring
- Speed of computation and type of computer on which the simulation is run
- Linkages provided with pre- and postprocessing packages, in particular the existing commercially available geometric modeler based CAD systems

Modeling of Solidification Heat Transfer

John T. Berry, University of Alabama; Robert D. Pehlke, University of Michigan

The Data Base

All mathematical models of the solidification process should possess (Ref 36):

- An accurate representation of geometry
- An adequate treatment for evolution of latent heat
- A sensitivity to the thermophysical properties of the materials involved in this process

The first item listed above has been discussed in this article. The second item, an important part of the data base, is discussed in the article "Modeling of Microstructural Evolution" in this Volume. The thermophysical property data base for solidification modeling is a vast but sometimes sparsely populated region. By considering the most common molding material in shaped casting (bentonite-bonded silica sand), particularly the relationship that its apparent (or effective) thermal conductivity k has with temperature, one can appreciate part of the problem associated with data base development or expansion. As shown in Fig. 10, k is a complex function of temperature. In addition, one must specify the moisture content (even when considering dried sand), ramming density, average grain fineness, and the sand source (Ref 37). Recognizing the burgeoning number of mold materials, which now include zircon, olivine, and chromite sands (Fig. 11), the potential for data base depth seems almost limitless. A collection of such data has been made that includes curve-fitted relationships linking temperature with thermal conductivity, specific heat, and other properties of molding and casting media (Ref 38). If such data were not found to be readily available, estimates were made. This was especially true for the thermophysical properties of metals and alloys above their melting points or ranges.

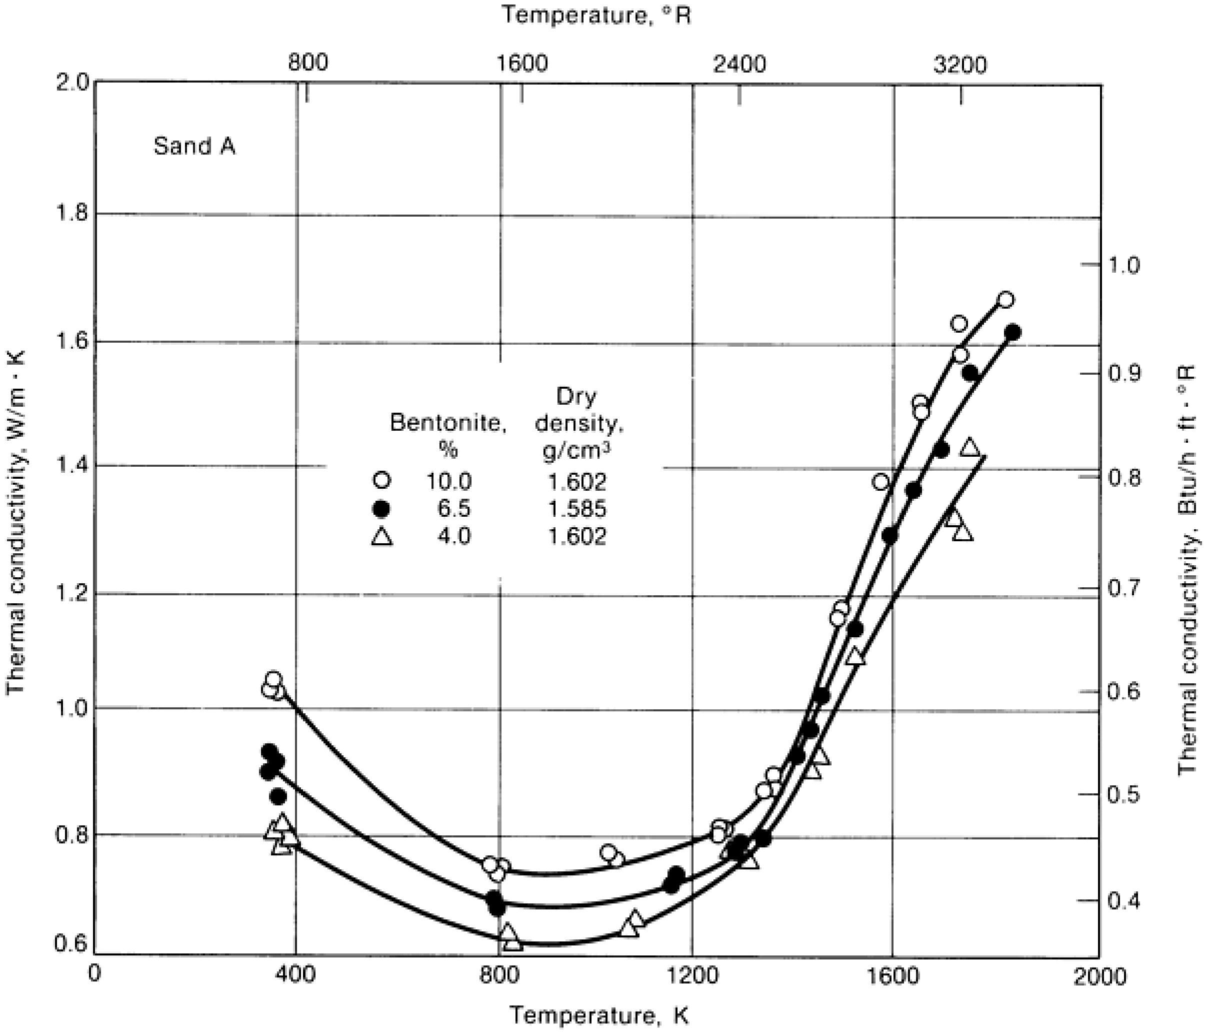

Fig. 10 Variation of apparent thermal conductivity with temperature for compacts of silica sand containing various binder contents. Source: Ref 37, 38

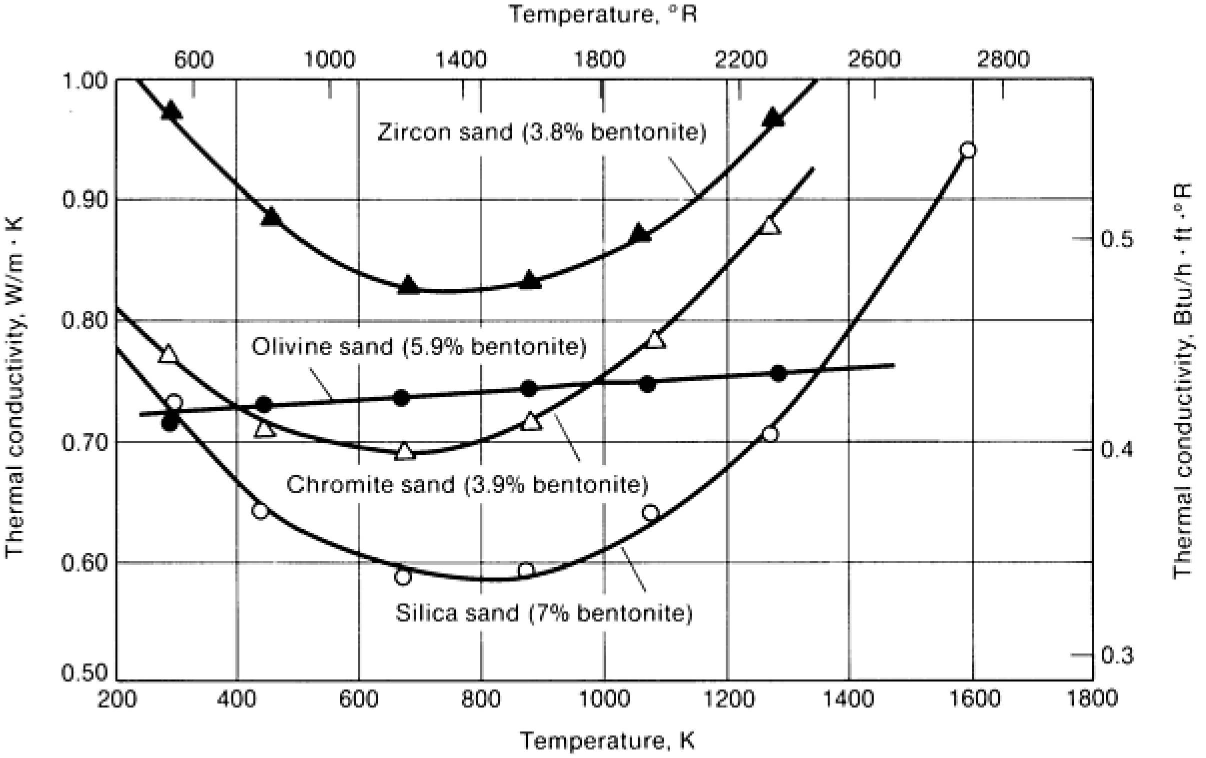

Fig. 11 Apparent thermal conductivities of four types of clay-bonded molding sands. Source: Ref 38

It was mentioned earlier that in most modeling problems in this area, where numerical analysis is used, the number of elements (or nodes) located within the mold itself vastly outnumbers those within the casting. In recent years, there has been a determined effort on the part of several workers to replace the mold in the simulation with either a heat flux data map or a tabulated series of equivalent heat transfer coefficient values, thus essentially changing the boundary condition (Ref 39, 40, 41, 42, 43, and 44). Initially proposed independently by Niyama (Ref 39) and Berry (Ref 40), this approach has since been developed extensively, in particular by Wei and Berry (Ref 41, 42) and most recently and with considerable practical success by Dantzig and coworkers (Ref 43). Figures 12 and 13 compare conventional (mold enmeshment constrained) and these alternative (boundary heat flux or boundary curvature governed) calculations.

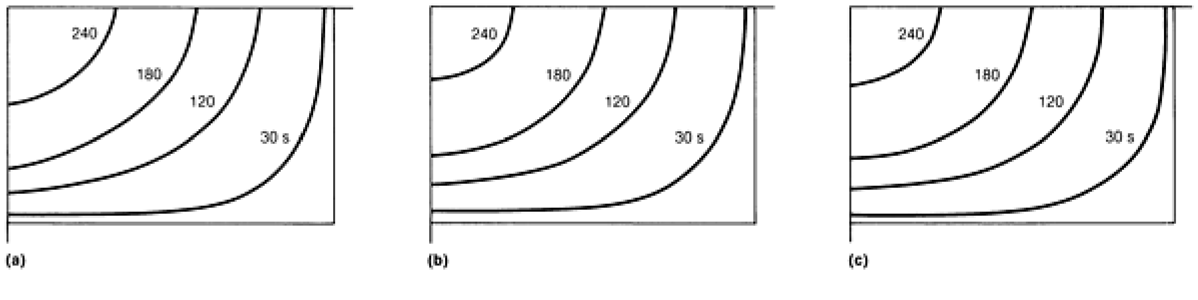

Fig. 12 Computed solidification front movement for pure aluminum in a sand mold. One quarter of a rectangular bar section is shown. (a) Results of FDM simulation using conventional approach, in which the mold is enmeshed and mold properties depend on temperature. (b) Same as (a), except mold properties are assumed to be constant. (c) Mold is not enmeshed, and heat flux *q* is specified at the mold/metal interface.

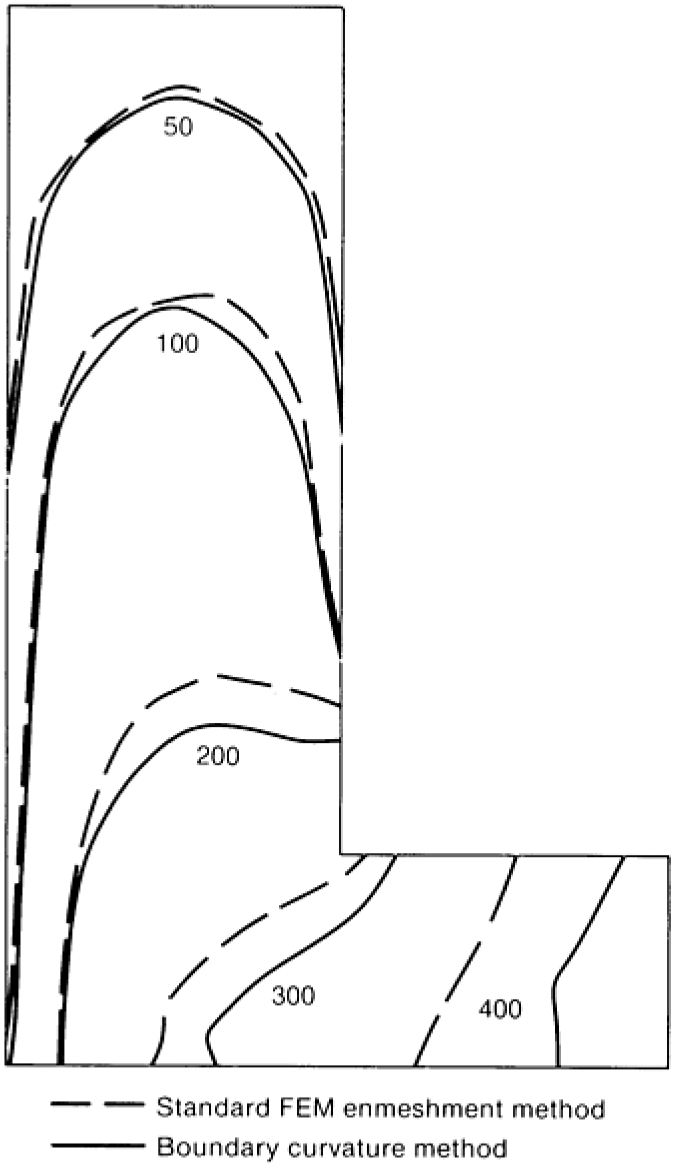

Fig. 13 Successive positions of the solidus isotherms in a one-quarter section of an H-shaped casting (low-carbon steel in sand). Time is in seconds, H half-height is 50 mm (2 in.), and half-width is 30 mm (1.2 in.). Results using standard FEM method are compared with those obtained using boundary curvature method. Interpreting the Output of the Computer Simulation

A common failing of many early computer applications to design engineering lay in the inability of the software to summarize the meaning of the many lines of data emerging as output. This led to the appearance of efficient postprocessing software capable of displaying, for example, two- or three-dimensional stress plots or isotherms, depending on the nature of the numerical analysis. Commercially available postprocessing routines display such information superimposed on the geometric outline of the component (Fig. 14).

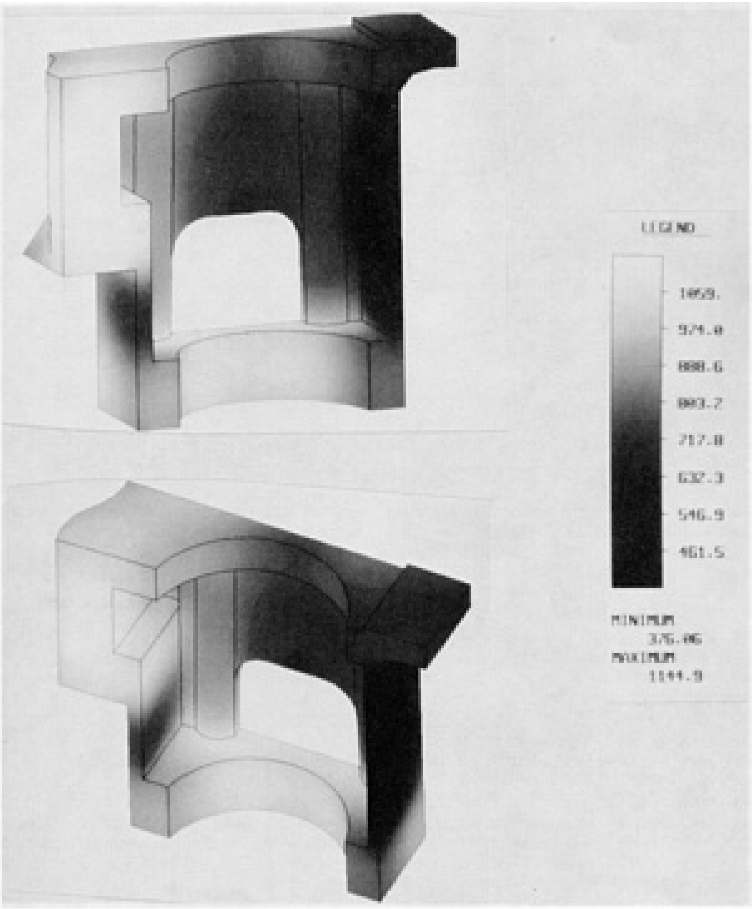

Fig. 14 Two views from a simulation of the solidification of a John Deere engine block 253 s after pouring. The material is eutectic gray cast iron with a freezing point of 1140 °C (2085 °F). The back surface is a plane of symmetry. Courtesy of J.A. Dantzig

With suitable interaction, certain routines will permit the generation of maps displaying the change of specific criteria functions affecting casting soundness. Such functions are normally selected on the basis of theoretical considerations and may, for example, involve some combination of local temperature gradient, *G*; freezing front speed, *V*; or cooling rate, *R*

or $\dot{T}$. The effect of combinations of such parameters on governing feeding characteristics of steels is illustrated in Fig. 15. Similar criterion functions for other cast metals, although data are currently unavailable, are the focus of extensive research and development.

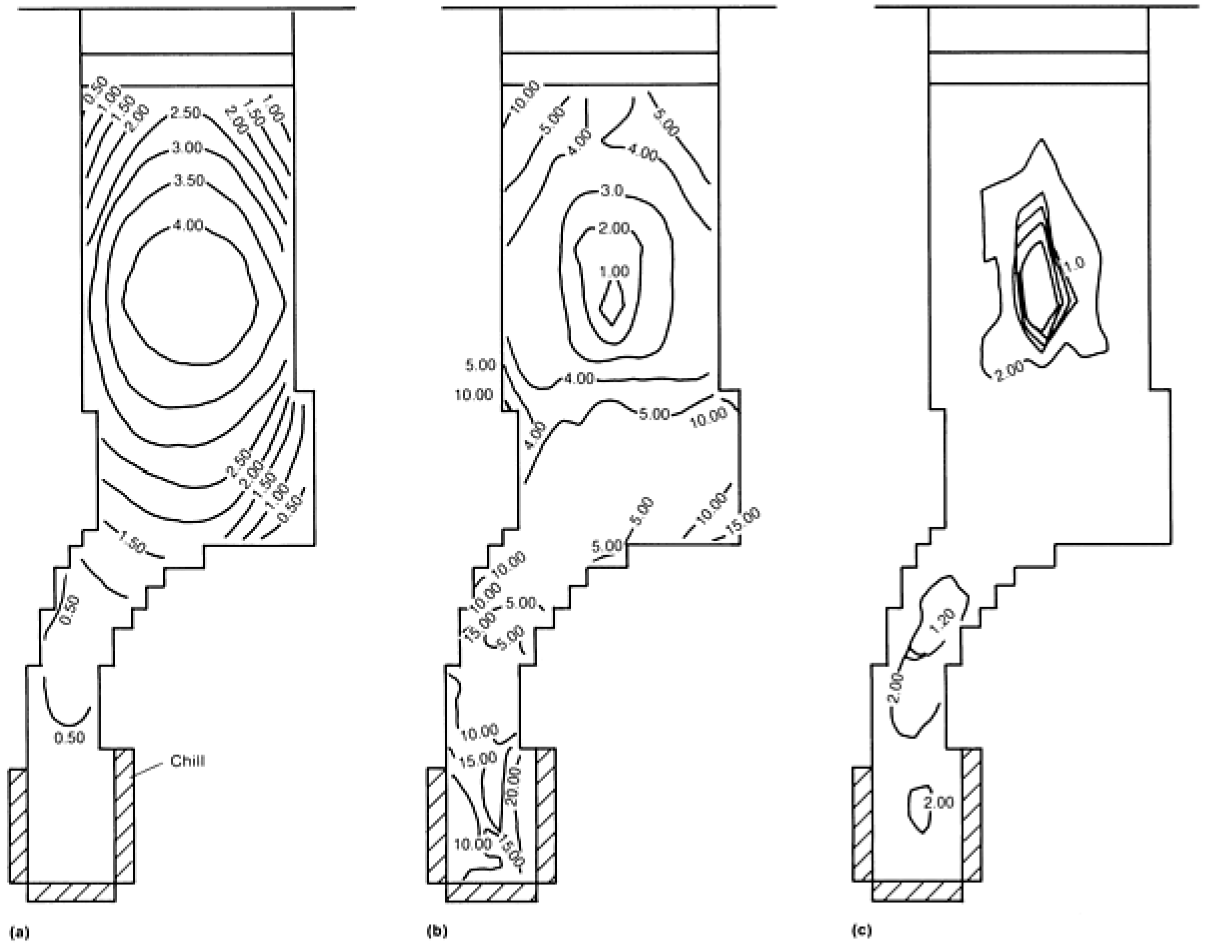

Fig. 15 Results of an FDM simulation of portions of a steel casting. Shown are local solidification time (hours), local temperature gradient during freezing (°C/cm), and a criterion function $G/\sqrt{R}$, where R is rate of cooling during freezing. The freezing isotherm suggests that shrinkage could occur in the upper half of the casting. The criterion function does not suggest shrinkage, and the casting was sound. Source: Ref 39

Outlook for the Future

As has been indicated, the most successful phase of bringing the computer to the foundry industry has involved the use of first-level personal-computer-supported planning-type software--for example, weight estimation, freezing order, and simple gating and risering calculations rather than full-scale simulation of freezing. Some such software items are now very comprehensive groups of programs and also permit the planning of pattern plate arrangement and part nesting.

Currently, a second, separate growth period is occurring that involves the application of minicomputer-supported, first-generation or subsequent CAD systems. Most of the software used is not tailored to a foundry, die sinking, or patternmaking environment. Therefore, to implement such systems, metal casting plants are undergoing serious changes. These changes involve the recruitment of a new type of computer-literate/technical person into the foundry team. Turning to the software itself, the majority of installations have been concerned with the improvement of tooling design and have only rarely involved solidification simulation. Some installations, however, have incorporated results of the personal-computer-supported software referred to above in connection with rigging design.

Although many organizations possess successfully applied CAD systems that have resulted in substantial savings in pattern and die tooling, other organizations procrastinate while asking:

- Will computer acquisition and maintenance costs decrease?
- Will software acquisition costs decrease?
- Will software capabilities increase?
- Will total user-friendliness increase?
- Will model-building times decrease?

Although these are not trivial questions, much is to be gained by early exposure to this new technology. At the same time, it must be observed that some of the CAD systems implemented have been examples of the first generation of such systems. They are mostly of a two-dimensional or two and a half dimensional type and often have associated volume-calculation-related limitations. Several of these systems have recently acquired solid-modeling capability, while other new systems are entering (or are about to enter) the market that are completely based on the solid-modeling approach discussed earlier in this article.

A third phase which is now beginning and is especially pertinent to this article, represents the implementation and growth of the low-cost high-flexibility mini/micro-supported computer-aided engineering system. This is most often based on the solid-modeler approach and is fully capable of being networked or linked with separate or parallel processing systems. With such systems, one can also undertake enmeshment for FEM-based stress analysis (performance checks) or with solidification simulation packages (castability checks).

One such system that is available and operating on personal computers permits the user to build a solid model of the part under development, to cut sections, to view from various angles, and to obtain drawings as hard copy if desired. More important, the two-dimensional or two and a half dimensional features of the part can then be enmeshed by accessing a new file that works on the information already implanted in the system describing external boundary geometry. All of the enmeshment and node-numbering information is also held in the small host computer memory. This system can be locally interfaced with a larger machine (for example, a mini-type computer) that can support an FEM program, where stress analysis or solidification simulation can be done. Upon completion of the chosen task, the computed information can be postprocessed on the large machine for viewing.

However, small (non-mainframe) machines generally involve difficulty with part complexity and long execution times. Part complexity is merely a function of contemporary computer capability, and long execution times may not be of primary importance for a foundry in which not all parts to be cast are of a supercritical nature. Consequently, an analysis of either stress distribution or heat transfer that runs overnight on a small machine may not be a great detriment. Similarly, the representation of the casting and the rigging using a personal-computer-based solid modeler may present no problems; the solid modeler can exchange files with a parallel system capable of generating the numerical control code needed to drive patternmaking or diemaking machinery. Although large-scale, mainframe-supported integrated systems are available with many or all of these capabilities, a significant expansion is expected in the area of micro/mini-based systems employing user-oriented software.

Looking ahead to the turn of the century, the dramatic advances currently taking place in this area should be fully realized, particularly the developments expected in the area of computing power. As chip technology moves into its next phase (10^9 devices per chip), the possibility of the personal computer handling 10 million instructions per second (mips) will become a reality. Because these specifications represent the limits of the capabilities of super-minis, computer mainframes will still be required for determining parameters of most complex components. In combination with developments in computer architecture, including parallel processing and beyond, one can anticipate that multiple simultaneous operations will become commonplace. Software specifically designed to exploit these developments is already evolving. Castings will be computer designed, planned, and rehearsed. On-line monitoring and control of melting,

liquid-metal pouring, solidification, and cooling of castings will be in place. Castings will be produced directly to near-net shapes and sections. Surface finishes of the cast product will be optimized. Finishing properties will also be predictable, leaving little to cut and try.

Modeling of Solidification Heat Transfer

Modeling of Fluid Flow

W.-S. Hwang, National Cheng Kung University, Taiwan; R.A. Stoehr, University of Pittsburgh

---

Introduction

FLUID FLOW MODELING is a technique that uses computers to investigate flow phenomena. These flow phenomena, particularly during the initial filling stage, have major effects on the quality of castings. Designers have commonly relied on experience, rule of thumb, and handbook information to achieve their objectives of smooth flow, proper filling time, minimum gas entrapment, elimination of inclusions and dross, and the desired distribution of metal during mold filling. The goal of improving the quality and cost-effectiveness of castings by means of computer-aided design (CAD) and modern process control requires that data be expressed more scientifically, so that they are amenable to computation.

Knowledge about fluid flow during the filling of castings is important not only in itself, but because it affects heat transfer both during and after filling. This must be taken into account in models of heat transfer and stress analysis in castings if they are to give the most accurate results.

It is difficult to make direct observations of fluid flow inside molds, because the molds and the molten metal are opaque, the temperatures are high, and the conditions are highly transient. Even when observations are made, as by the techniques described later in this article, the location of the metal as a function of time is usually the only information that can be obtained. Not only is fluid flow modeling using computers usually the most economical and practical way to get information about what is going on inside a mold during filling, it is often the only feasible way. Furthermore, it can give information about the velocity and pressure distributions within the molten metal which cannot be obtained by direct observation.

Computational techniques for modeling flow during mold filling can be divided into two categories (Ref 1):

- Energy balance techniques based on the Bernoulli equation and the Saint-Venant equations
- Momentum balance techniques based on the Navier-Stokes equations as embodied in the Marker-and-Cell group of programs which include the Marker-and-Cell (MAC), Simplified Marker-and-Cell (SMAC), and Solution Algorithm (SOLA) techniques

The energy balance techniques are most useful for modeling flow through sprues, runners, and gates when the direction of flow is dictated by the configuration of the system. The momentum balance techniques are needed for calculating flow inside mold cavities where the direction of flow and the location of the fluid must be calculated.

Energy Balance Methods

Because energy is a scalar rather than a vector quantity, these methods are primarily useful in determining flow rates in cases in which the direction of flow is established by the configuration of the system. The Bernoulli equation is used for calculating flow in completely filled channels such as sprues, pressurized runners, and gates, while the Saint-Venant equations are used for partially filled channels such as nonpressurized runners and troughs. Information provided by these calculations is extremely important to the design and manufacture of castings, and industry has used them routinely for many years. Now, CAD programs can apply these techniques to complicated systems with speed and accuracy.

A schematic of a gravity-filled casting system is shown in Fig. 1. The Bernoulli equation applicable to this system may be written (Ref 2):

$$\frac{P_j - P_i}{r} + \frac{V_j^2}{2b_j} - \frac{V_i^2}{2b_i} + g(Z_j - Z_i) + E_{f_{i,j}} = 0 \quad \textbf{(Eq 1)}$$

where P_i and P_j are pressures at positions *i* and *j*, V_i and V_j are mean velocities at positions *i* and *j*, z_i and z_j are elevations at positions *i* and *j*, b_i and b_j are velocity distribution factors (0.5 for laminar flow and 1.0 for highly turbulent flow), *g* is the acceleration due to gravity, ρis the fluid density, and $E\,f_{i,j}$ is the friction energy loss between positions *i* and *j.*

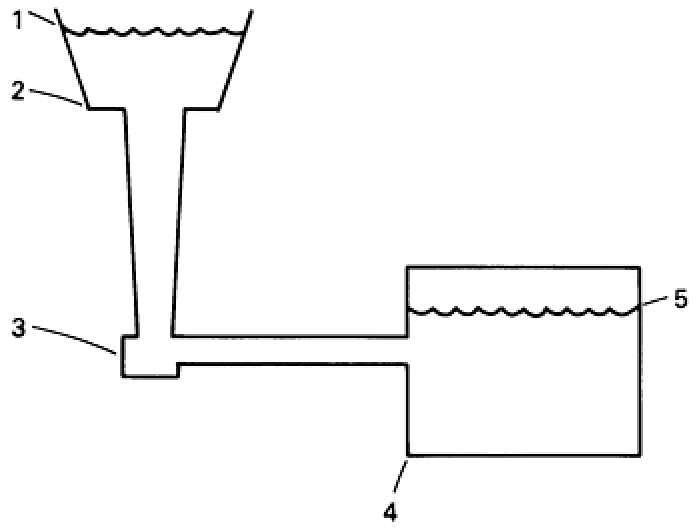

Fig. 1 Gravity-filled casting system analyzed by the Bernoulli equation approach. Numbered planes correspond to the subscripts used in Eq 1.

The friction energy loss term $E f_{i,j}$ is a function of the velocity, the Reynolds number, and the configuration of the system between positions *i* and *j* (Ref 2, 3, 4). The Reynolds (N_{Re}) number is defined by:

$$N_{\text{Re}} = \frac{VD_e}{n} \qquad \textbf{(Eq 2)}$$

where ν is the kinematic viscosity and D_e is the equivalent diameter.

The configuration of the system may change from point to point resulting in variations of the velocity and the N_{Re}.Thus, $E f_{i,j}$ must be calculated for each segment of the system and then summed for the whole system.

For some uses, it is not necessary to consider friction energy loss. For example, the calculation of sprue taper (Fig. 2) is often done without it (Ref 5). The objective is to calculate the change in the cross section of a vertical sprue that will compensate for the acceleration of the molten metal as it drops through the sprue under the influence of gravity. This yields the following equations for the ratio of the cross-sectional areas at the top (A_2) and bottom (A_3) of the sprue, or for the diameters of a round sprue at the same points:

$$\frac{A_3}{A_2} = \sqrt{\frac{Z_1 - Z_2}{Z_1 - Z_3}} \text{ or } \frac{D_3}{D_2} = \sqrt[4]{\frac{Z_1 - Z_2}{Z_1 - Z_3}} \qquad \textbf{(Eq 3)}$$

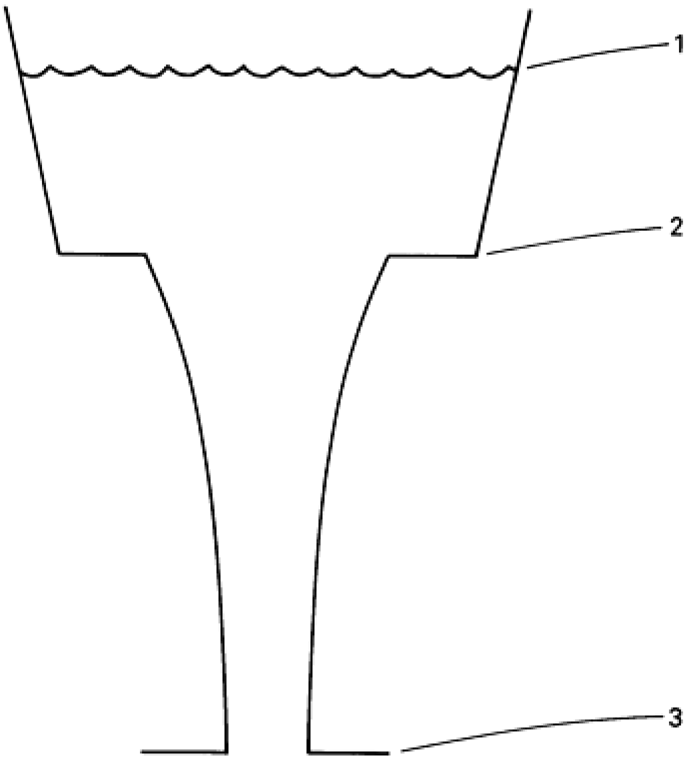

Fig. 2 Sprue taper needed to compensate for the acceleration of molten metal in gravity feed calculated using Eq 3 or Eq 4. Numbered planes correspond to subscripts in either equation.

If friction is considered, this equation is modified to:

$$A_3/A_2 = \{(z_1 - z_2)/[z_1 - z_3 - (z_1 - z_2)e\,f_{2,3} + (z_2 - z_3)e\,f_{1,2}]\}^{1/2} \quad \textbf{(Eq 4)}$$

where the $e\,f_{i,j}$ are friction energy loss coefficients such that: $E\,f_{i,j} = \frac{1}{2} e\,f_{i,j}\ f_2^2$. Introduction of a friction energy loss $e\,f_{2,3}$ within the sprue reduces the taper required, while a friction energy loss $e\,f_{1,2}$ above the sprue increases it.

In nonferrous casting, it is common practice to use nonpressurized filling systems in which the runners are only partially filled with liquid metal. These can be modeled with the Saint-Venant equations (Ref 6), which are useful when the bottom of the channel and the free top surface of the stream slope at different angles (Fig. 3). They are also used when the flow rate and the top surface of the stream vary with time. The equation of continuity is written:

$$W_T \frac{\partial Y}{\partial t} + \frac{\partial (VA)}{\partial X} = 0 \quad \textbf{(Eq 5)}$$

where W_T is the width of the channel at flow depth Y, t is time, and VA is the product of velocity and fluid cross-sectional area (that is, the volumetric flow rate).

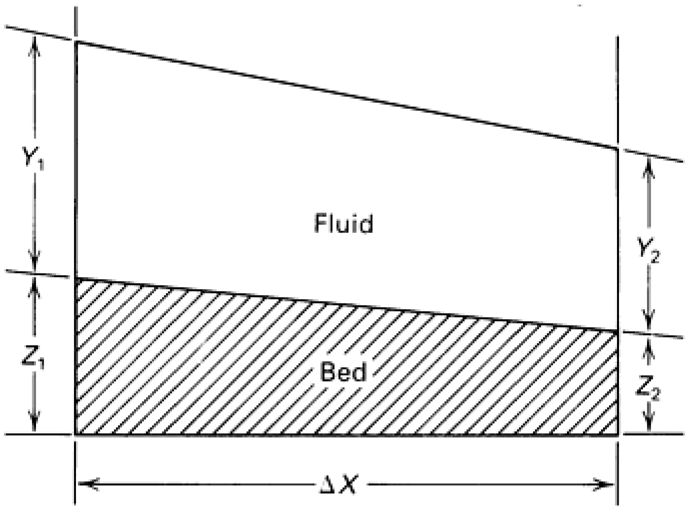

Fig. 3 Bottom of a partially filled runner or open channel (designated by cross-hatched area, or bed) having a slope of (Z_1 - Z_2)/Δ*X* and fluid depth of Y_i.

The equation of motion for the steady state case may be written:

$$\frac{V}{g}\frac{\partial V}{\partial X}+\frac{\partial Y}{\partial X}-S_o+S_f=0 \qquad \textbf{(Eq 6)}$$

where the actual slope of the bottom of the runner S_o is:

$$S_o=\frac{Z_1-Z_2}{\Delta X} \qquad \textbf{(Eq 7)}$$

and the so-called friction slope S_f is defined by:

$$S_f=\frac{n^2V^2}{R_h^{4/3}} \qquad \textbf{(Eq 8)}$$

where R_h is the hydraulic radius and *n* is Manning's roughness coefficient, the values of which are determined empirically using similarity principles.

For the time-dependent case, the equation of motion may be written:

$$d\left(Z+Y+\frac{V^2}{2g}\right)=-S_f dX-\frac{1}{g}.\frac{\partial V}{\partial t}dX \qquad \textbf{(Eq 9)}$$

in which the last term represents the acceleration.

Note that the roughness factor *n* takes into account the channel configuration as well as the surface roughness and may change frequently along the course of the channel. It is larger at the tip of the entering stream than in areas already containing a layer of molten metal.

For CAD and analysis of mold-filling systems, the Bernoulli and/or Saint-Venant representations of each of the individual sections of the system can be combined into a network of series and parallel paths. The friction energy loss factors and the friction slopes must be obtained from empirically derived correlations with the N_{Re} and other dimensionless numbers. Their use commonly calls for iterative solutions, because they are functions of the velocity and free surface height, which are dependent variables one seeks to determine. The literature most often presents the necessary empirical correlations in graphs (Ref 7). The relationships represented by the graphs can be reduced to a set of parametric equations for use by the computer. For example, the information shown in Fig. 4 may be reduced to:

$$\begin{aligned} e_b = \{&[(-0.194 \times 10^{-6}\beta - 0.246 \times 10^{-3})\beta + 0.0368]\beta \\ &- 0.184 + 0.03125/[(\beta - 6.1)^4 + 1.25] \\ &+ (4.529\beta^2 - 91.75\beta + 464.9)/(\beta^4 - 20\,\beta^3 \\ &+ 126.7\beta^2 - 500\beta + 2542)\}(1 - \sigma^2) \\ &+ 1.5/[(51\sigma - 17.87)^2 + (\beta - 29)^2 + 33.3] \\ &- 2/[(17.32\sigma - 5.196)^2 + (\beta - 60)^2 + 100] \end{aligned} \qquad \text{(Eq 10)}$$

where e_b is the head loss coefficient, β is the angle shown in Fig. 4, and σ is A_S/A_L. In spite of its complicated appearance, the solution may be found very swiftly on any computer.

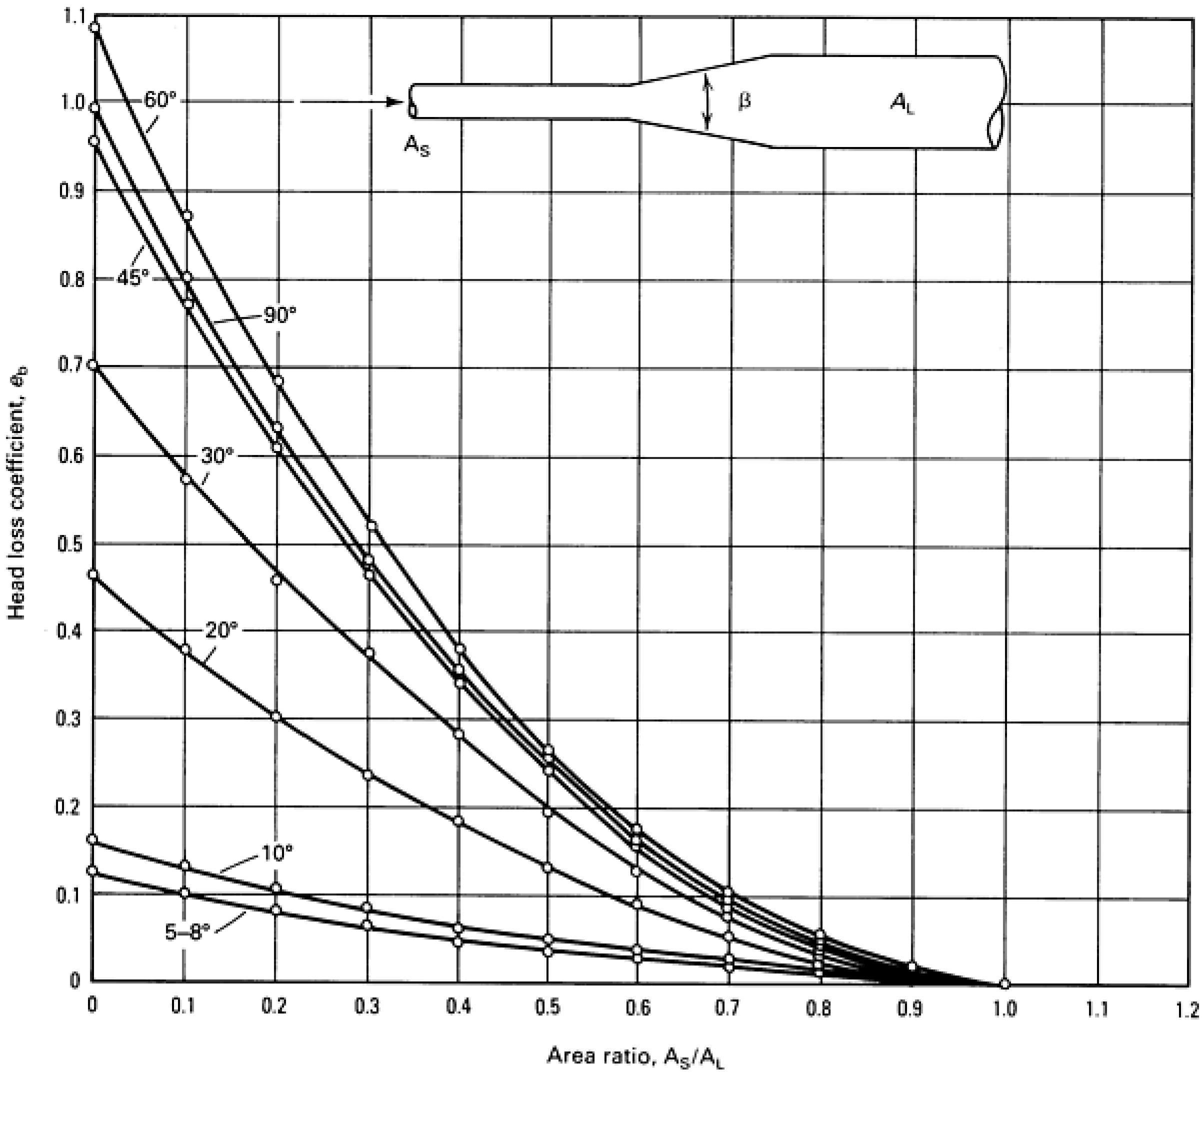

Fig. 4 Head loss coefficient for a gradual enlargement plotted as a function of the area ratio ($\sigma = A_S/A_L$) and the angle β. Open circles indicate selected e_b values obtained using Eq 10. Source: Ref 7.

The Bernoulli and Saint-Venant equations can be used in a design program that includes the rules of good practice frequently used in the foundry industry. From experience, for example, rules have been established that specify the acceptable range of filling times for castings of a given type as a function of the casting weight. These rules also suggest a certain size for the sprue, one for the runner, and one for the gate, which can be used to produce an initial design. The accuracy can then be verified by performing the energy balance calculation described above (Eq 10). The design can be modified and the energy balance calculation performed again until the calculated result agrees with the desired filling rate. This technique allows special plant conditions to be considered, such as limitations on the amount of molten metal available at one time, and limitations on the flasks and patterns available for making the mold.

This type of modeling of metal flow during mold filling has been integrated into CAD systems that produce finished drawings for the pattern and mold shops. In some cases they even produce numerical-control (NC) tapes for cutting the pattern. An example of a drawing for the pouring basin, sprue, runner, and gates for a particular casting is shown in Fig. 5.

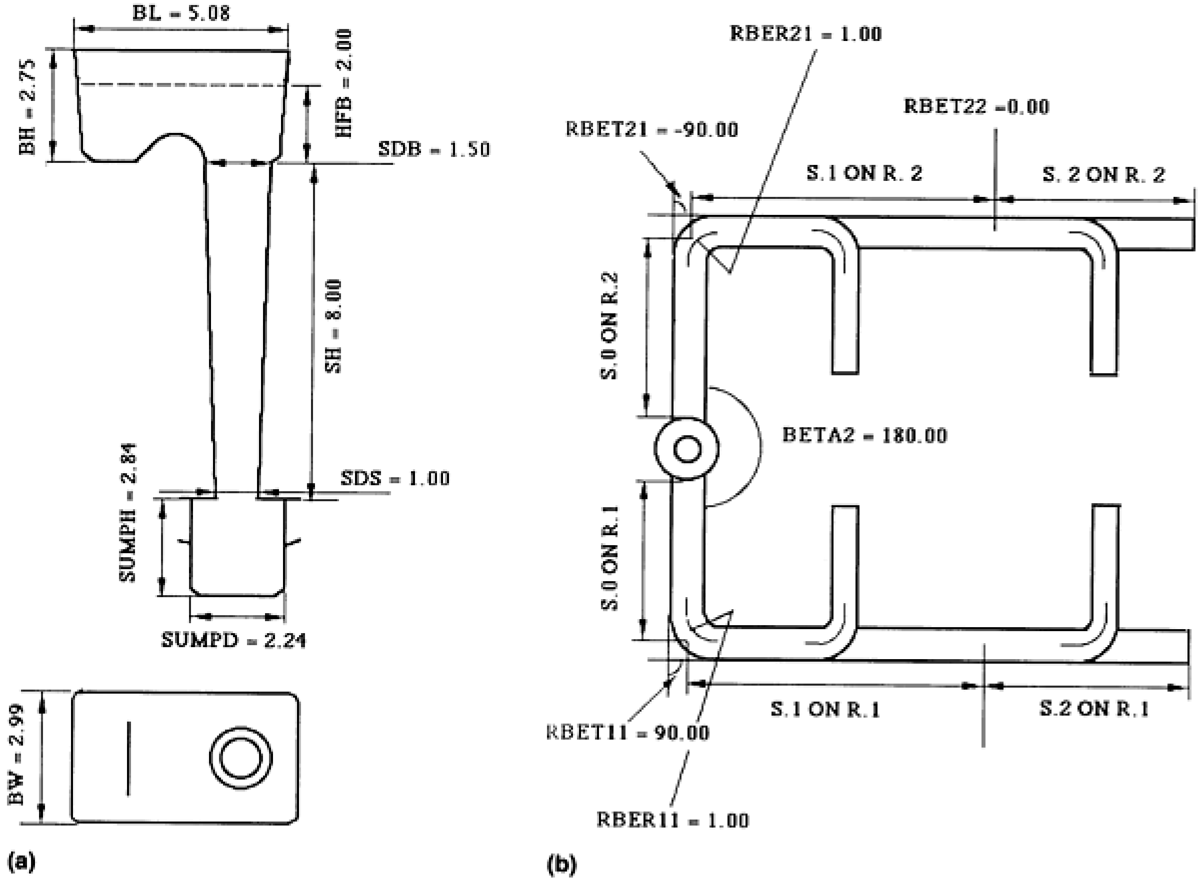

Fig. 5 Typical layouts of a mold-filling system obtained from a CAD program based on sound foundry industry practice and refinements by Bernoulli and Saint-Venant equations. (a) Pouring basin, sprue, and sprue base layout. (b) Runner-gate layout. Dimensions given in inches.

Physical Modeling of Mold Filling

It is important to verify computational models of mold filling with physical experiments. Physical modeling of metal flow is most often done with water in transparent molds. Water is a suitable fluid model because its kinematic viscosity is nearly the same as that of common metals at their normal pouring temperatures, especially if the temperature of the water is properly controlled. For example, the kinematic viscosity of water at 35 °C (95 °F) is the same as that of 0.5%C steel at 870 °C (1600 °F) (Ref 8). To model the flow of liquids influenced by inertial, viscous, and gravitational forces requires N_{Re} and Froude number, N_{Fr}, similarities, in which the Froude number is defined as $N_{Fr} = V^2/gL$, where L is the characteristic dimension of the system. This is obtained when water at the temperature to achieve proper kinematic viscosity is used in models of the same size as the real system. The application of water models to mold filling is illustrated in several high-speed motion picture studies of gravity-filling (Ref 9, 10) and die casting systems (Ref 11).

It is possible to observe the flow of actual metals into molds from x-ray cinematography studies (Ref 12). Greater detail of the flow of metal into sand molds was observed by filming with a high speed motion picture camera focused through a plate glass window on the side of the mold (Ref 13). Molten cast iron entering a silica sand mold was filmed with this technique. The molten metal locations traced from these films will be shown in the section "Correlations With Actual Metal Flow."

Recently, computerized data acquisition systems have been used to observe the flow of molten metal into nontransparent three-dimensional molds (Ref 14, 15). Two types of sensors have been used: simple contact wires and thermocouples. The simple contact wires are connected to the digital inputs of the data acquisition unit. Molten metal contacting a bare copper wire completes a circuit, and this is then detected by the data acquisition unit. The digital inputs can be read very rapidly by the computer; it is possible to read hundreds of such contact points many times during the filling of a single mold. An accurate picture of the location of the metal at any time can be developed from these data. A clever system for using a finite element postprocessor for presenting the results of such experiments has been reported (Ref 14). Figure 6 shows such a result.

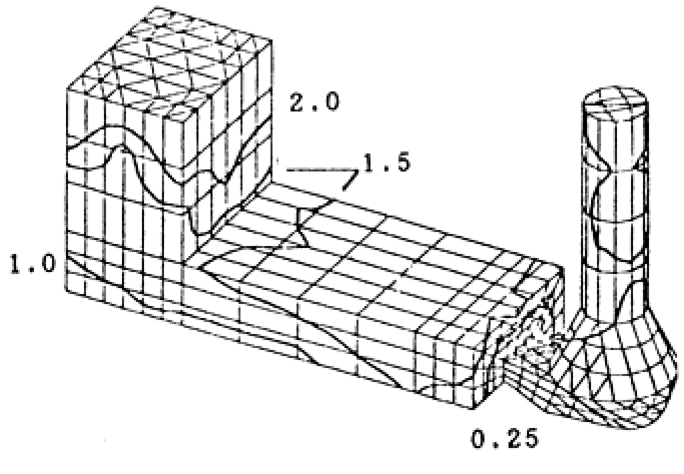

Fig. 6 Three-dimensional visualization of molten metal locations determined by the contact wire method and displayed by a finite-element postprocessor. Numbers in the figure are filling times in seconds. Source: Ref 14.

Thermocouples can be used alone or in conjunction with the contact wire sensors. Although they give more information than do simple contact wires, thermocouples produce an analog signal that takes longer to read. The combination of contact wires and thermocouples is particularly useful for observing the flow and solidification patterns in thin-wall castings having the problem of premature freezing (namely, cold shuts).

Modeling of Fluid Flow

W.-S. Hwang, National Cheng Kung University, Taiwan; R.A. Stoehr, University of Pittsburgh

Momentum Balance Techniques

Fluid flow within the mold cavity during filling is transient; the amount and location of the liquid changes rapidly. Calculation of the location of the liquid and the orientation of its free surface must be an integral part of the computational techniques used to model it. The family of computational techniques called MAC (Ref 16), SMAC (Ref 17), and solution algorithm-volume of fluid (SOLA-VOF) (Ref 18) are well suited for handling these problems. Although they differ from each other in the way they keep track of the location of the free surface and the way in which they perform some of the internal iterations, they are based on the same principles. To simplify the discussion, the acronym MAC is used to represent this whole family of computational fluid dynamics techniques.

MAC Technique Highlights

MAC uses a finite-difference scheme for the mathematical analysis of fluid flow problems (Ref 19). Like most of these techniques, MAC first divides the system (that is, the configuration of the casting cavity under discussion) into a number of subdivisions, called cells, which are usually rectangular. Then a set of imaginary markers (in MAC and SMAC) or fluid function values called F (in SOLA-VOF) is introduced into the system to represent the location of the fluid at any instant. Figure 7 shows the division of the system into cells and the representation of the fluid domain with markers, while Fig. 8 shows a portion of the fluid domain with the fluid function F (see the section "Fluid Domain Identification" below). The velocity field of the moving fluid domain can be calculated by the application of fluid dynamics principles. Next, the markers are moved, or the fluid function is updated, according to the calculated velocity field in order to represent the new location of the fluid domain. This procedure can be repeated from the beginning when the cavity is empty until it is completely filled.

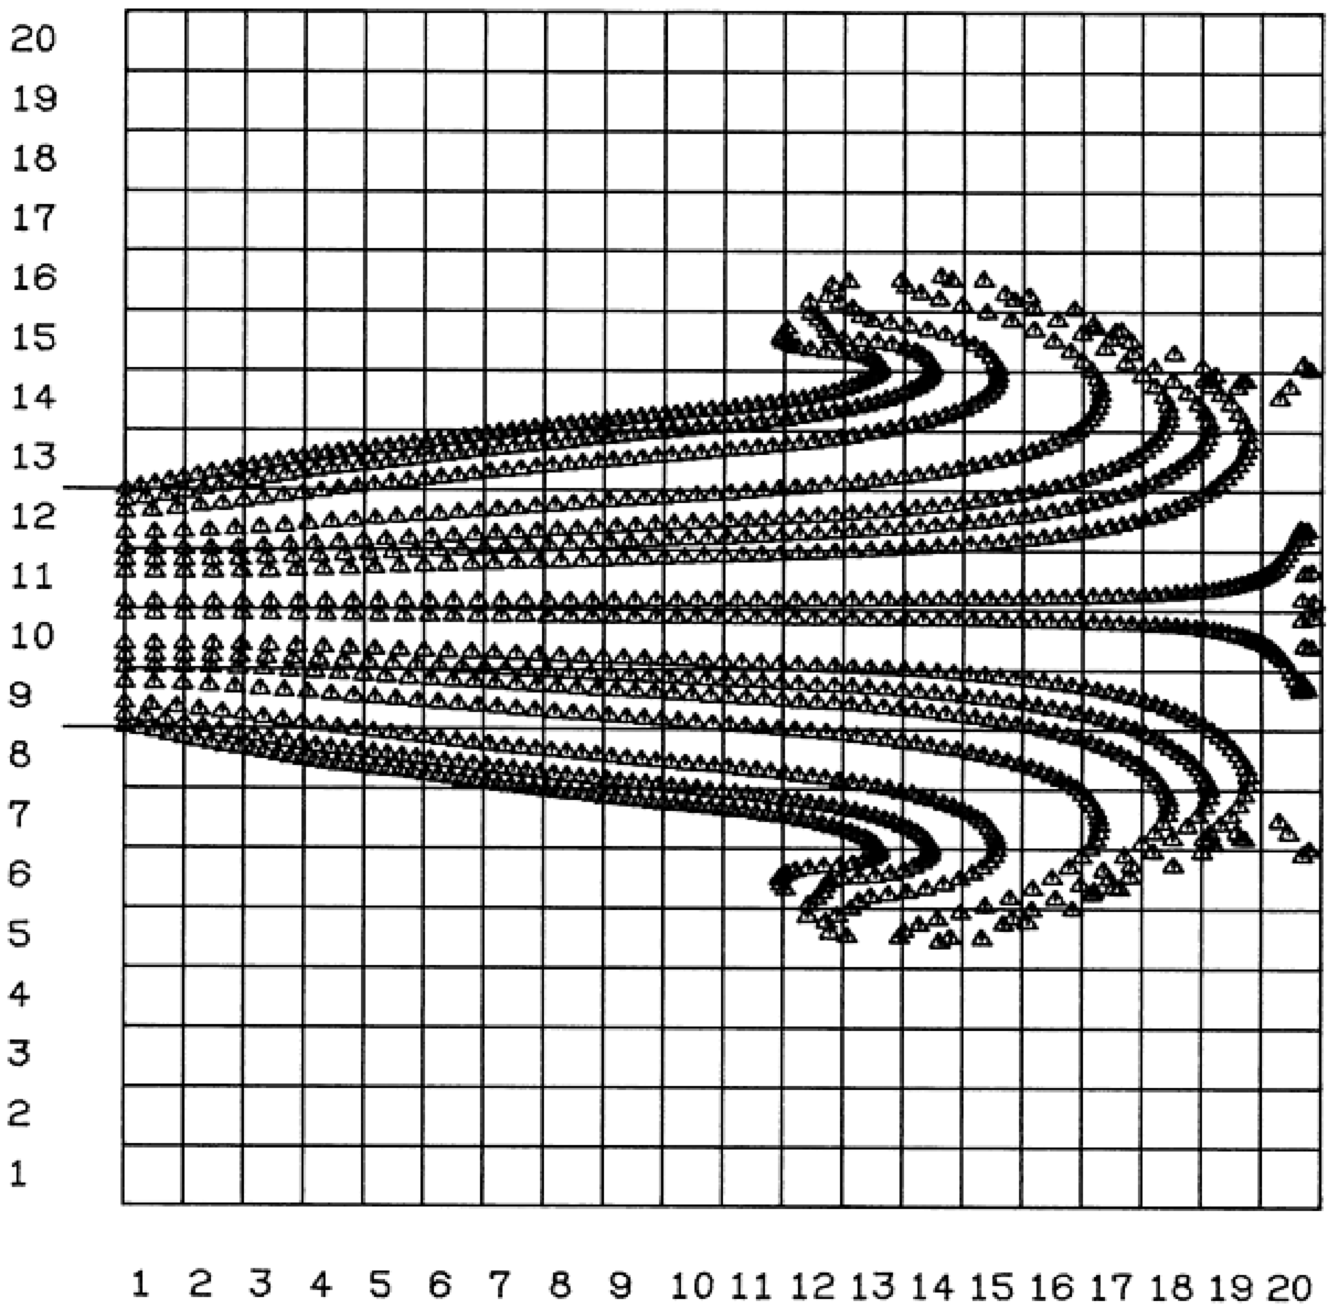

Fig. 7 Flow pattern obtained 3.95 s after pouring begins showing MAC cell divisions and fluid domain locations (indicated by triangular markers).

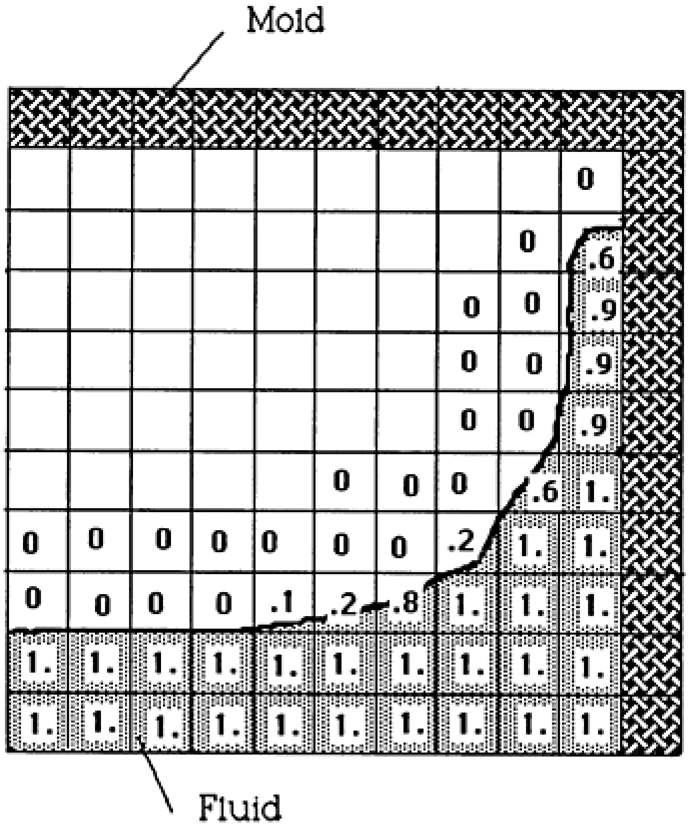

Fig. 8 Fluid domain plot obtained with the fluid function *F* using the SOLA-VOF technique. $F = 1.0$, $0.0 < F < 1.0$, and $F = 0$ indicate full, surface, and empty cells, respectively.

Fluid Domain Identification

In MAC, the cells are designated as full, surface, or empty, based on the location of markers or the distribution of the fluid function. With the marker approach, a full cell is one that contains at least one marker, if all of its neighboring cells contain markers as well. A surface cell contains at least one marker, but has at least one neighbor without any markers. An empty cell is any cell with no markers.

With the fluid function technique, *F* represents the fraction of the volume of a cell that is filled with fluid. *F* can have values from 0 to 1. *F* is 1 for a full cell, 0 for an empty cell, and some fractional value for surface cells. The fluid function *F* can also be used to calculate the approximate location and orientation of the free surface of the fluid. Collectively, the full cells constitute the interior region, and the surface cells constitute the surface regions.

Calculating Velocity Field in Moving Molten Metal

After the flow domain and the corresponding interior and surface regions of the domain have been identified, the velocity and pressure fields within the flow domain are calculated. The physical conditions that govern the flow behavior in the interior regions are somewhat different from those in the surface regions.

Interior-Region Flow Behavior. In the interior regions, the following principles should be obeyed in a cell volume:

Mass Flow In Equals Mass Flow Out. This is due to the incompressible nature of molten metal. This gives the following form of the continuity equation in two dimensions:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \qquad \textbf{(Eq 11)}$$

where u and v are the velocity components in the *x*- and *y*-directions.

Momentum Change Equals Momentum In Minus Momentum Out. In mathematical form this is:

In the *x*-direction:

$$\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-\frac{\partial p}{\partial x}+v\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right)+g_x \qquad \textbf{(Eq 12)}$$

In the *y*-direction:

$$\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}=-\frac{\partial p}{\partial y}+v\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right)+g_y \qquad \textbf{(Eq 13)}$$

where *t* is time, *p* is pressure/density, *v* is viscosity/density, and *g* is the acceleration of gravity. Equations 12 and 13 are commonly called the Navier-Stokes equations. In case of turbulent flow, *v* may be replaced by the effective viscosity. The velocity and pressure fields for the interior region are calculated using these three governing equations and the finite-difference technique.

Surface Region Flow Behavior. In the surface region, the momentum balance principle, and thus Eq 12 and 13, still applies. However, Eq 11 is not valid because the mass within the cells of the surface region is changing. Instead, the surface region contains the interface between the molten metal and the atmosphere surrounding it, and free surface boundary conditions should be obeyed. This means that:

Tangential Stress on the Free Surface Should Vanish. This may be expressed by:

$$v\left[2n_x m_x\frac{\partial u}{\partial x}+(n_x m_y+n_y m_x\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)+2n_y m_y\frac{\partial v}{\partial y}\right]=0 \qquad \textbf{(Eq 14)}$$

where n_x, n_y, m_x, m_y are the *x* and *y* components of the unit vectors normal to and tangent to the free surface, as shown in Fig. 9.

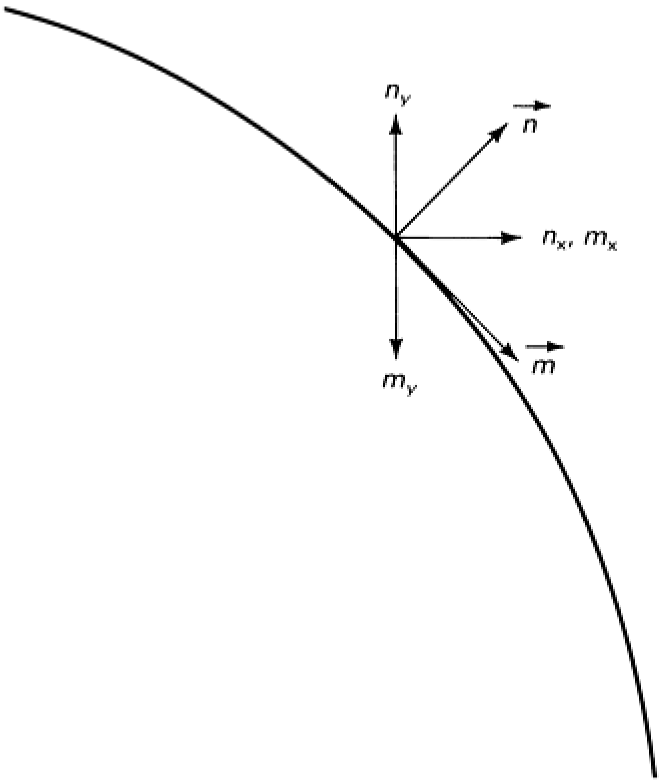

Fig. 9 Orientation of the free surface represented in Eq 14 and Eq 15.

Normal Stress Should Balance the Applied Pressure Plus the Surface Tension. This may be expressed by:

$$2v\left[n_x n_x \frac{\partial u}{\partial x} + n_x n_y \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) + n_y n_y \frac{\partial v}{\partial y}\right] = p + p_s \quad \textbf{(Eq 15)}$$

where p_a is the applied gas pressure in the empty region and p_s is the surface tension pressure. The flow field in the surface region is calculated using these principles.

Fluid Flow Phenomena in the Filling of Metal Castings

Fluid flow calculations can help gain an understanding of flow phenomena occurring during mold filling (Ref 10). To illustrate this, the results of MAC calculations applied to some simple mold designs are presented below. All of the designs have thin cross sections so that the metal flow is restricted to two dimensions. (Although the MAC technique can be applied to three dimensions, it requires a lot of computer time, so most of the computations of metal flow have been done in two dimensions.)

Example 1: Filling of a Large, Horizontal Square Plate Casting.

The first case is a horizontal square plate 610 × 610 mm (2 × 2 ft), with a 122 mm (0.4 ft) wide ingate at the center of the left wall, through which metal enters at 305 mm/s (1 ft/s). The mold fills in 10 s. For numerical analysis, the casting was divided into 400 square cells (20 in each direction). Results of the computation (Fig. 10) show that as the metal enters the mold, the stream expands slightly before reaching the far wall. Upon reaching the wall, the stream splits in two, building up along the far side of the cavity and then reflecting back toward the ingate. The two vortices that form, one on either side of the gate, are the last regions to fill, and any gases in the mold are squeezed to these areas near the end of the filling process.

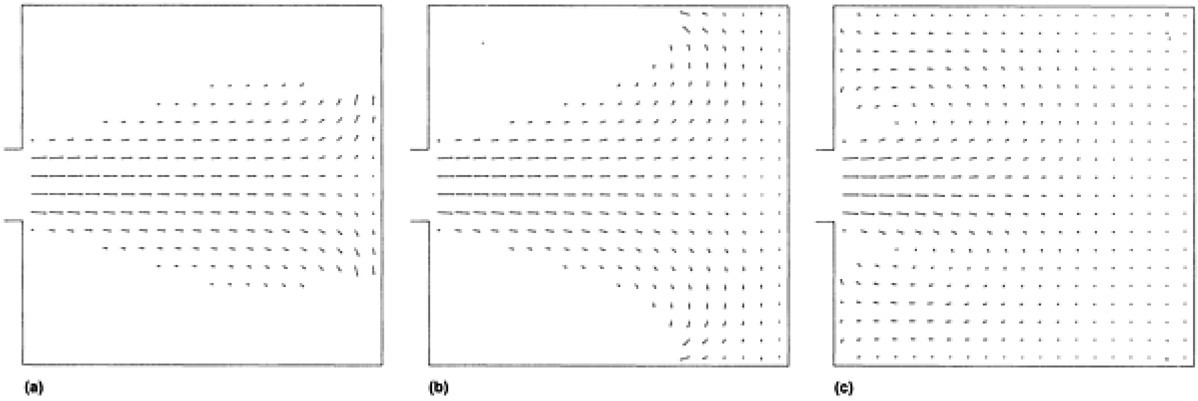

Fig. 10 Vector plot showing flow patterns and velocity profiles obtained when filling a horizontal 610 × 610 mm (2 × 2 ft) square plate casting. Entrance velocity was 305 mm/s (1 ft/s), and vector plots shown are at elapsed times. (a) 3.95 s. (b) 5.45 s. (c) 9.95 s.

Example 2: Filling of a Small, Horizontal Square Plate Casting.

The second casting is similar but smaller, and it demonstrates the effect of size (and/or relative entrance velocity) on the flow pattern (Fig. 11). The cavity is 61.0 × 61.0 mm (0.2 × 0.2 ft) with an ingate 12.2 mm (0.04 ft) wide. The entrance velocity, again, is 305 mm/s (1 ft/s), so it fills in 1.0 s. For computation, the system is divided into 400 cells. The flow pattern is quite different. Metal enters the mold like a jet, hitting the opposite wall before spreading. When the jet hits the wall, it flows rapidly outward in two symmetrical streams that cling much closer to the wall than in the previous case. These streams race back against the side walls, then along the ingate wall, where they encounter the incoming jet. In contrast to Example 1, the last areas to fill are much farther from the ingate, and the vortices, one on either side of the centerline, are somewhat larger. Also, the calculations show that the initial momentum is directed at a small area of the opposite wall, resulting in high pressures and the possibility of mold erosion.

(c)

Fig. 11 Vector plot showing flow patterns and velocity profiles obtained when filling a horizontal 61.0 × 61.0 mm (0.2 × 0.2 ft) square plate casting. Entrance velocity was 305 mm/s (1 ft/s), and vector plots are shown at elapsed times. (a) 0.299 s. (b) 0.599 s. (c) 0.879 s.

Example 3: Filling of a Vertical Square Plate Casting to Illustrate the Effect of Gravity on Flow Pattern.

The third design demonstrates the capability of the model to include the influence of gravity, or other body forces. It is a vertical square plate 152 × 152 mm (0.5 × 0.5 ft) with a 38.1 mm (0.125 ft) wide ingate located at the lower left corner. The velocity varies from 975 mm/s (3.2 ft/s) to 518 mm/s (1.7 ft/s), depending on the metal level and gas pressure in the mold. The entrance velocity is determined by coupling a Bernoulli equation calculation for flow through the filling system with the MAC calculation for flow within the mold. This casting also was divided into 400 equal-size square cells for computation. The results of the simulations (Fig. 12) show the melt enters as a bore with a sloping top surface. When it hits the opposite wall, it jumps up the wall about 0.8 of the distance to the top, rolling back over on the incoming stream and forming a strong vortex. Then it jumps up the wall above the ingate, and a wave works its way from side to side. The last area to fill is the top left corner. This flow behavior has been verified by high-speed movies of a water model, some frames of which are shown in Fig. 13. An actual casting of Al-7.5Si alloy made in a sand mold of this design showed low density in the area where the vortex was last located and entrapped gas porosity in the last area to fill. A photograph and a radiograph of this casting are shown in Fig. 14.

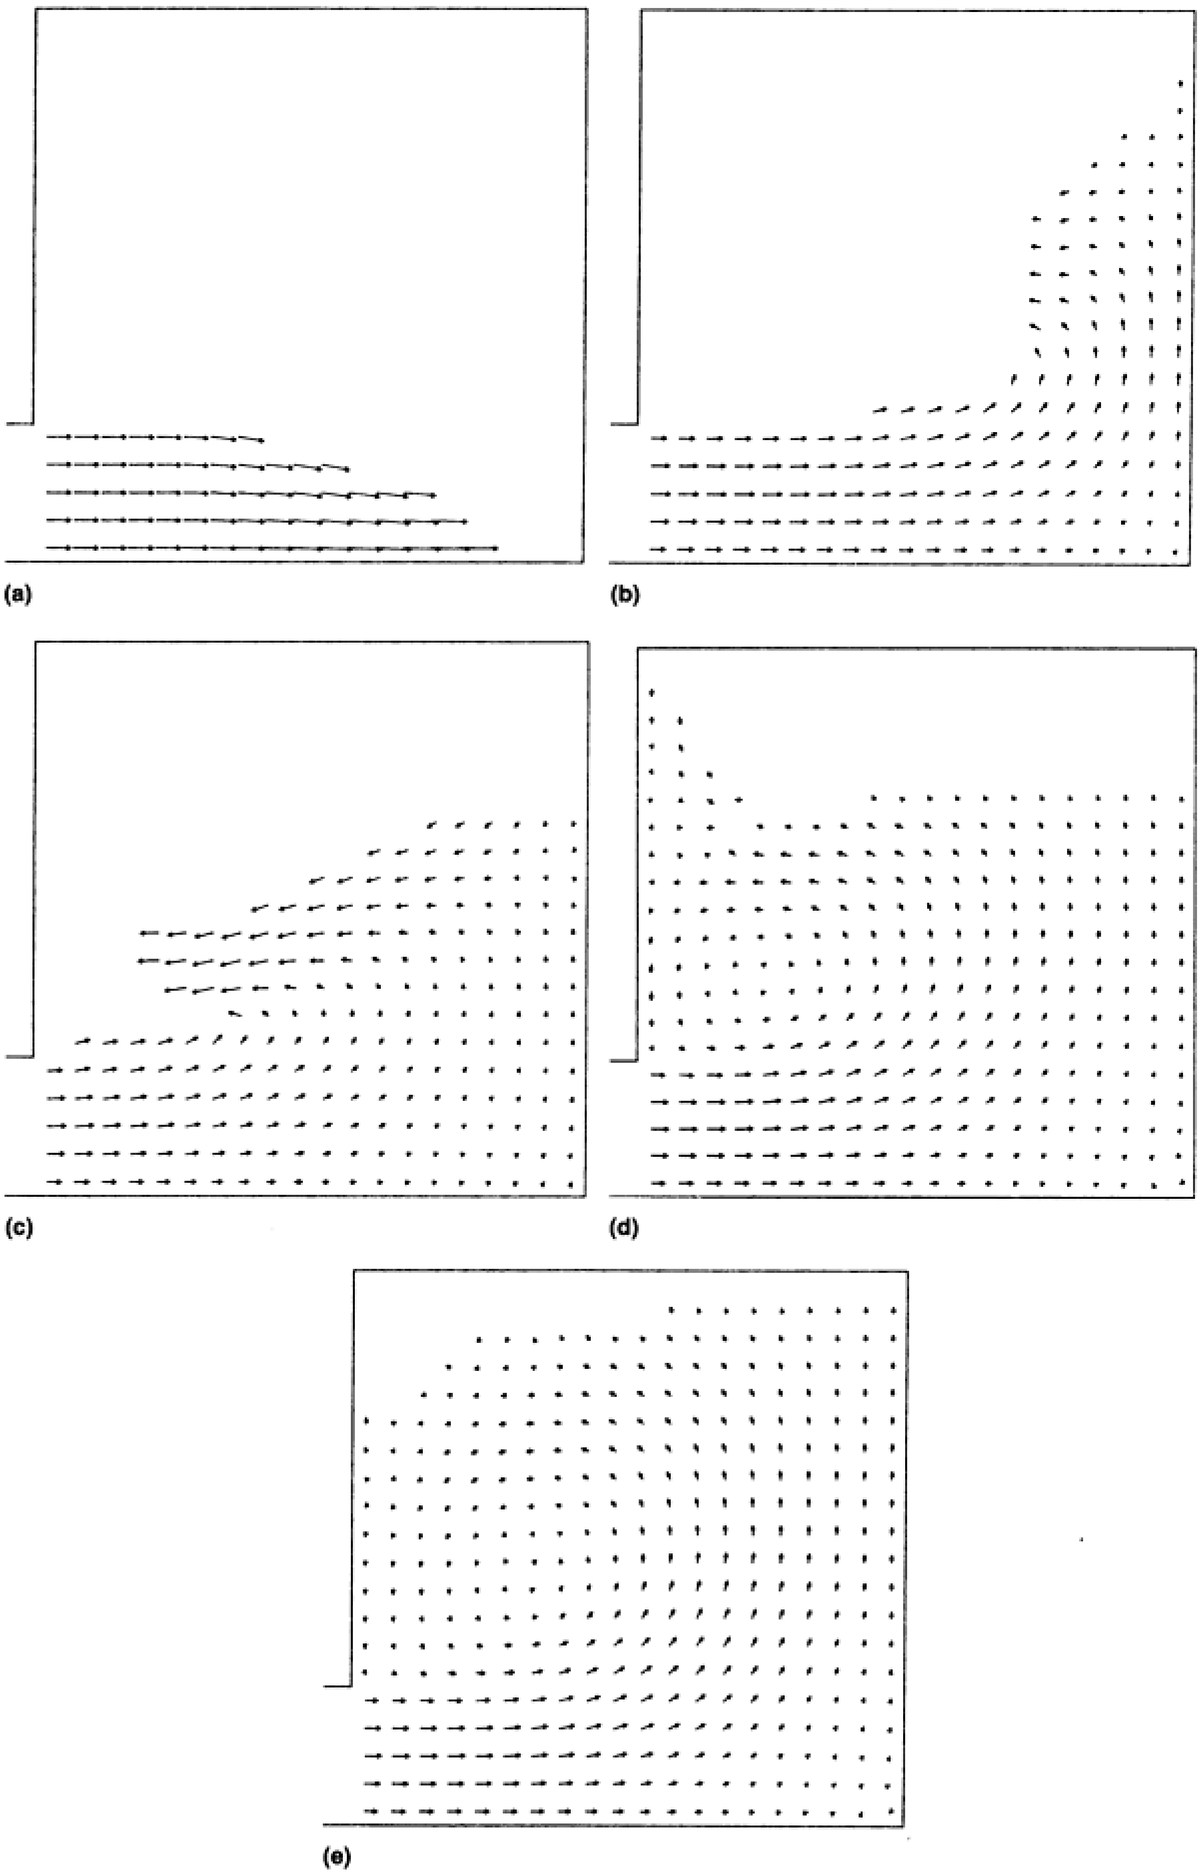

Fig. 12 Vector plot showing flow patterns and velocity profiles obtained when filling a vertical 152 × 152 mm

(0.5 × 0.5 ft) square plate casting. Entrance velocity is determined by Bernoulli equation calculation and varies from 975 mm/s (3.2 ft/s) to 518 mm/s (1.7 ft/s). Plots are shown at elapsed time. (a) 0.10 s. (b) 0.32 s. (c) 0.42 s. (d) 0.62 s. (e) 0.76 s.

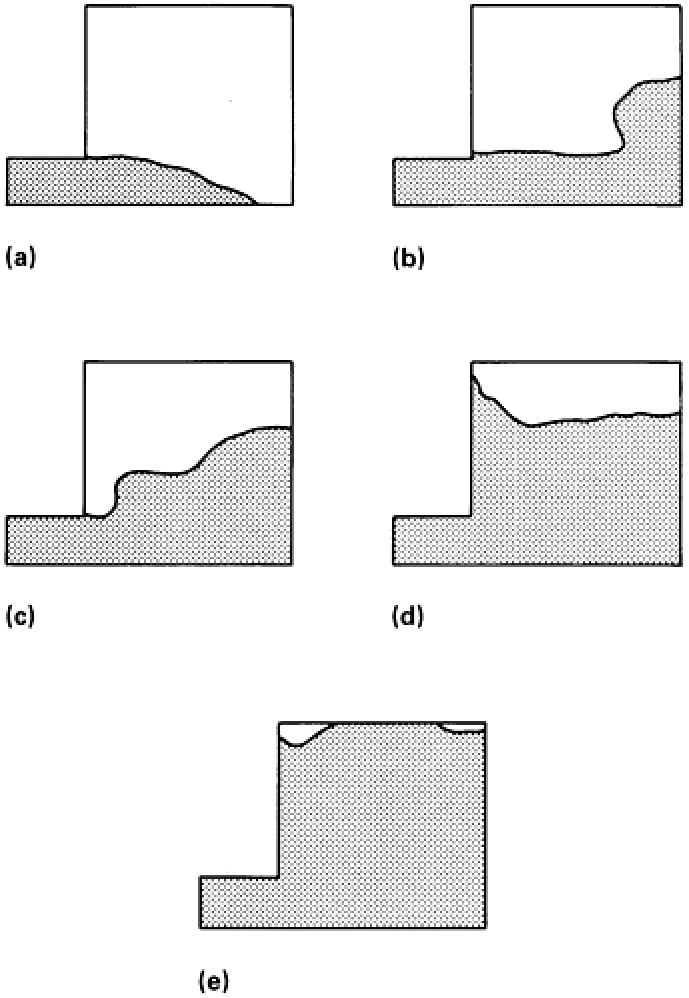

Fig. 13 Tracings of still photographs from a high-speed motion picture of a water model of the vertical 152 × 152 mm (0.5 × 0.5 ft) square plate casting calculated in Fig. 12. (a) 0.10 s. (b) 0.30 s. (c) 0.45 s. (d) 0.65 s. (e) 0.90 s.

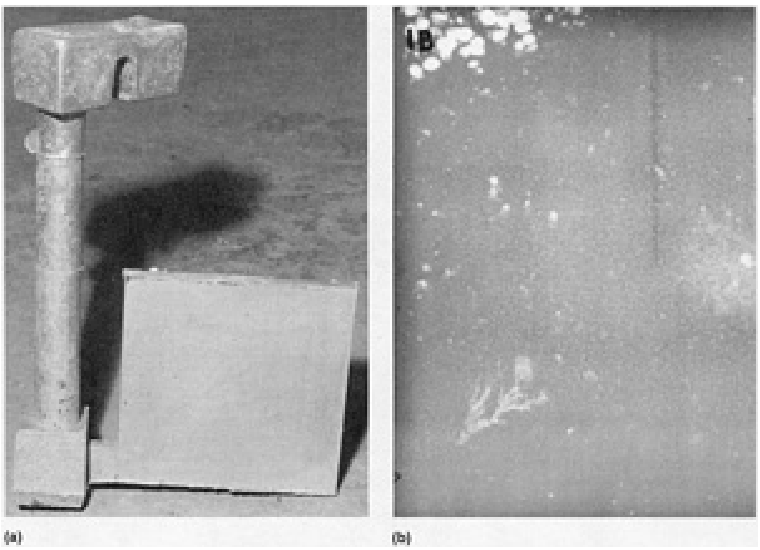

Fig. 14 Photograph (a) and radiograph (b) of an Al-7.5Si alloy casting produced in a vertical square plate mold identical to that used to obtain Fig. 12 and Fig. 13 data. The radiograph shows a large accumulation of gas bubbles in the last area to be filled by the alloy.

Example 4: Filling of a Vertical Stepped Plate Casting.

The design and dimensions of a somewhat more complicated mold are shown in Fig. 15. It is a plate casting with steps on the bottom. The entrance velocity starts at 975 mm/s (3.2 ft/s) and gradually decreases as the level of molten metal and the gas pressure build up in the mold. The calculated results shown in Fig. 16 indicate that the metal forms a vortex beneath the ingate (which is located above the bottom in this case) and standing waves above each of the steps. Before the flow reaches the far end of the mold, metal begins to rise in the vertical section (which represents a riser), and another vortex forms in this region. This flow pattern has been verified by high-speed movies of a water model.

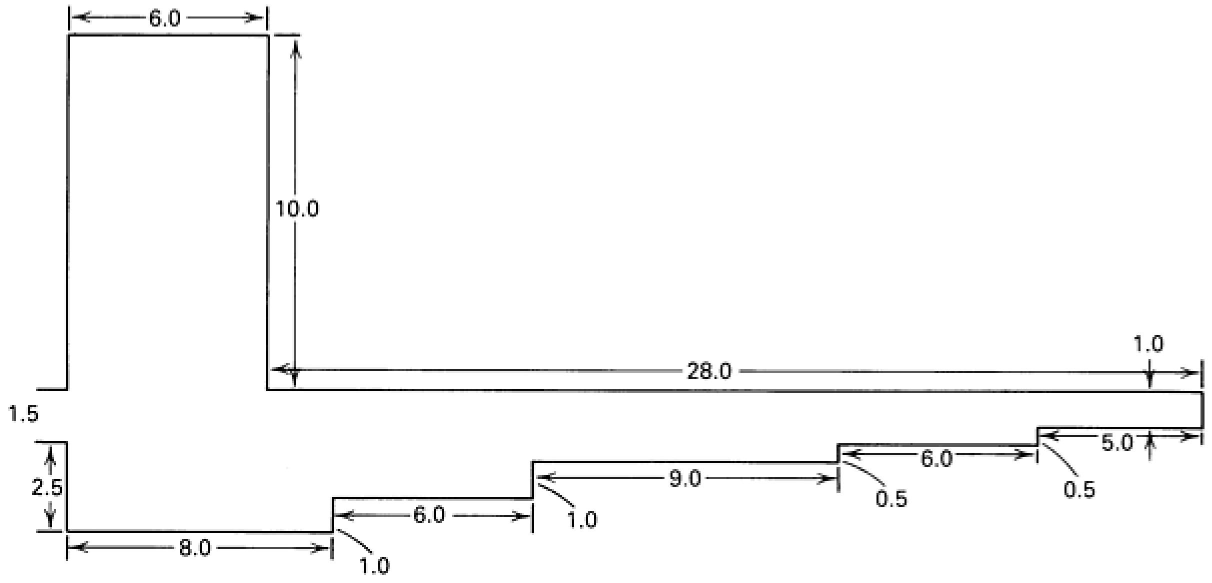

Fig. 15 Configuration and dimensions of a vertical stepped plate mold. Dimensions given in inches.

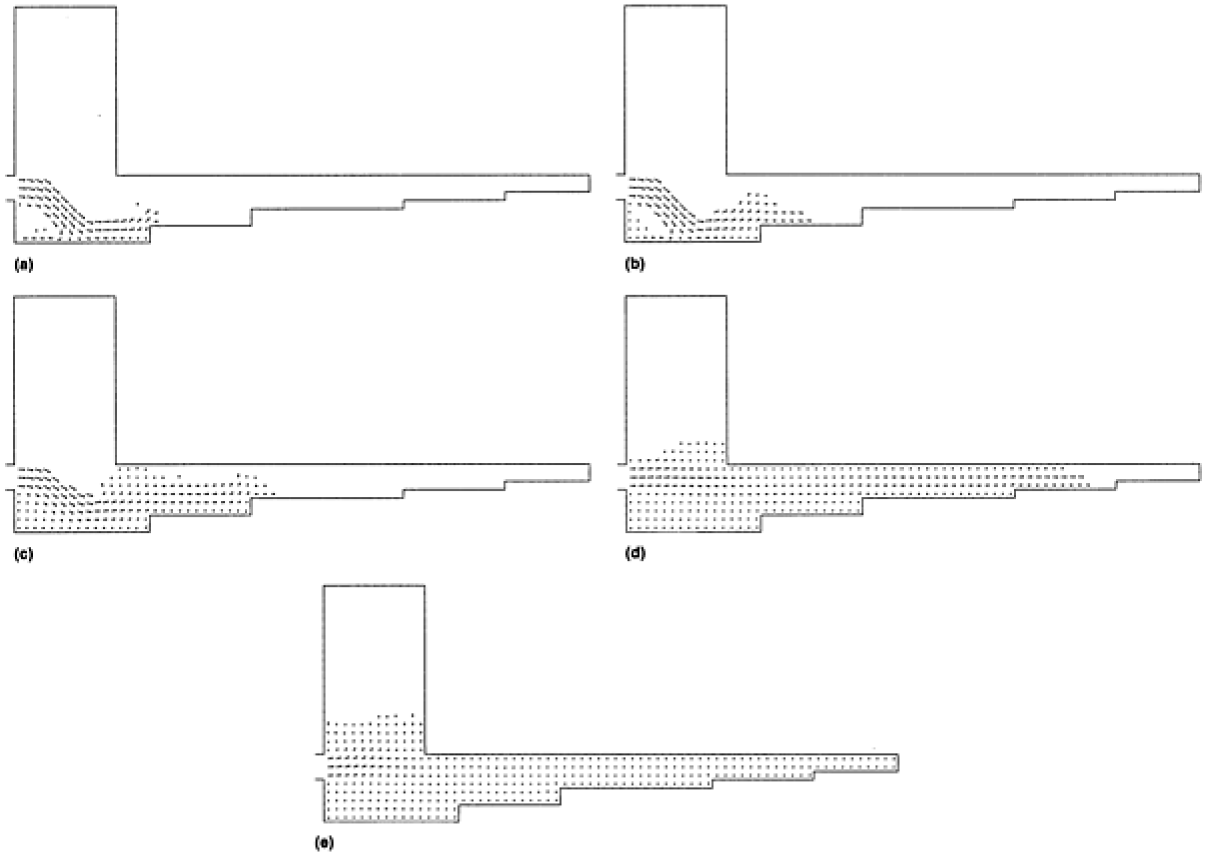

Fig. 16 Vector plot showing flow patterns and velocity profiles of a vertical stepped plate casting produced by using the mold illustrated in Fig. 15. The initial entrance velocity was 975 mm/s (3.2 ft/s), and the plot is shown at elapsed times. (a) 0.27 s. (b) 0.39 s. (c) 0.72 s. (d) 1.47 s. (e) 1.80 s.

The MAC technique can be applied to flow through the filling system as well as in the mold cavity. Figure 17 shows flow in such a system and demonstrates the undesirable condition in which the descending metal pulls away from the walls of an untapered sprue. Some detailed studies of flow in the sprue and runner have been made using the SOLA-VOF version of these techniques (Ref 20).

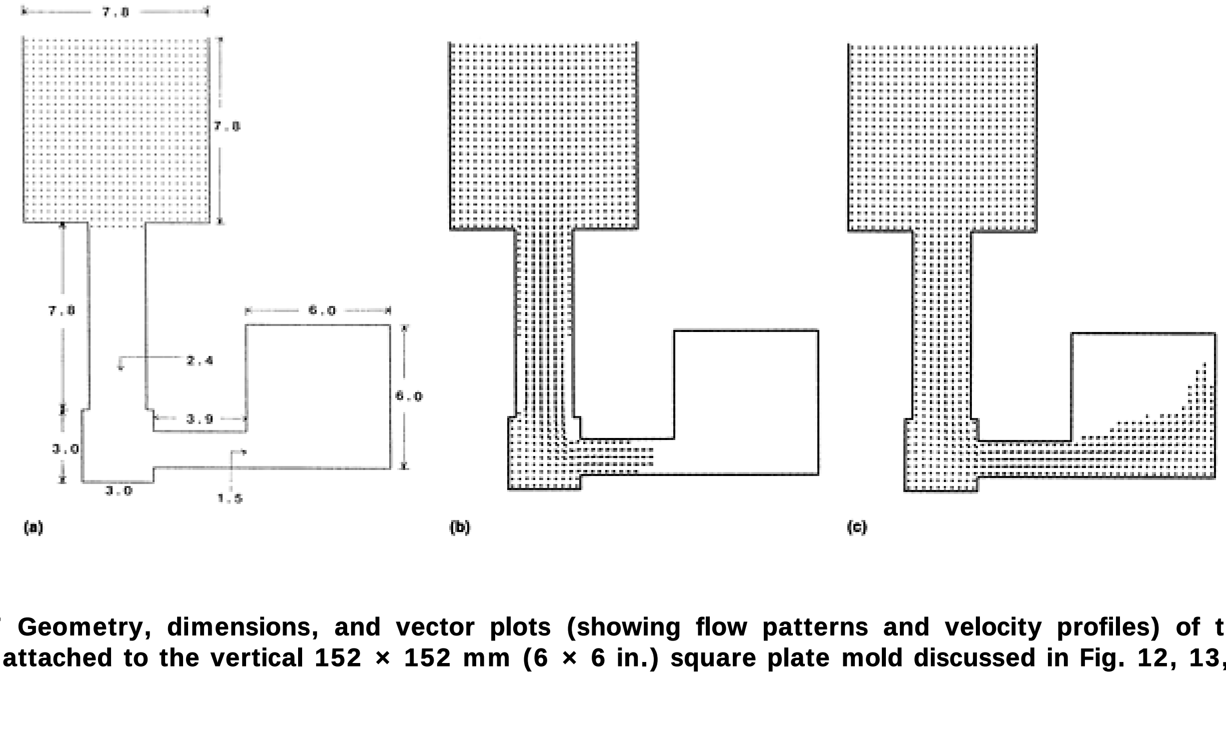

Fig. 17 Geometry, dimensions, and vector plots (showing flow patterns and velocity profiles) of the filling system attached to the vertical 152 × 152 mm (6 × 6 in.) square plate mold discussed in Fig. 12, 13, and 14.

The vector plot is shown at elapsed times. (a) 0.0 s. (b) 0.290 s. (c) 0.570 s. Dimensions given in inches.

Correlations With Actual Metal Flow

Correlations of calculated flow with observations of actual metal flow are shown in Fig. 18 and 19 (the flow of cast iron into silicate-bonded sand molds was recorded by a high-speed motion picture camera through a glass window on the side of the mold) (Ref 21). The casting is a three-spoke wheel. In one of the configurations, the metal enters through a gate at the top, and the gate is positioned midway between two spokes (Fig. 18). In the other, the gate is at the bottom directly opposite a spoke (Fig. 19). The results, calculated using a modified SOLA-VOF technique, are shown. The agreement between the observed patterns and the calculated ones is very good, particularly in the way in which the metal misses the diagonal spokes in the top-gated castings and pours around the rim until filling is about two-thirds complete. It can clearly be seen from these experiments that the bottom-gated casting fills more smoothly and uniformly and probably results in a better-quality casting.

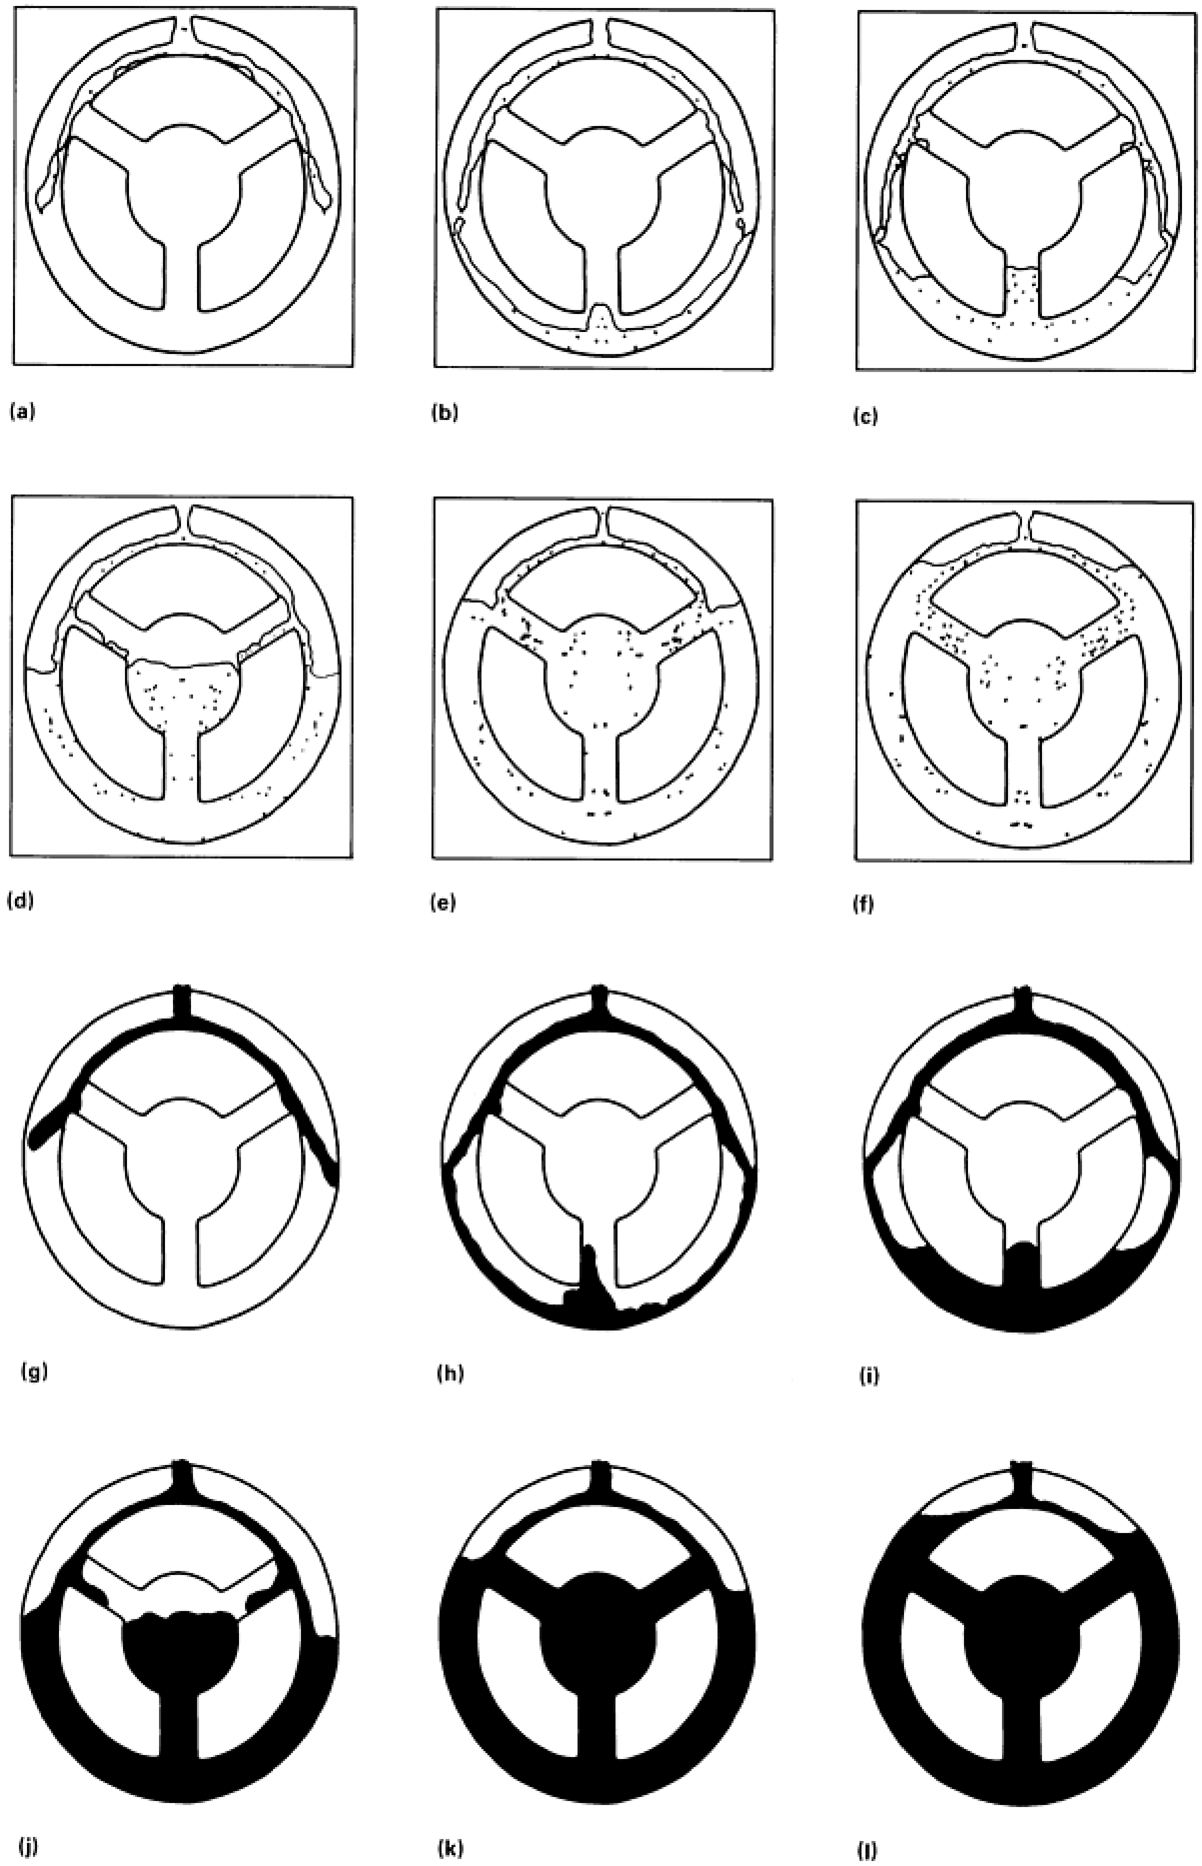

Fig. 18 Calculated flow patterns, (a) to (f), and comparable high-speed motion picture frame tracings, (g) to

Fig. 19 Calculated flow patterns, (a) to (f), and comparable high-speed motion picture frame tracings, (g) to (l), of molten cast iron entering a bottom-gated sand mold to produce a three-spoke wheel. Elapsed times for the calculated patterns. (a) 0.100 s. (b) 0.200 s. (c) 0.500 s. (d) 1.000 s. (e) 2.200 s. (f) 2.900 s.

Figure 20 shows the solidification pattern that occurs in the bottom-gated casting 36 s after the start of the pour. The residual influence of the entering stream of hot metal is shown by the molten state of the bottom spoke after the two upper spokes have solidified. These calculations were done by a program that uses SOLA-VOF to calculate fluid flow and couples it with a finite-difference heat transfer program to calculate temperature distributions. This is particularly useful in modeling thin castings, in which solidification may begin before the mold is completely filled.

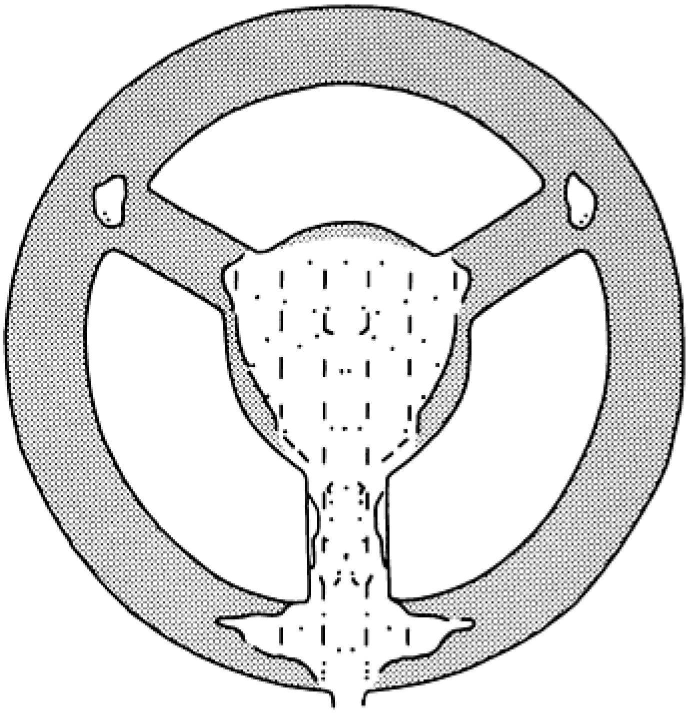

Fig. 20 Calculated solidification pattern in the bottom-gated three-spoke wheel casting in Fig. 19 after an elapsed time of 36.192 s. Fraction solid is greater than 0.5 in shaded area and less than 0.5 in unshaded area to show the residual effect of fresh hot metal flow through the bottom spoke throughout the filling period.

Modeling of Combined Fluid Flow and Heat/Mass Transfer

Prateen V. Desai, Georgia Institute of Technology; K.V. Pagalthivarthi, GIW Industries, Inc.

Introduction

FLUID FLOW AND HEAT/MASS TRANSFER principles are increasingly gaining acceptance as a means of improving the quality and yield of castings. The benefits to be derived from adopting such an approach range from slag- and dross-free gating system design to a desired microstructure of the finished product. In general, the transport of heat, mass, and momentum during solidification processing controls such varied phenomena as solute macrosegregation, distribution of voids and porosity, shrinkage effects, and overall solidification time. These parameters, in turn, result in a variation of the mechanical, thermophysical, and electrical properties of the solidified product.

The complex nature of the coupling between heat and mass transport with fluid flow during solidification necessitates a fundamental understanding of the processes and the mechanisms of interaction in relation to empirical formulas and charts. Heat transfer by forced convection predominates during the filling stages. Once the mold cavity is filled, buoyancy-generated natural convective heat and mass transfer occur before the phase change (Ref 1).

The principles of heat transfer by forced convection are shown schematically in Fig. 1, which is a representation of flowing metal at a superheated pouring temperature T_{01} and a velocity u advancing into a mold channel of width $2d$ and length L, initially at an ambient temperature T_{02}. Stage 1 shows the channel just before the liquid metal enters. Stages 2 and 3 show the liquid region R_1 occupying half and almost full lengths of the channel, respectively. The temperature at the liquid metal/mold wall interface keeps evolving as the flowing metal front advances into the channel. The portion of the mold wall not yet covered by the flowing metal remains at a considerably lower temperature. Stage 4 shows the completely filled channel with conventional steady flow and heat transfer processes.

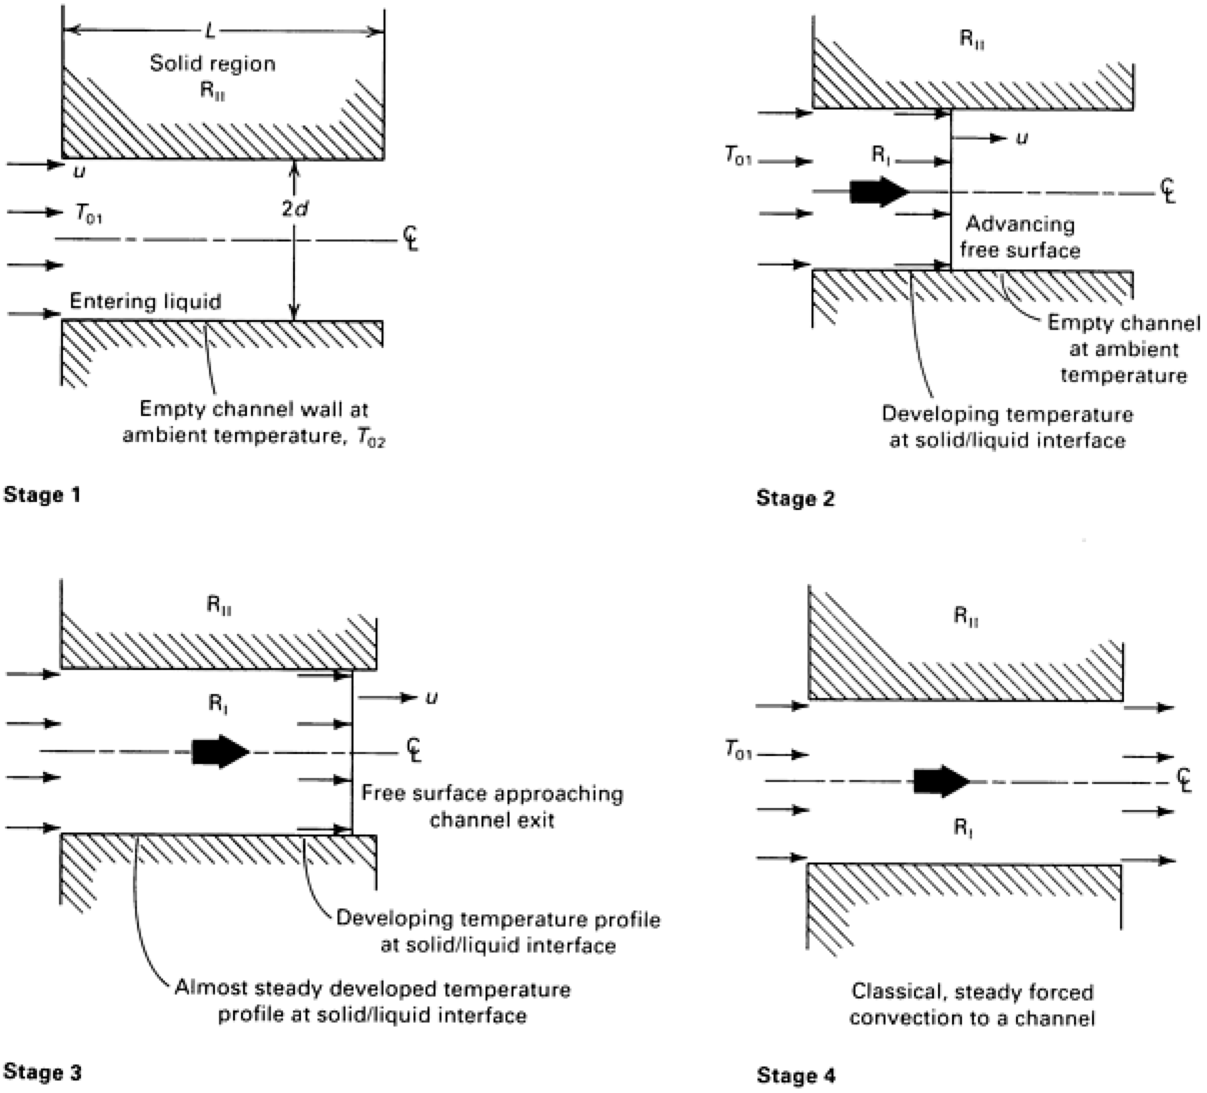

Fig. 1 Filling stages in an empty channel. See the corresponding text for a description of Stages 1 through 4. Source: Ref 2

Subsequent stages during the solidification of a binary alloy involve both phase change heat and mass transfer as well as buoyant thermosolutal convection (Ref 3).

Figure 2 shows a schematic representation of the stages in the solidification of a binary alloy. Solidification begins with cooling across boundary B_{II} between the liquid metal region R_{IV} and the mold region R_I, together with cooling at boundary B_I between the mold and the ambient (Fig. 2a). Next, the solid/liquid mushy region R_{III} evolves between boundary B_{II} with the mold and B_{IV} with the liquid metal (Fig. 2b). Further cooling leads to a typical steady-state picture

showing a solidified crust region R_{II} with boundaries B_{II} and B_{III} with the mold and the mush, respectively, and the mushy region R_{III} with boundaries B_{III} and B_{IV} with the crust and the liquid, respectively (Fig. 2c). The final transient stage shows the depletion of the all-liquid region R_{IV} (Fig. 2d).

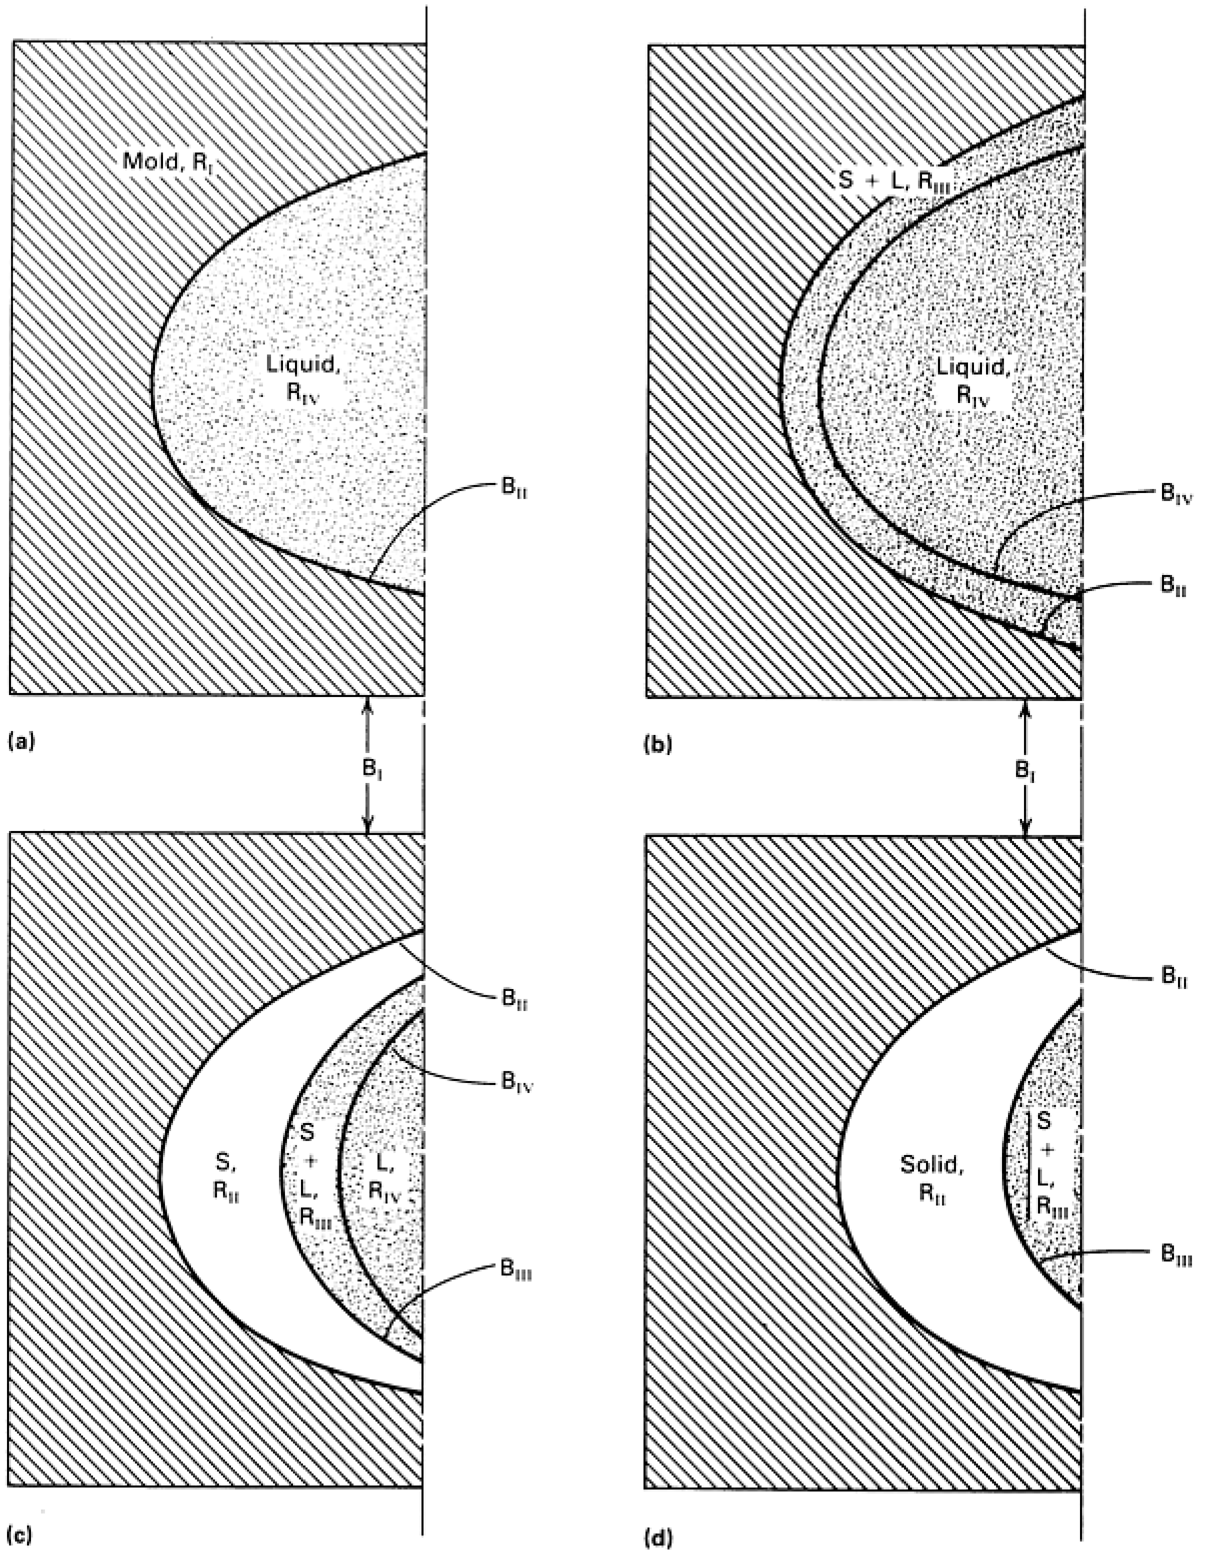

Fig. 2 Stages in binary alloy solidification. (a) All liquid. (b) Initial transient. (c) Steady state. (d) Final transient. See the corresponding text for details. Source: Ref 3

Modeling of Combined Fluid Flow and Heat / Mass Transfer

Prateen V. Desai, Georgia Institute of Technology; K.V. Pagalthivarthi, GIW Industries, Inc.

Heat Loss During Filling

Pioneering work on heat loss from the flowing metal to the sand mold runners consisted of obtaining plots of temperature loss versus time, with the ratio of surface area to flow rate used as a parameter (Ref 4). Assuming instantaneous filling and negligible contact resistance between the sand mold and the flowing metal, this method gives good results. A modified version of the method, intended for a constant or linearly decreasing average velocity of the molten metal, indicates that the temperature loss in the runner decreases with time and is proportional to the residence time of the fluid element in the runner (Ref 5). These results can be used to calculate temperature loss for a variety of runner lengths, flow rates, runner diameters, pouring temperatures, and sand mold thermal properties. However, the results are not accurate for metallic molds, nor for very short times after pouring.

Based on more detailed mathematical models of the transient filling process, finite-element solutions for the mold/metal interface temperature for very short times after pouring have been developed (Ref 6). Typical results of such calculations for a horizontal runner channel are shown in Fig. 3. In this case, the maximum temperature difference in the system, that is, the difference between the pouring temperature and the initial mold temperature, is represented by T_{01} - T_{02}. Figure 3 shows that the instantaneous filling assumption (open triangles) yields a midchannel value of wall temperature at a time of 0.1 s after pouring as [T_{01} - 0.96(T_{01} - T_{02})], while the corrected value after accounting for the fluid flow (convection) effects during filling (closed circles) is [T_{01} - 0.64(T_{01} - T_{02})]. Although this may indicate an instantaneous freezing, the subsequent flow of superheated metal causes remelting. The temperature profiles across the channel at various times are shown in Fig. 4. Similar calculations have been performed for the vertical gating sprue for a variety of geometries (lengths, tapers, and diameters), flow rates, pouring temperatures, and properties of the melt and the sand mold (Ref 7). The competing effects of conduction heat transfer to the mold and convection due to the flow determine the interface temperature. In other words, both the thermal conductivity of the sand and the thermal capacity of the flow are important.

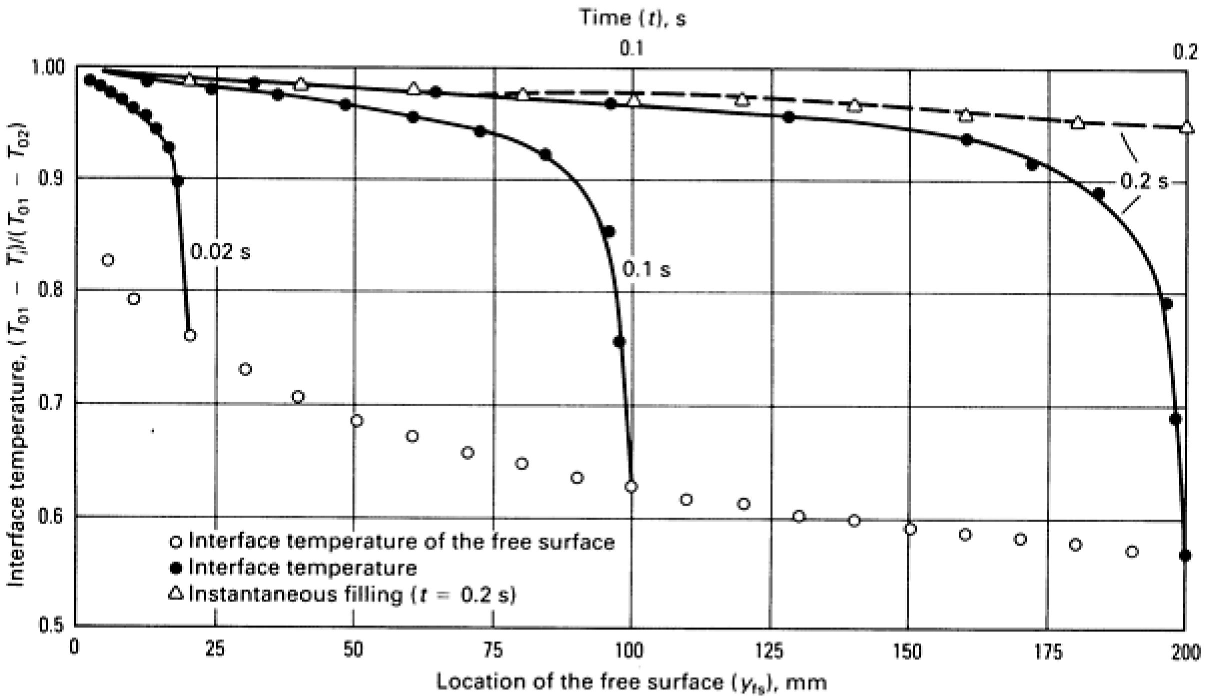

Fig. 3 Interface temperature distribution in a filling channel

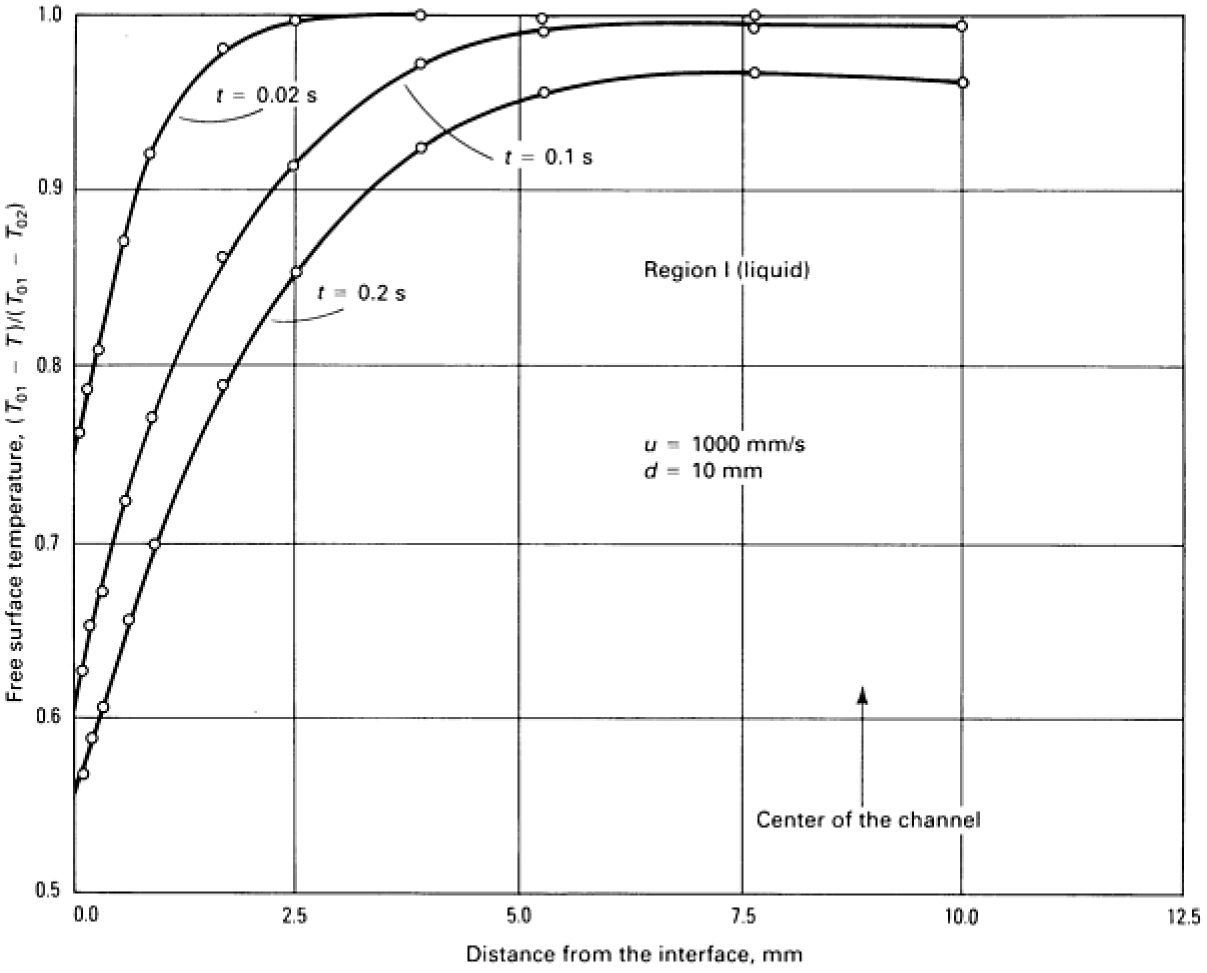

Fig. 4 Transient temperature profiles across filling channel

Experimental verification of the calculated results during the transient filling of a gating system for eutectic iron sand castings is provided in Ref 8. Temperature variations at the mold/metal interface and along the centerline of the longitudinal flow section have been recorded for sprues, runners, and ingates. Table 1 lists the experimental conditions. The furnace charge and chemical analysis of the resulting alloy are shown below:

Constituent	Charge 1	Charge 2
Brazil pig iron, kg (lb)	56 (123)	60 (132)
Steel billet, kg (lb)	24 (53)	20 (44)
Carbon powder, g	980	800

(a) Diameters of round section.

Figure 5 shows the two gating systems used in the experiments. Typical results for the interface temperature variation at different locations are shown in Fig. 6 for the filling and solidification stages. The number beside each curve indicates the height of the measurement point from the bottom to the top of the melt. The earlier the interface is in contact with the hot melt, the earlier the temperature changes. Most interface temperatures are near the solidus value when the filling is complete. Therefore, any subsequent solidification calculations must include the initial temperature distribution.

Modeling of Combined Fluid Flow and Heat/Mass Transfer

Prateen V. Desai, Georgia Institute of Technology; K.V. Pagalthivarthi, GIW Industries, Inc.

Postfilling Buoyant Convection

The loss of liquid metal superheat in the casting cavity of the mold after the filling transients have died out occurs by buoyancy-generated convection currents. These currents tend to redistribute the melt temperature and composition until solidification begins. Subsequent solidification sequences (Fig. 2) also involves heat loss by thermosolutal buoyant convection during the phase change. Figure 7(a) shows patterns of calculated convection currents in a pure melt for a vertical rectangular cavity. The indicated Rayleigh number in Fig. 7(a) characterizes the strength of the buoyant transport in relation to that by pure diffusion. Although miniscule in comparison with the patterns of flow during filling, these currents significantly shift the hot metal to the top and then redistribute the thermal state of the melt before solidification begins. A typical upward shift of the hot isotherm is shown in Fig. 7(b). Any subsequent simulation of the solidification sequence must account for this initial temperature distribution within the cavity.

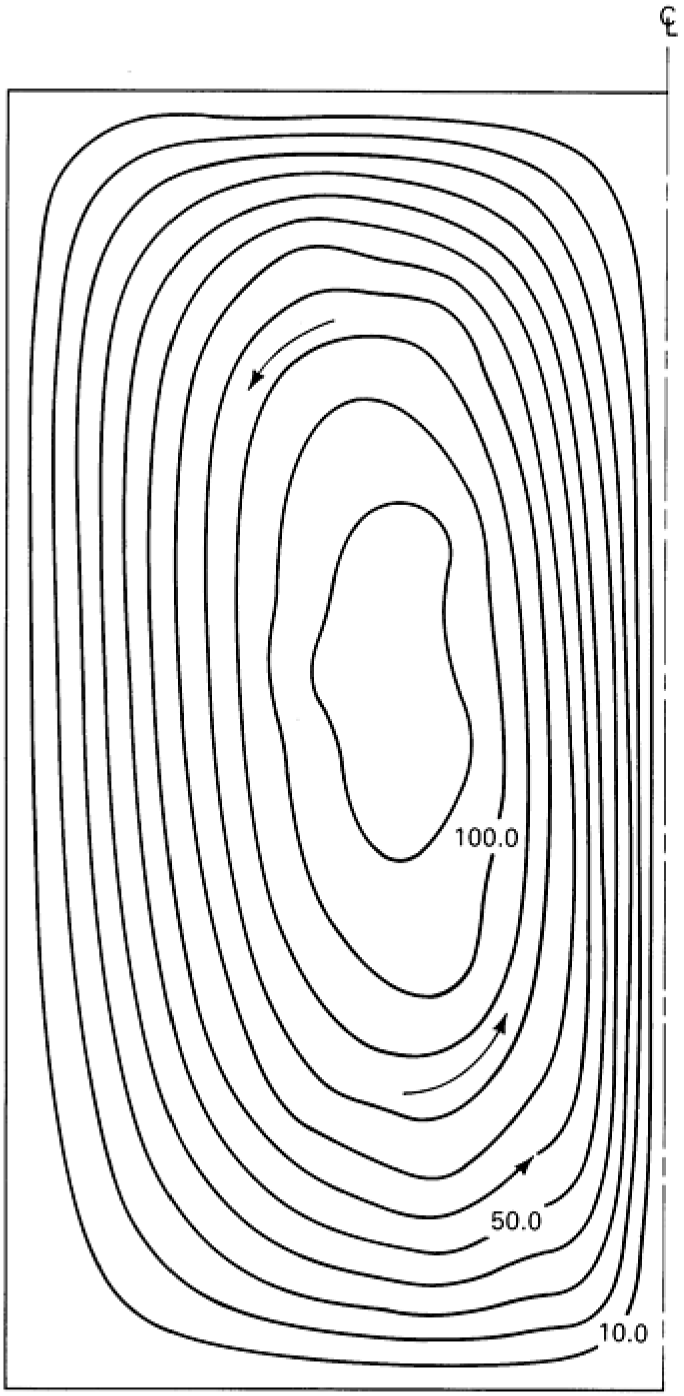

Fig. 7(a) Final steam function distribution in cavity filled with liquid copper. Cavity aspect ratio is 2, and the Rayleigh number of the process is 7000. Only the left half of the two symmetric halves of the cavity is shown. Moving horizontally to the right from center of the illustration to the centerline of the cavity, the distance between the adjacent stream lines decreases, indicating faster upward flow between adjacent stream lines. The centerline forms an insulating boundary between the two symmetric halves of the cavity.

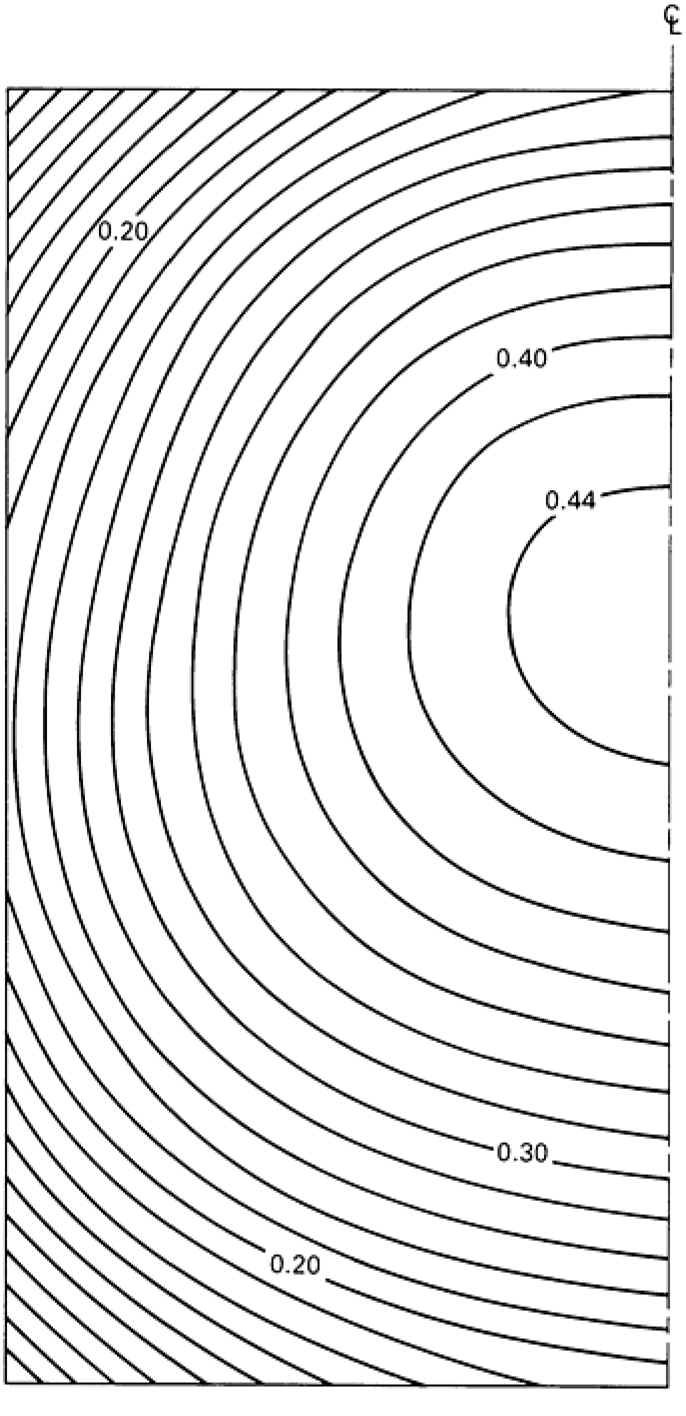

Fig. 7(b) Final temperature distribution in cavity filled with liquid copper. Cavity aspect ratio is 2, and the Rayleigh number of the process is 7000. Only the left half of the two symmetric halves of the cavity is shown. The curve labeled 0.44 is the hottest of the isotherms shown. Its temperature excess over the solidification temperature equals 44% of the maximum temperature difference that existed between the super-heated liquid and the solidification temperature at the start of the natural convection process in the cavity.

In the case of alloy melts, the difference in atomic weight of the constituent metals causes an additional convection pattern. The temperature and solute redistributions due to buoyant thermal convection occur in a coupled fashion, each driving and being driven by the other. Both the scale of the convective motion and the time during the solidification sequence when buoyant convection becomes significant must be determined to identify the process parameters governing subsequent microstructural behavior. Mathematical models of the buoyant transport processes during binary alloy solidification can be examined to obtain the applicable time, length, and motion scales for the liquid, the solid, and the mushy zones depicted in Fig. 2. Of these, the most crucial issue from the metallurgical viewpoint is the evolution of the mushy zone and the factors that govern it.

The mushy zone in a tall vertical sample casting (Fig. 8a) is viewed as a forest of dendrites submerged in a melt pool and is characterized by a field distribution of the solidified mass fraction f. The solid-liquid mixture under local thermodynamic phase equilibrium is in turn characterized by the pressure, the temperature, and the average mixture composition. The lever rule then yields the local liquid and solid concentrations. Balance statements for mass, momentum, species, thermal energy, and vorticity for a variable-mass-fraction partially solidified mixture of this type, together with the liquidus equation, are detailed in Ref 3. The buoyant flow can be driven by heat or mass transfer, depending on the magnitude of the buoyancy parameter *N:*

$$N = \frac{b_c \Delta_c}{b_T \Delta_T}$$

where β_C is the fractional change in density due to concentration changes and β_T is the fractional change in density due to temperature changes. However, for most cases of binary alloy solidification of practical interest, the buoyant current is mass transfer driven.

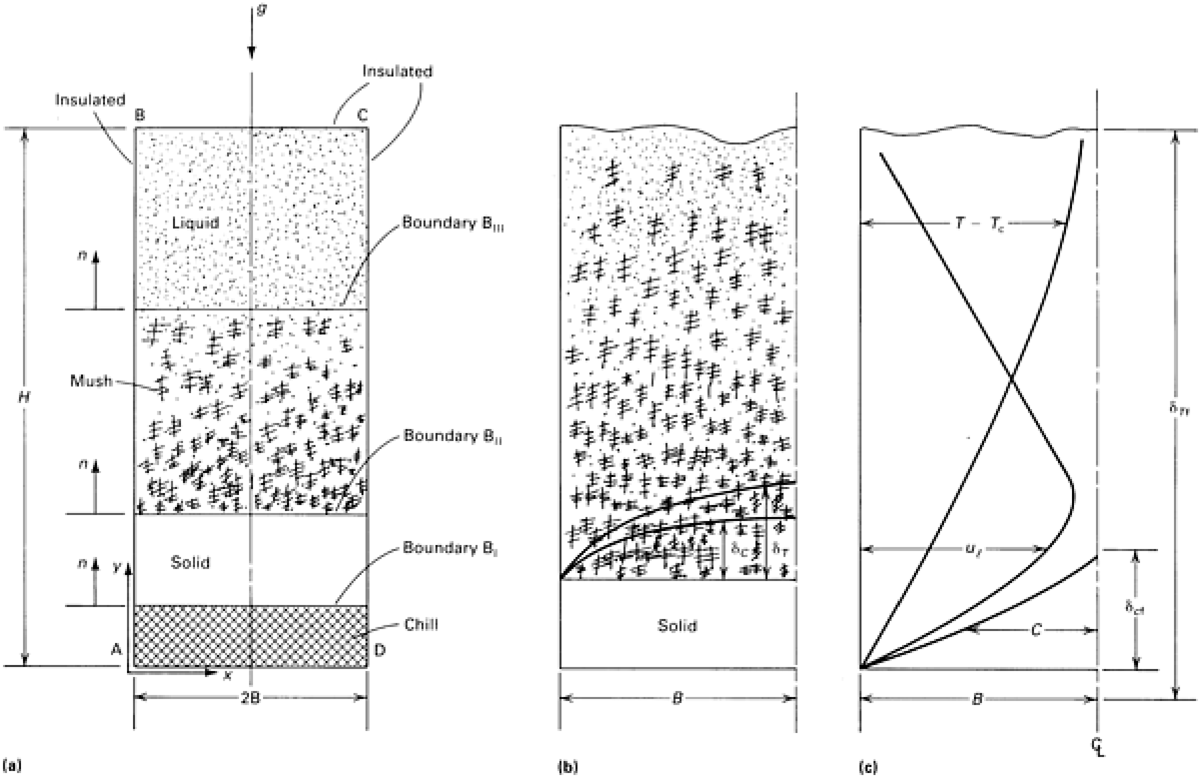

Fig. 8 Solidification of a tall, vertical casting. (a) Stages of a solidifying alloy. (b) Evolution of boundary layer in the mushy zone. (c) Boundary layer concentration, velocity, and temperature profiles

The boundary layer provides concentration, temperature, and velocity in a mass transfer driven flow for the tall, vertical casting, as shown in Fig. 8(b) and 8(c). In the boundary layer regime, the orders of magnitude *x, y,* ΔT, and ΔC can be represented as:

$$x \sim B, y \sim \delta_C, \Delta T \sim (T_0 - T_c), \Delta C \sim C_0 - C_e$$

where the subscripts 0, c, and e are the initial, liquidus, and eutectic states, respectively. For short times after solidification begins, all transport processes are diffusive, until a time t_f, when convection overtakes diffusion. A scale analysis of the mixture equations for the balance of mass, species, and vorticity yields order of magnitude of this time (the end of initial diffusion transport period) as:

$$t_f \sim \frac{B^2}{D(R_{SB})^{2/5}}$$

where B is the semi-width of the casting, D is the mass diffusivity of the alloy mixture, and R_{SB} is the solutal Rayleigh number, which is defined as:

$$R_{SB} = \frac{g b_c \Delta C B^3}{v D}$$

where ν is the kinematic viscosity and g is the acceleration due to gravity. The order of magnitude of the concentration boundary layer thickness at this time is given as:

$$\delta_{Cf} \sim B(R_{SB})^{-\frac{1}{5}}$$

and the steady-state mass transfer rate in the mushy zone is estimated from the Sherwood number, Sh, as:

$$\mathrm{Sh} \sim (R_{SB})^{\frac{1}{5}}$$

The corresponding values for the thermal boundary layer thickness and the Nusselt number for heat transfer rate calculations in the mushy zone can be obtained by a similar scale analysis of the thermal energy equation and the vorticity transport equation. Detailed computations for the actual values for alloy solidification are being performed and are expected to appear in the open literature in the near future.

Modeling of Microstructural Evolution

M. Rappaz, Ecole Polytechnique Fédérale de Lausanne; D.M. Stefanescu, University of Alabama

Introduction

THE MODELING OF SOLIDIFICATION of castings has received increased attention as the computer revolution has matured. The main application of this technique has traditionally been calculation of the path of the isotherms (lines of constant temperature) through shaped castings. In turn, this was used to predict the locations of hot spots in castings and thus to check, using the computer, a proposed gating and risering system, rather than following the classical trial-and-error technique used in foundries.

A pioneering paper by Henzel and Keverian (Ref 1) describing the application of the Transient Heat Transfer program was published in 1965. The Transient Heat Transfer program, a finite-difference method (FDM) program developed in 1959, was used for castings. Soon after this paper appeared, a variety of publications dealt with the use of different numerical techniques in the area of solidification of castings (Ref 2, 3, 4, and 5). The next logical step forward was to include nucleation and growth kinetics in simulations to generate information about the microstructure of the alloys and to treat the heat generation problem; although this step was envisioned by Oldfield as early as 1966 (Ref 6), progress in this direction was slow. A follow-up paper by Stefanescu and Trufinescu (Ref 7) in 1974 seems to be the only one until 1984, although nucleation and growth kinetics were used in modeling cooling curves to interpret inoculation in cast iron (Ref 8).

Beginning in 1984, a renewed interest in the modeling of microstructural evolution as part of the simulation of casting solidification is manifested in the literature. An analytical approach was applied by Fredriksson and Svensson (Ref 9) to the solidification of eutectic gray, ductile, and white iron and then extended to hypoeutectic irons and to the eutectoid transformation by Stefanescu and Kanetkar (Ref 10). Su *et al.* (Ref 11) used an inner nodal direct FDM scheme combined with a model assuming growth of graphite spheroids controlled by diffusion of carbon through the austenite shell. More recently, similar developments have been made for the dendrite growth of equiaxed grains (Ref 12, 13, 14). Hunt has also addressed the question of columnar-to-equiaxed transition (Ref 15).

This article will discuss techniques used for the simulation of solidification of castings. These techniques combine the modeling of heat transfer (macromodeling) with the modeling of microstructural evolution (micromodeling).

Macroscopic Modeling

Solidification of alloys is primarily controlled by heat diffusion and to some extent by convection within the liquid region. In most approaches to the solidification modeling of complex-shaped castings, the continuity equation of motion is not solved explicitly. Instead, correction is taken into account by increasing the heat conductivity above the melting point or the liquidus temperature. Under this assumption, the basic continuity equation governing solidification at the macroscopic scale is that of conservation of energy:

$$div[k(T).\overrightarrow{grad}\ T(\vec{x},t)] + \dot{Q} = \rho C_p(T)\frac{\partial T(\vec{x},t)}{\partial t} \quad \textbf{(Eq 1)}$$

where $T(\vec{x},t)$ is the temperature field, $k(T)$ is the thermal conductivity, $\rho C_p(T)$ is the volumetric specific heat, and $\dot{Q}$ is the source term associated with the phase change. In solidification modeling, $\dot{Q}$ can be written as:

$$\dot{Q} = L\frac{\partial f_s(\vec{x},t)}{\partial t} \quad \textbf{(Eq 2)}$$

where $f_s(\vec{x},t)$ is the solid fraction and L is the volumetric latent heat.

To solve Eq 1, a relationship between the fields $T(\vec{x},t)$ and $f_s(\vec{x},t)$ must be found. A simple and widely used approach is to assume that the fraction of solid f_s depends only on the temperature T and not upon cooling rate or growth rate. For pure metals or eutectic alloys, one can assume that $f_s = 0$ above the melting point or the eutectic temperature and that $f_s = 1$ below the equilibrium temperature. For dendritic alloys, various models of solute diffusion have been developed (Ref 16, 17). They all assume complete mixing of solute within the liquid, thus resulting in a unique $f_s(T)$ curve.

Assuming that f_s depends only on T, Eq 1 and 2 can be combined to give:

$$div[k(T).\overrightarrow{grad}\ T(\vec{x},t)] = \left[\rho C_p(T) - L\frac{df_s}{dT}\right]\frac{\partial T(\vec{x},t)}{\partial t} \quad \textbf{(Eq 3)}$$

defining enthalpy *H* as:

$$H(T) = \int_0^T r\,C_p(q).dq + L[1 - f_s(T)] \qquad \textbf{(Eq 4)}$$

Equation 3 can also be written as:

$$div[k(t).\overrightarrow{grad}\;\; T(\bar{x},t)] = \frac{\partial H(\bar{x},t)}{\partial t} \qquad \textbf{(Eq 5)}$$

This is known as the enthalpy method.

An effective specific heat, ρC^*_p, can be derived from Eq 4:

$$r\,C_p^*(T) = \frac{dH}{dT} = r\,C_p(T) - L\frac{df_s}{dT} \qquad \textbf{(Eq 6)}$$

which, when introduced in Eq 3, gives:

$$div[k(t).\overrightarrow{grad}\;\; T(\bar{x},t)] = r\,C_p^*(T).\frac{\partial T(\bar{x},t)}{\partial t} \qquad \textbf{(Eq 7)}$$

This is known as the specific heat method.

The curves *H*(*T*) and $\rho C^*_p(T)$ can be calculated by various methods, for example, using a Brody-Flemings model of solute diffusion (Ref 16, 17). A detailed comparison of the enthalpy method (Eq 5) and the effective specific heat method (Eq 7) is beyond the scope of this article.

Both methods can be used in macro-micro modeling. Other techniques, such as the latent heat method (Ref 18) or the micro-enthalpy method (Ref 19), have been specifically developed for macro-micro modeling. These methods, which are reviewed in Ref 20, will be discussed in the section "Macro-Microscopic Modeling of Equiaxed Solidification" in this article.

Modeling of Microstructural Evolution

M. Rappaz, Ecole Polytechnique Fédérale de Lausanne; D.M. Stefanescu, University of Alabama

Modeling of Columnar Structures

The macroscopic approach described briefly in the previous section can be reasonably applied to columnar solidification because the growth rate of the microstructure (eutectic front or dendrite tips) is more or less equal to the speed at which the corresponding isotherms move (eutectic or liquidus isolines). Therefore, microstructural parameters and undercooling can be directly calculated from the temperature field in this case.

Columnar growth morphologies are encountered in both dendritic and eutectic alloys (Ref 16, 17). Solidification occurs in a columnar fashion when the growth speed of the dendrite tip or the eutectic front v_s is directly related to the speed v_m of the isotherms calculated from a macroscopic approach (Fig. 1). It is therefore necessary to have a positive thermal gradient G at the solid/liquid interface. However, this condition is not sufficient to ensure the formation of columnar structures (Ref 13, 15).

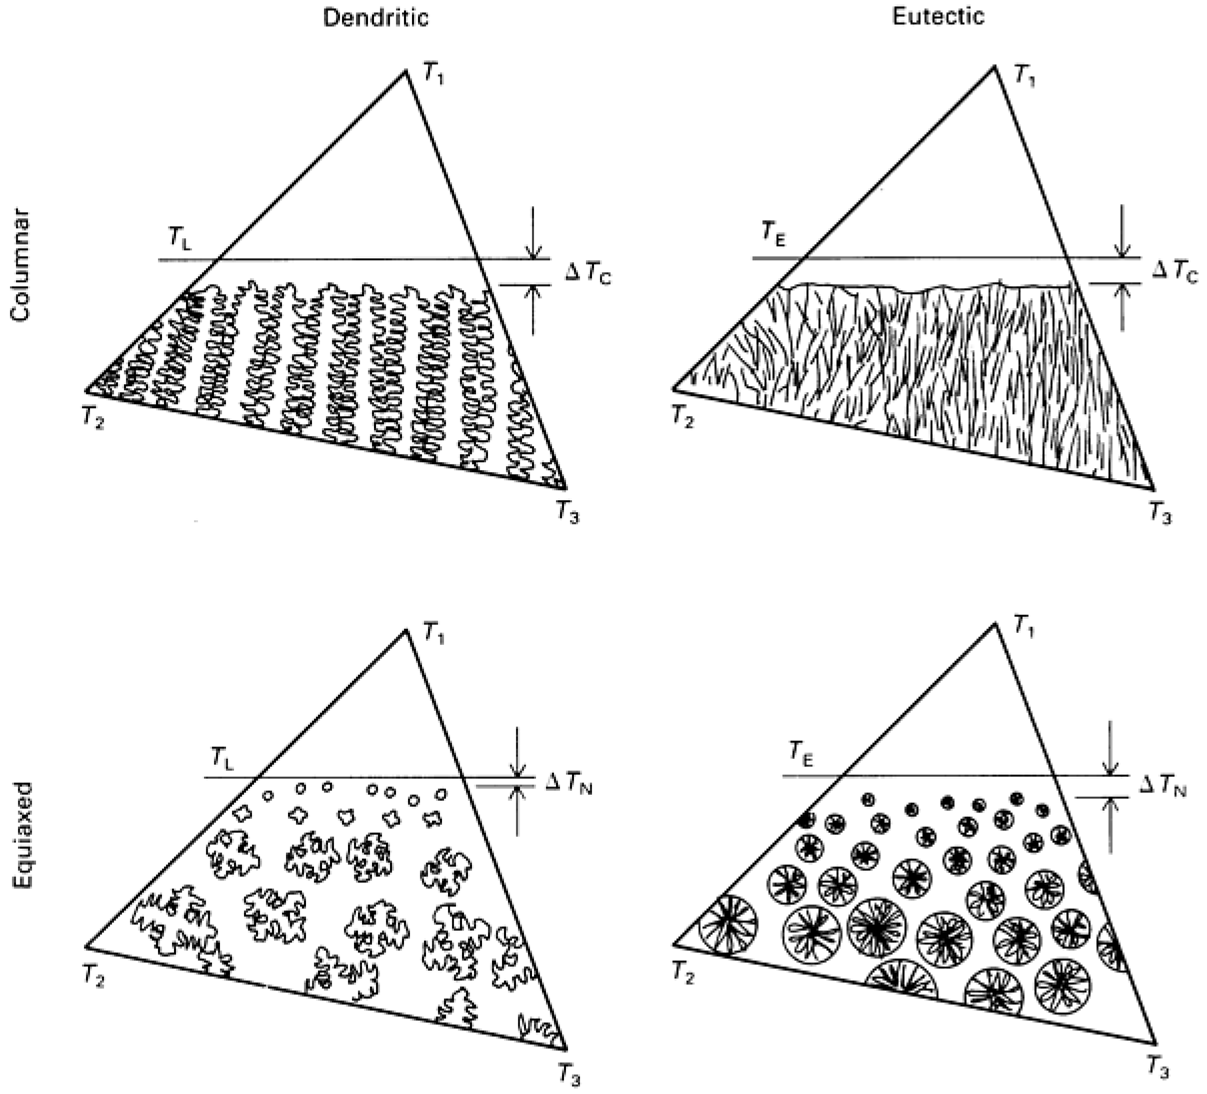

Fig. 1 Schematic of columnar and equiaxed growth of dendritic and eutectic alloys in a thermal gradient *G*

The competition between columnar and equiaxed morphologies, in particular the columnar-to-equiaxed transition, is analyzed in Ref 15. In a given macroscopic thermal environment, one can calculate:

- The undercooling ΔT_C associated with the formation of a columnar structure
- The nucleation undercooling ΔT_N at which nuclei are formed within the melt

- The undercooling ΔT_E required to drive equiaxed solidification

Under steady-state growth conditions and considering these three undercoolings, a simple criterion to obtain a fully columnar structure can be defined by:

$$G > A.N_0^{1/3}\left[1-\left(\frac{\Delta T_N}{\Delta T_C}\right)^3\right].\Delta T_c \qquad \textbf{(Eq 8)}$$

where N_0 is the density of grains nucleated at the undercooling ΔT_N, and A is a constant.

Assuming that the thermal gradient G is large enough to ensure that a columnar structure is produced, microstructure formation theories can be easily implemented into macroscopic heat flow calculations if one makes the following hypotheses:

- The kinetics of the eutectic front or the dendrite tip are given by the steady-state growth analysis
- The velocity of the microstructure v_s is related to the velocity v_m of the corresponding equilibrium isotherm, as shown in Fig. 2

In Fig. 2, four different microstructures frequently encountered in solidification are shown: regular and irregular eutectics and cellular and dendritic morphologies. In the first three cases, one has simply:

$$v_s = v_m \qquad \textbf{(Eq 9a)}$$

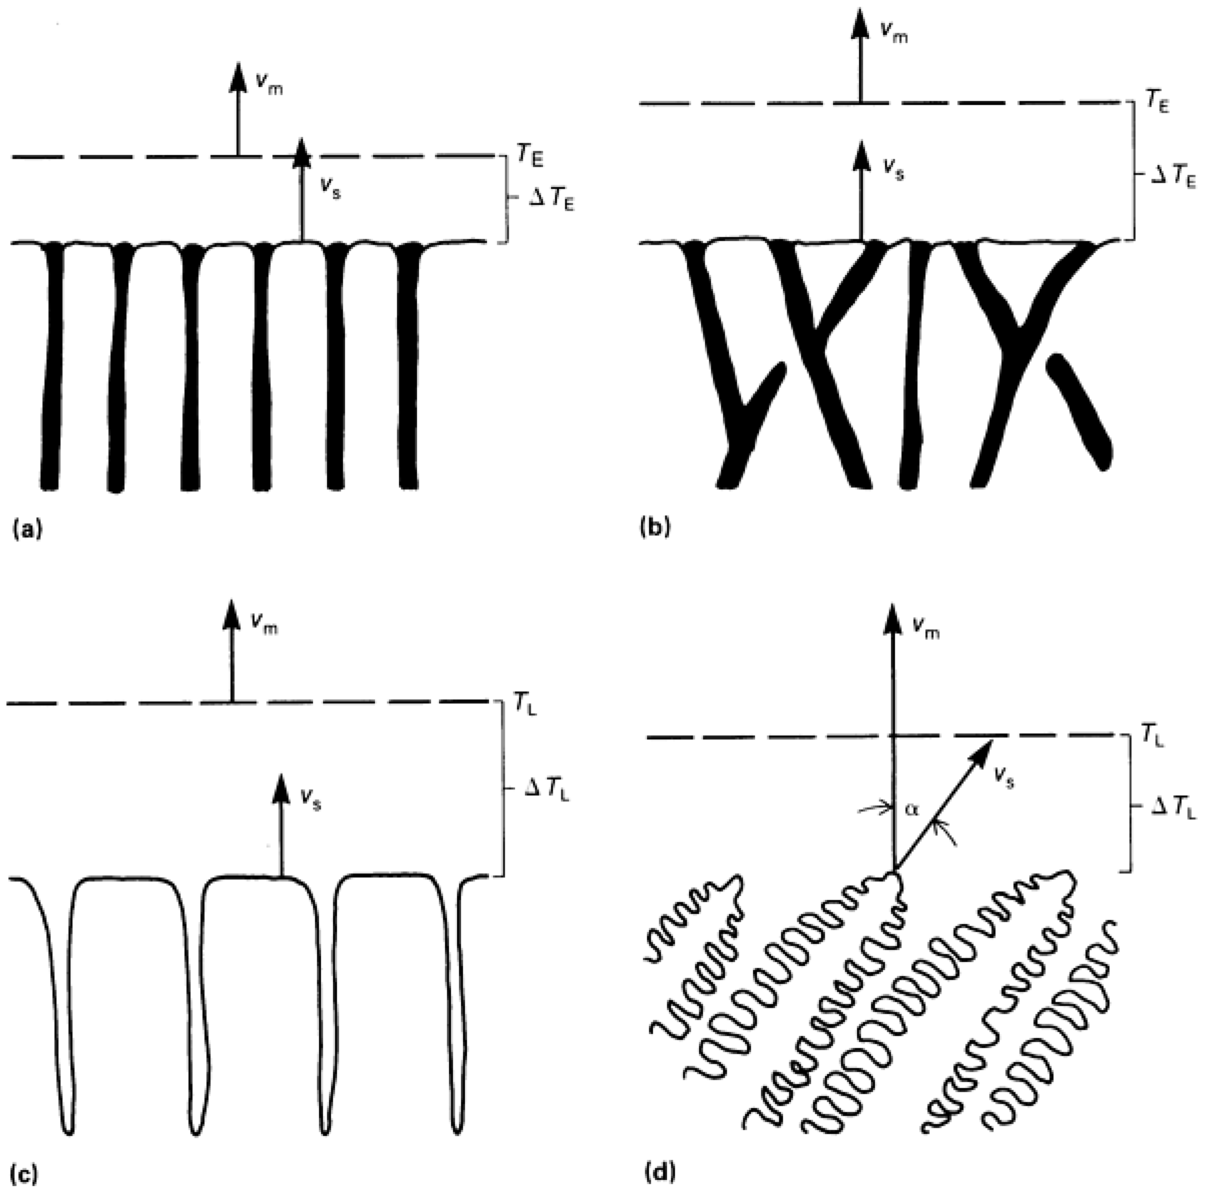

Fig. 2 Relationship between growth velocity of the macroscopic isotherms v_m and growth velocity v_s of four different columnar microstructures. (a) and (b) Regular and irregular eutectics, respectively. (c) Cells. (d) Dendrites

For dendritic alloys, the velocity of the dendrite tip is essentially dictated by the trunk orientation, which is imposed more or less by the crystallographic orientation of the solid (for example, <100> for cubic metals). If α is the angle between the trunk orientation and the heat flow direction, then:

$$v_s = \frac{v_m}{\cos a} \quad \textbf{(Eq 9b)}$$

In castings, grain selection will occur such that those grains whose angle α is close to zero will grow preferentially. However, dendritic single-crystal growth (Ref 21) or epitaxial dendritic growth from single-crystal substrates (Ref 22) can be characterized by an α value that can deviate substantially from zero.

Based on the two hypotheses mentioned previously, the kinetics of microstructure formation can be implemented into macroscopic heat flow calculations according to the following simple scheme. One first calculates the temperature field evolution without taking into account any undercooling (see the section "Macroscopic Modeling" in this article). Once the temperature field is known, the velocity of the corresponding isotherms (liquidus or eutectic temperature) can be deduced

as well as the thermal gradient at the interface. From these values, the undercooling of the columnar microstructure and the associated parameters of the microstructure (eutectic or dendrite trunk spacings) can be calculated using recent theories of microstructure formation.

Calculation of the undercooling of columnar microstructures for one-dimensional heat flow is described in Ref 23. Nucleation and columnar growth have also been considered in the modeling of rapid solidification (Ref 24).

Two researchers have achieved a real coupling between dendritic microstructure formation theory and one-dimensional nonstationary heat flow calculations in the case of spot laser remelting of material surfaces (Ref 25). In particular, they have developed a model of solid fraction that takes into account the large undercooling experienced by the dendrite tips under rapid solidification conditions. They have shown that even under such circumstances the results predicted by this detailed approach do not differ significantly from the simplest model that neglects the undercooling at the macroscopic scale.

This last approach has been applied to the laser treatment of materials surfaces to predict the lamellar spacings of a eutectic aluminum-copper alloy from the calculated stationary shape of the liquid pool (Fig. 3). More recently, this approach has been used to analyze dendritic microstructures produced in electron beam welding of stainless steel single crystals (Fig. 4). It was shown, from the macroscopic shape of the liquid pool, that a simple criterion of minimum undercooling, that is, of minimum speed, can be applied to determine which dendrite trunk orientation is selected.

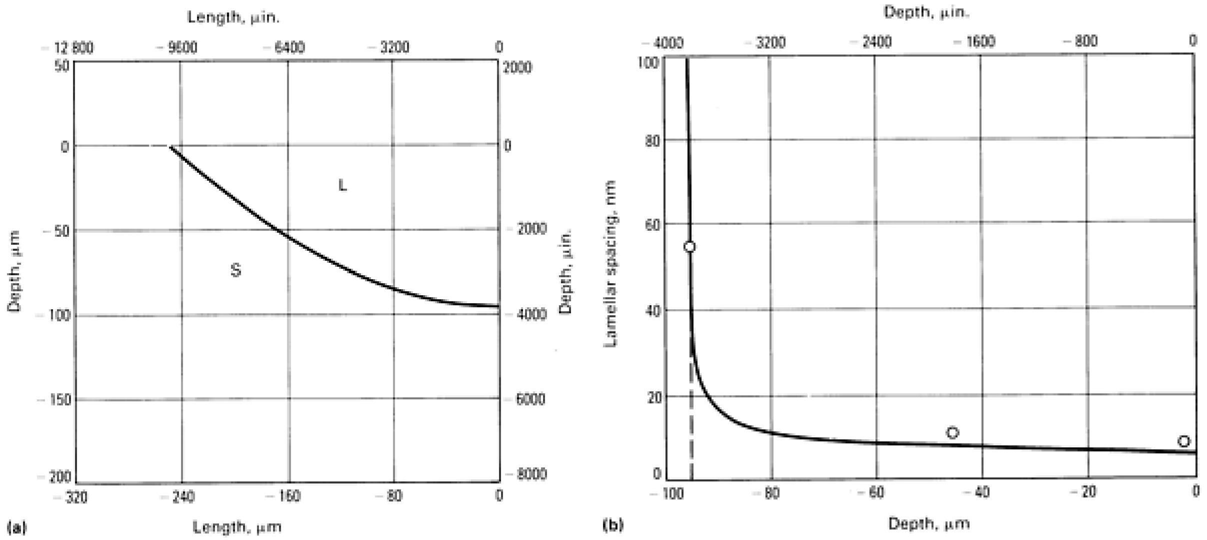

Fig. 3 Calculated stationary shape (a) of the liquid pool that forms during laser treatment of an aluminum-copper eutectic alloy surface. The laser, with 1500 W of total power focused onto a spot 0.2 mm (0.008 in.) in diameter, is moving to the right with a velocity v_b of 1 m/s (3.2 ft/s). Absorption coefficient is 0.15. Although the calculation was made in three dimensions, only the resolidifying back part of the pool within a longitudinal section is shown. (b) Lamellar spacing of the aluminum-copper eutectic alloy versus depth of the laser-treated surface as calculated from the shape of the liquid pool (a) and using the recent theory of eutectic formation. Source: Ref 26

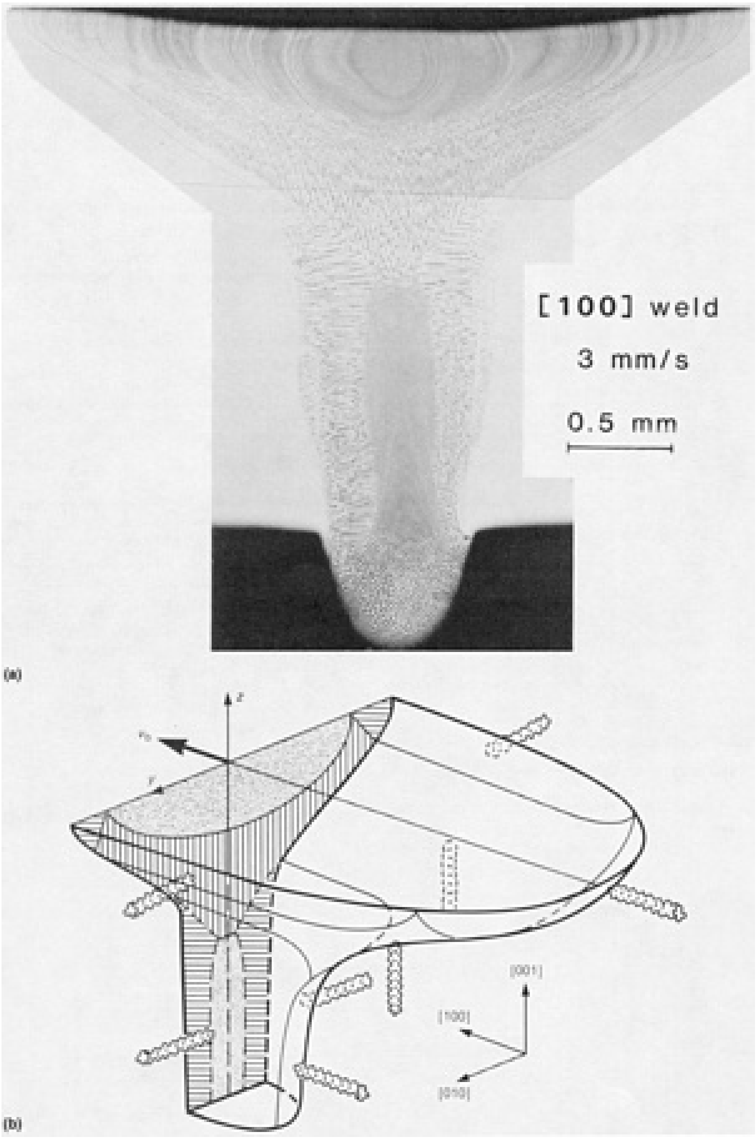

Fig. 4 Transverse section micrograph (a) of electron beam weld of an Fe-15Ni-15Cr single crystal. The electron beam was moved at a velocity of 3 mm/s (0.12 in./s) over the (001) surface along a [100] crystallographic orientation. The dendrites epitaxially grown at the monocrystalline surface of the weld can have their trunks aligned along one of the three <100> orientations. Microstructure selection is made according to a criterion of minimum undercooling (or of minimum speed); therefore, the information in this micrograph can be used to reconstruct the three-dimensional shape of the weld pool, as shown in (b). Modeling of Microstructural Evolution

M. Rappaz, Ecole Polytechnique Fédérale de Lausanne; D.M. Stefanescu, University of Alabama

Modeling of Equiaxed Structures

When dealing with equiaxed microstructures, the growth speed of the grains is no longer related to the speed of the isotherms, but rather to local undercooling (Fig. 1). Furthermore, the solidification path is also dependent on the number of grains that have been nucleated within the undercooled melt. In such a case, the approach used must relate the fraction that has solidified to the local undercooling.

Microscopic Modeling of Equiaxed Structures

Consider a small volume element V of uniform temperature T, within which equiaxed solidification (Fig. 5) is proceeding. At a given time t, the fraction of solid $f_s(t)$ is given by (Ref 27):

$$f_s(t) = n(t) \cdot \frac{4}{3}\pi R^3(t) \cdot f_i(t) \qquad \textbf{(Eq 10)}$$

where $n(t)$ is the density of the grains, $R(t)$ is the average equiaxed grain radius characterizing the position of the dendrite tips or that of the eutectic front, and $f_i(t)$ is the internal fraction of solid. For eutectics, the grains are fully solid, and accordingly $f_i(t)$ = 1 at any time. For dendritic alloys, $f_i(t)$ represents the fraction of the grains that is really solid.

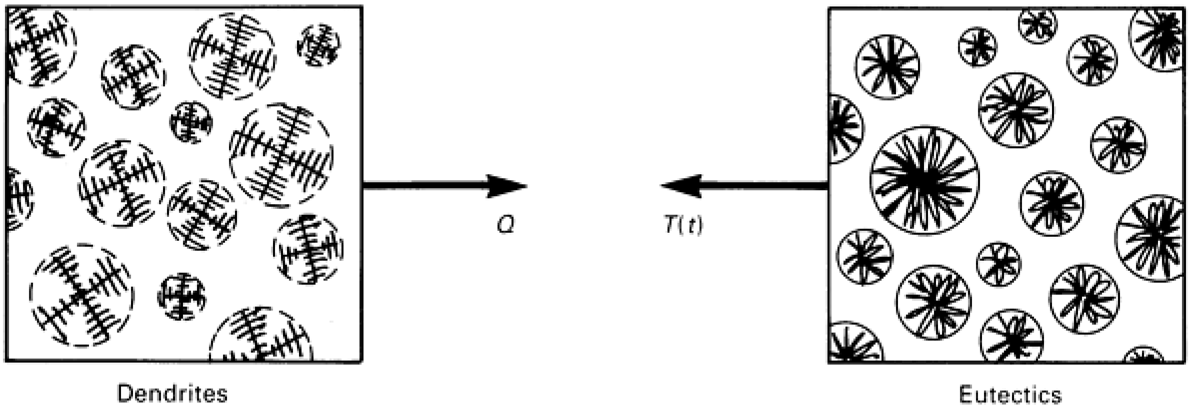

Fig. 5 Schematic showing equiaxed dendritic and eutectic solidification

To predict the evolution of the solid fraction $f_s(t)$, one must relate the three variables $n(t)$, $R(t)$, and $f_i(t)$ to the undercooling ΔT. This can be done by considering nucleation kinetics, growth kinetics, and, for dendrites, solute diffusion.

Nucleation Kinetics. The rate $\dot{n}(t)$ at which new grains are heterogeneously nucleated within the liquid can be given at low undercooling by (Ref 28):

$$\dot{n}(t) = k_1[n_o - n(t)]\exp\left\{\frac{-k_2}{\Delta T(t)^2}\right\} \quad \textbf{(Eq 11)}$$

where K_1 is proportional to a collision frequency with nucleation sites, n_0 is the total number of sites present in the melt before solidification, and K_2 is a constant related to the interfacial energy between substrate and nucleated grain. The constants K_1, n_0 and K_2 must be deduced from experiment. Once they are known, the grain density $n(t)$ can be predicted at each time by integrating Eq 11 over time or temperature:

$$n(t) = \int_{t0}^{t} \dot{n}(t)dt = \int_0 \dot{n}(T).\frac{dT}{dT/dt} \quad \textbf{(Eq 12)}$$

However, this approach fails to predict the correct grain density, in part because the temperature interval within which nucleation proceeds is very narrow. For an undercooling ΔT smaller than a critical value, $\Delta T_N = \sqrt{k_2}$, there is no significant nucleation. When ΔT_N is reached, $n(t)$ increases very rapidly to its saturation limit n_0 (Fig. 6 and 7). Therefore, it is suggested to replace the complex nucleation law of Eq 11 by a Dirac function in solidification modeling:

$$\frac{dn}{dT} = n_0.d(T - T_N) = n_o.d(\Delta T - \sqrt{k_2}) \quad \textbf{(Eq 13)}$$

If more than one type of nucleation site is present, one can introduce a set of Dirac functions (Fig. 6):

$$\frac{dn}{dT} = \sum_i n_{0.i} d(T - T_{N,i}) \quad \textbf{(Eq 14)}$$

This discrete distribution of nucleation site types can also be replaced by a continuous distribution (Fig. 8). Although this last approach may not reflect the complex phenomena of heterogeneous nucleation, it has some advantages in microscopic modeling of solidification (Ref 20, 27).

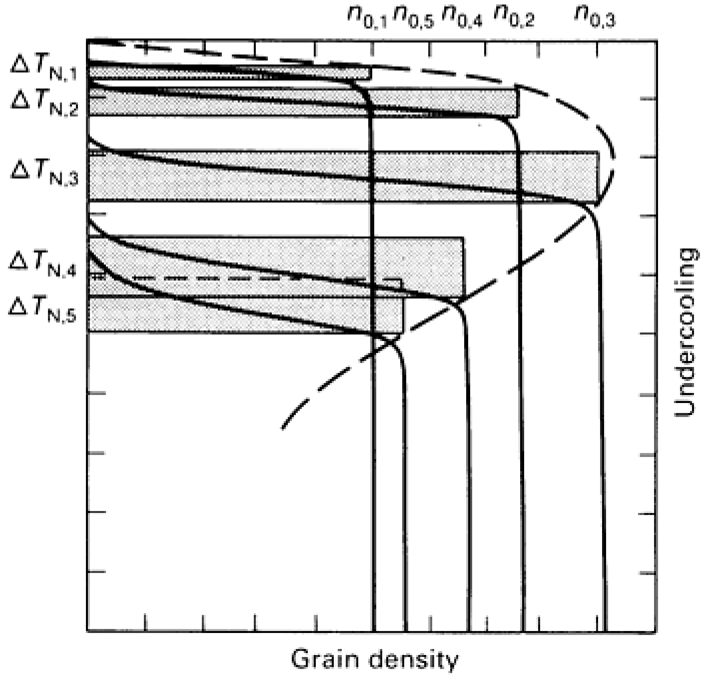

Fig. 6 Schematic of heterogeneous nucleation occurring on a family of inoculant sites, characterized by a density of sites $n_{0,i}$ and by a critical temperature $T_{N,i}$ at which nucleation occurs. Source: Ref 27.

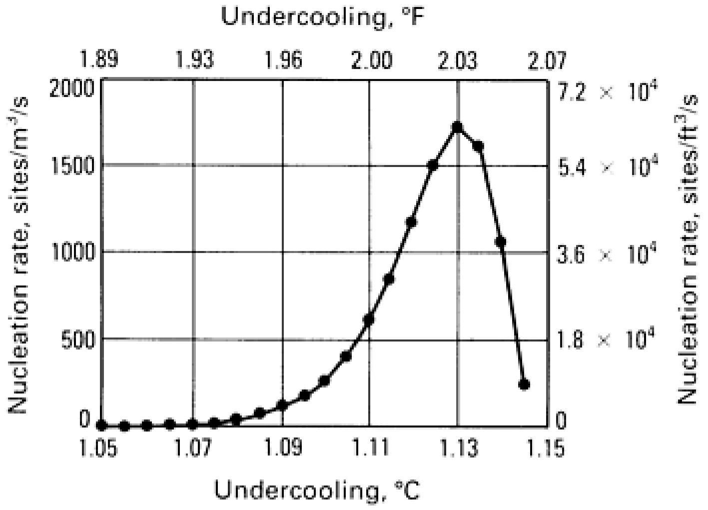

Fig. 7 Calculated relationship between nucleation rate and undercooling in cost iron. Source: Ref 29

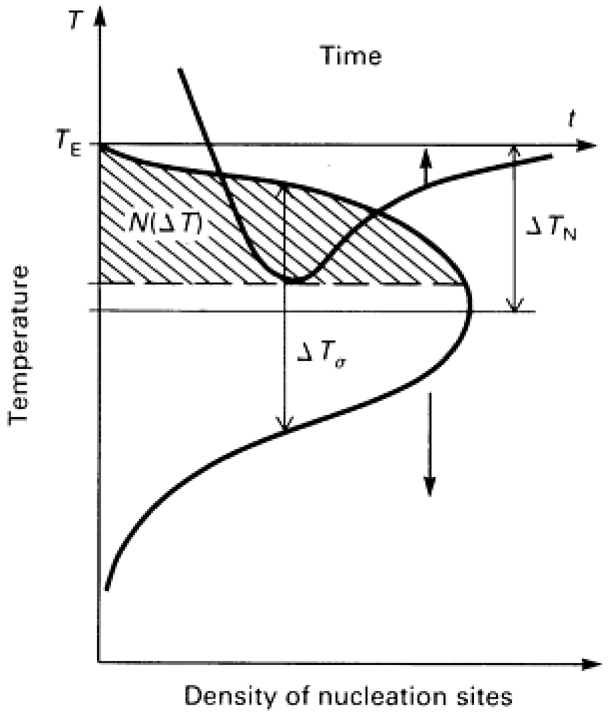

Fig. 8 Continuous distribution of nucleation site types. Source: Ref 27

In fact, a continuous distribution of nucleation site types can be replaced by a very narrow distribution if one only wants to simulate heterogeneous nucleation occurring at a given undercooling ΔT_N with a given density of sites n_0 (Eq 13). This last approach can be used for eutectic solidification based on the fact that, as previously discussed, the nucleation interval is very narrow. For example, for cast iron, the nucleation interval was calculated to be about 0.1 °C (0.2 °F) (Ref 29). Thus, a nucleation temperature ΔT_N at which all eutectic grains nucleate at the same time can be chosen. For the case of alloys with nonuniform grains, it must be assumed that different types of substrates become active at different nucleation temperatures. Accordingly, several nucleation temperatures must be selected, at which fractions of the final number of nuclei are generated.

Growth. Evolution of the grain radius $R(t)$ can also be related to the undercooling ΔT of the volume element. The speed v of a eutectic front is related to the undercooling through the relationship (Ref 30):

$$v = \frac{dR}{dt} = m.(\Delta T)^2 \qquad \textbf{(Eq 15)}$$

where μ is a constant depending on the characteristics of the alloy.

For dendritic alloys, a similar relationship has been deduced in the approximation of a hemispherical dendrite tip, which relates the square of the undercooling ΔT to the velocity v of the dendrite tips (Ref 31). Therefore, Eq 15, with a different μ value, can be used to predict the evolution of grain size. However, in the case of dendrites, one must still calculate the evolution of the interval volume fraction of solid $f_i(t)$ (Eq 10). For that purpose, a solute diffusion model has recently been developed (Fig. 9). Assuming that there is complete mixing of solute within the interdendritic liquid of the spherical grain envelope outlined by the dendrite tip position, the researchers considered the solute balance at the scale of the equiaxed grain and the solute flow leaving out the grain envelope. They found that:

$$f_i(t) = \Omega(t) \cdot g(\delta, R) \qquad \textbf{(Eq 16)}$$

where $\Omega = (C^* - C_0)/[C^*(1 - k)]$ is the supersaturation, $g(\delta,R)$ is a correction function that takes into account the solute layer δ around the grain envelope, C^* is the concentration within the interdendritic liquid (Fig. 9), C_0 is the initial

concentration, and k is the partition coefficient. Because the undercooling ΔT is equal to $m(C^* - C_0)$, where m is the slope of the liquidus, $f_i(t)$ is again directly related to ΔT through Eq 16.

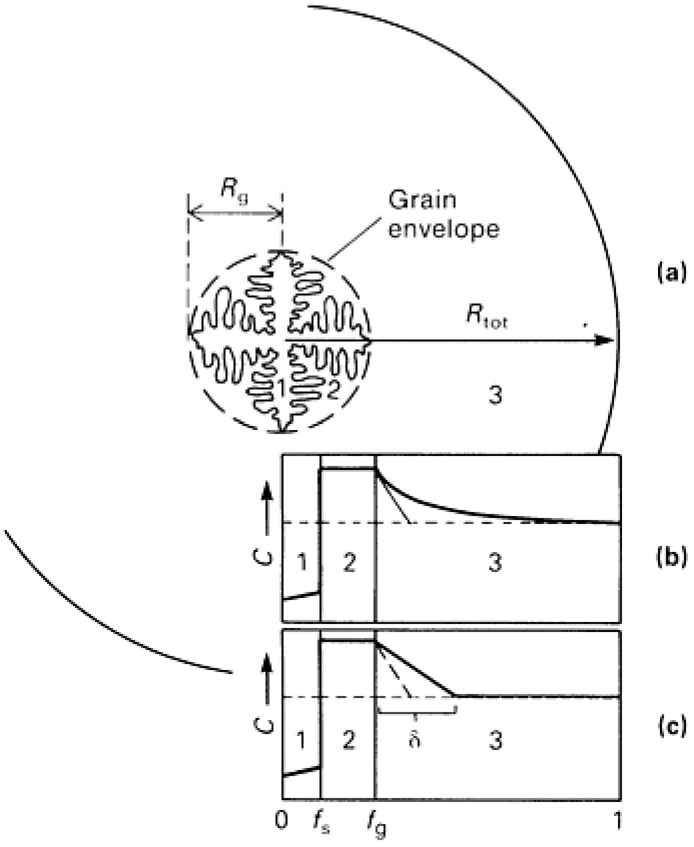

Fig. 9 Schematic showing the solute diffusion model developed for equiaxed dendritic growth. (a) The three regions that can be distinguished are (1) solid dendrite, (2) interdendritic liquid, where complete mixing of solute is assumed, and (3) liquid outside the grain envelope where diffusion occurs. (b) and (c) Concentration profiles corresponding to (a). Source: Ref 32

From the solute flux balance, it has been shown that the solute layer δ is simply given by the ratio $2D/v$, where D is the diffusion coefficient. The effect of δ on solidification is most noticed when the solute layers of neighboring dendritic grains overlap, thus changing the concentration C_0 in the supersaturation expression.

Grain Impingement. Equation 10 assumes that the grains are spherical during the entire solidification process. It is valid as long as the grains do not impinge on each other. For dendritic alloys, the diffusion layer δ outside of the grain envelope R somehow already takes grain impingement into account. For eutectic grains, grain impingement must be introduced.

The Johnson-Mehl correction for grain impingement predicts that (Ref 33):

$$f_s = 1 - \exp\left(-n \cdot \frac{4}{3}\pi R^3\right) \quad \textbf{(Eq 17)}$$

Macro-Microscopic Modeling of Equiaxed Solidification

The coupling between the macroscopic heat flow equation and the microscopic models of equiaxed solidification can be achieved according to various schemes. A detailed description of a possible procedure is given in Ref 20. Two basic coupling schemes for equiaxed solidification are shown in Fig. 10.

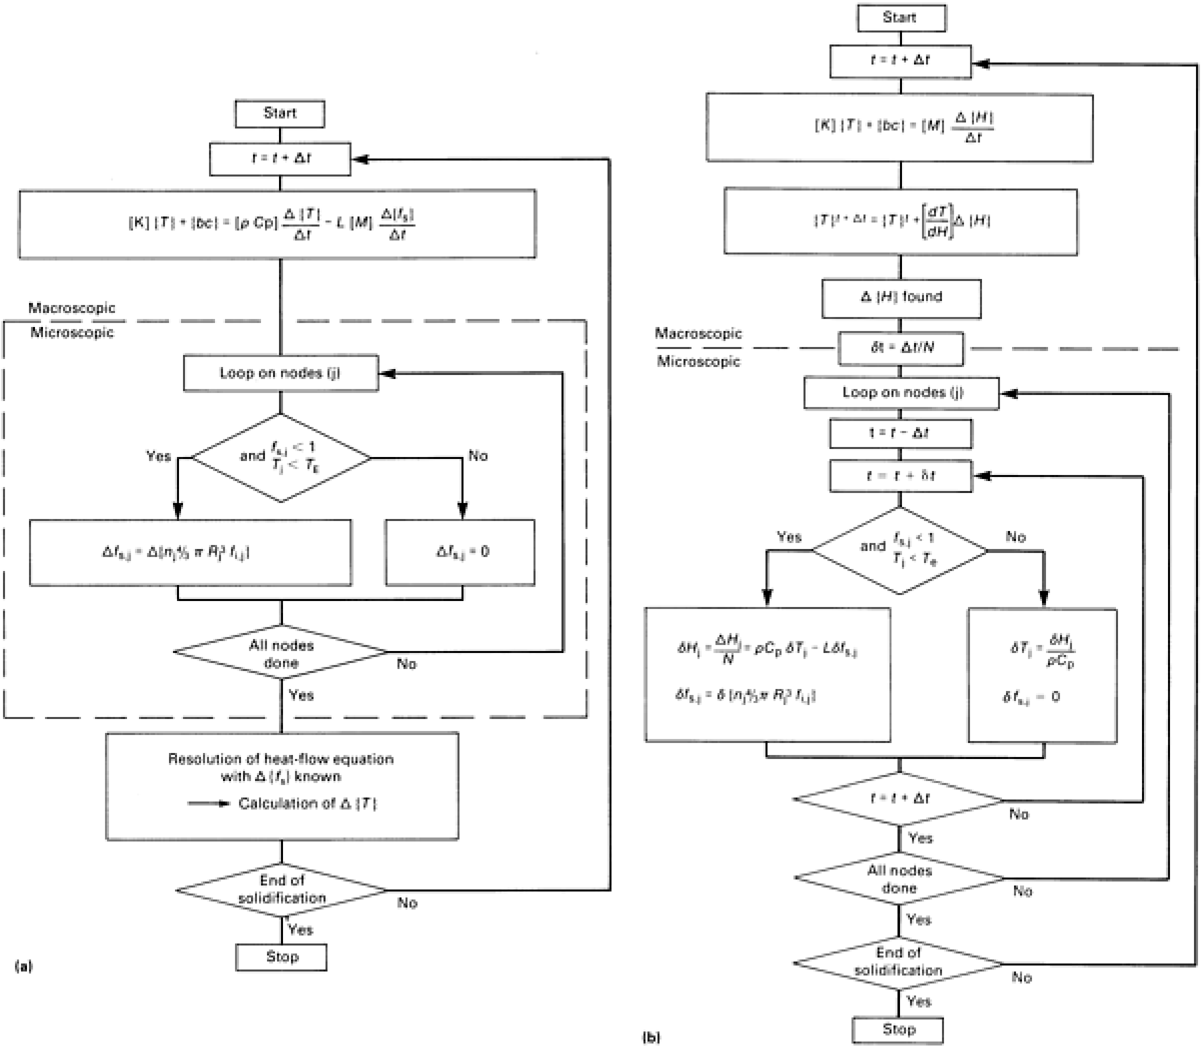

Fig. 10 Flow charts of the macroscopic-microscopic modeling of solidification based on two different schemes. (a) Latent heat method. (b) Microenthalpy method

The latent heat method shown in Fig. 10(a) is the most straightforward one (Ref 18, 29). Formulating Eq 3 with finite-difference method or finite-element method (FEM), the variations $\Delta\{f_s\}$ between t and $t + \Delta t$ at all nodes are calculated according to the microscopic model of solidification (Eq 10). In both dendritic and eutectic alloys, the variation $\Delta\{T\}$ can be derived explicitly or implicitly, while the variation $\Delta\{f_s\}$ is given explicitly by the undercoolings at each node at time t.

The source term $\dot{Q}$ (Eq 2) in the heat conduction equation (Eq 3) is directly coupling the macroscopic heat flow and the microscopic growth kinetics. The latent heat evolved is calculated so as to remain finite in the solidification region. Therefore, no special treatment is required for the latent heat term in solving Eq 3, such as those employed in specific heat and enthalpy formulation of heat conduction equations.

The departure from equilibrium solidification for a cast iron sample can be readily seen from the enthalpy-temperature diagram shown in Fig. 11. The predicted and experimental cooling curves at the middle of a cylindrical mold for the same eutectic cast iron are given in Fig. 12. Two computer programs, EUCAST and BAMACAST, have been used for calculation (Ref 34, 35). It is obvious from Fig. 12 that the macro-micro eutectic model not only accurately predicts the degree of undercooling and the arrest temperature but also the solidification time.

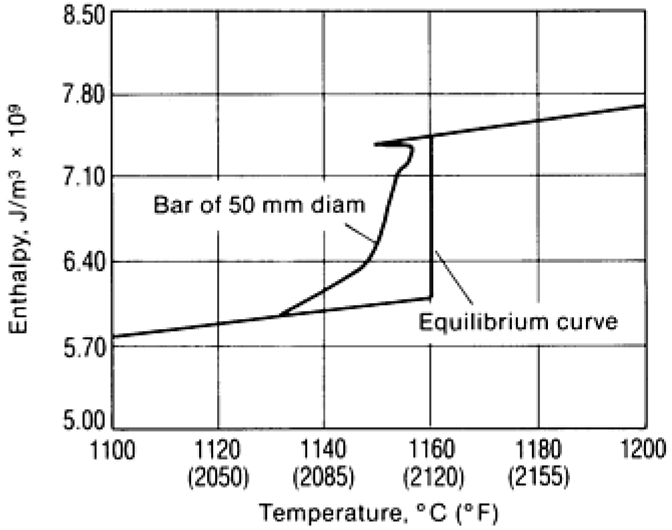

Fig. 11 Calculated and theoretical enthalpy versus temperature curves for cast iron of eutectic composition. Source: Ref 18

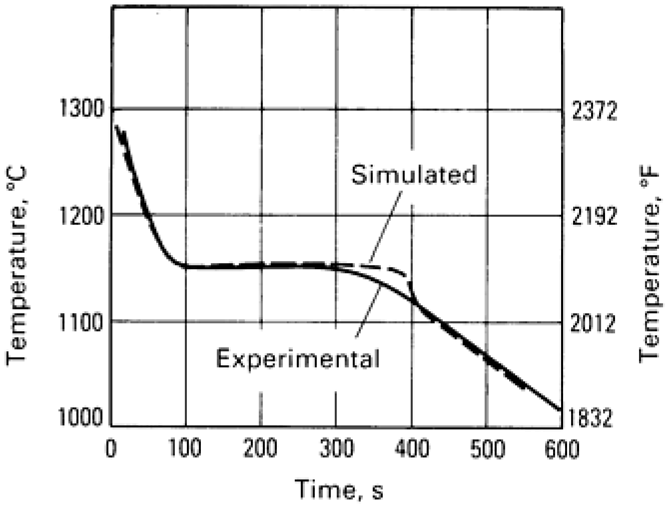

Fig. 12 Calculated and experimental cooling curves for eutectic gray iron poured in a 50 mm (2 in.) diam bar molded in resin bonded sand. Thermocouples were inserted in the middle of the casting. Source: Ref 34

Figure 13 gives theoretical predictions of the width of the mushy zone for the cast iron sample shown in Fig. 12. The data are in good agreement with the experimental values for the beginning and end of solidification for the thermocouple in the center of the sample.

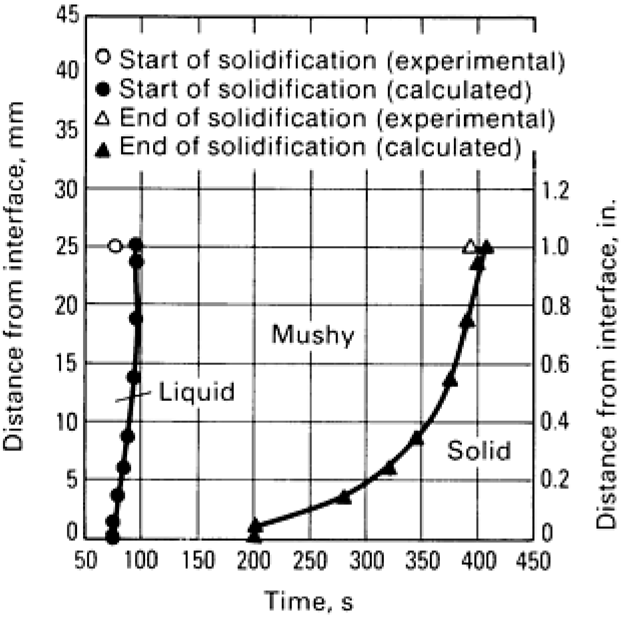

Fig. 13 Calculated beginning and end of solidification wave fronts for a 50 mm (2 in.) diam bar, and experimental points for a thermocouple placed at the center of the bar. Source: Ref 34

A macro-micro modeling approach can have many structure-related applications. For example, macro-micro modeling has been used to attempt to predict the gray/white structural transition in cast irons (Ref 35, 36).

As previously discussed, applications of this method can also be extended to the primary phase. Typical calculated and experimental cooling curves for a hypoeutectic Al-8.5Si alloy are given in Fig. 14.

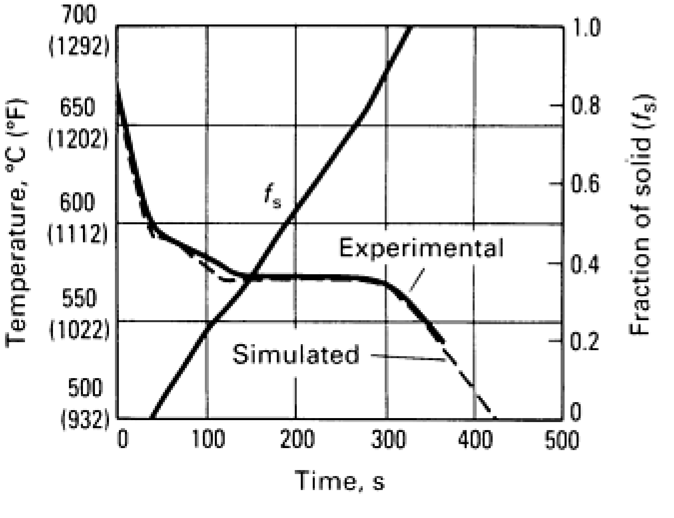

Fig. 14 Experimental and simulated cooling curves and calculated fraction of solid for an Al-8.5Si alloy. Source: Ref 37

The microenthalpy scheme (Fig. 10b) has been incorporated into the 3-MOS program, an FEM code developed in Switzerland from the library Modulef (Ref 19, 38, 39). It is essentially based on an enthalpy method. Because the variation of enthalpy is independent of the solidification path once the heat flow is known, the macro- and microscopic calculations can be somehow decoupled. At the macro level, one can still solve the heat flow equation, as mentioned in the section "Macroscopic Modeling" in this article. Once the variations of enthalpy $\Delta\{H\}$ at all nodes are known, the solidification path can be computed. As shown in Fig. 10(b), the macroscopic time-step Δt can be subdivided into many

smaller time-steps δt to perform the microscopic calculations, assuming that heat removal is made at a constant rate during Δt. The micro-macroscopic coupling scheme seems to give good convergence of the calculated values (undercooling or grain size) (Ref 19). The results (discussed below) illustrate the possibilities of integrating microscopic modeling of solidification into macroscopic heat flow calculations by using an enthalpy method.

Figure 15 shows the recalescences of two Al-7Si specimens. The dotted curves have been measured at the center of two small volumes containing the alloy. The solid curves shown in Fig. 15 have been computed with the analytical model of solute diffusion and are based on the measured grain sizes.

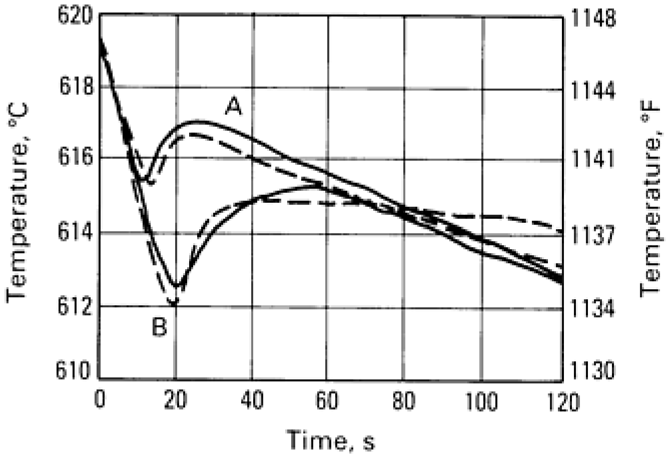

Fig. 15 Measured (dashed lines) and calculated (solid lines) recalescences for two Al-7Si alloys. With 50 ppm Ti inoculant (curve A), the final grain radius was 0.5 mm (0.02 in.). Without inoculant (curve B), the final grain radius was 2 mm (0.08 in.). Source: Ref 32

The six cooling curves shown in Fig. 16 have been measured for a one-dimensional gray cast iron (3% C, 2.5% Si) casting poured in a ceramic mold over a copper chill plate (Ref 39). The effect of silicon on the mechanism of eutectic growth was taken into account by modifying the equilibrium eutectic temperature according to a Scheil model of silicon segregation. Although the agreement between modeling and experiment is poor in the liquid region (above 1160 °C, or 2120 °F), solidification is very well predicted with the macro-micro model. In particular, calculated recalescence undercooling and end of solidification are in good agreement with the experimental curves. However, the solidification of the primary phase close to 1190 °C (2175 °F) was not included in the modeling.

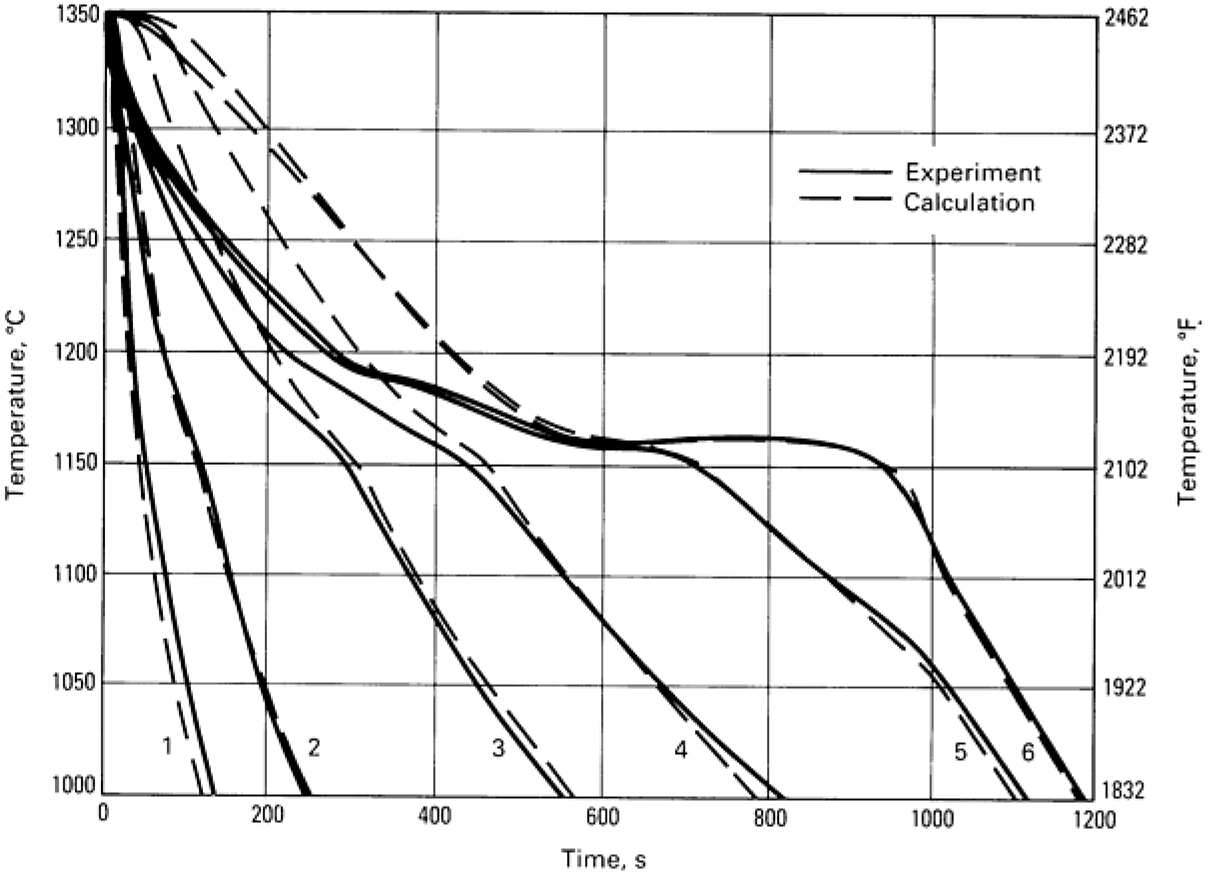

Fig. 16 Measured (dashed lines) and calculated (solid lines) cooling curves for cast iron. Numbers on curves indicate locations of thermocouples in the casting. Height of castings: 120 mm (4.7 in.); number of meshes: 120. The parameters of nucleation deduced from separate microcasting experiments are the following: Gaussian distribution: center at 20 K undercooling, standard deviation: 4.75 K, and total density of sites: 1.2 × $10^{11}/m^3$. Source: Ref 39

One of the primary applications of the macro-microscopic modeling of solidification is the prediction of microstructural features. Figure 17 compares the grain radii measured and calculated at the six locations of the thermocouples where the cooling curves shown in Fig. 16 are recorded. These radii are plotted as a function of the distance from the copper chill plate. The distribution of nucleation sites was a Gaussian line shape whose parameters were deduced from microcastings of the same alloy. Although the discrepancy between experiment and modeling may be substantial (especially for thermocouple No. 5), the trend of increasing the grain size with increasing distances from the chill (or decreasing cooling rates) is correctly predicted. Figure 18 shows a map of grain sizes, calculated with the same micro-macroscopic approach for a two-dimensional Al-7Si casting (Ref 19). As can be seen, the trend of larger grain size at the center of the casting is correctly predicted from the model.

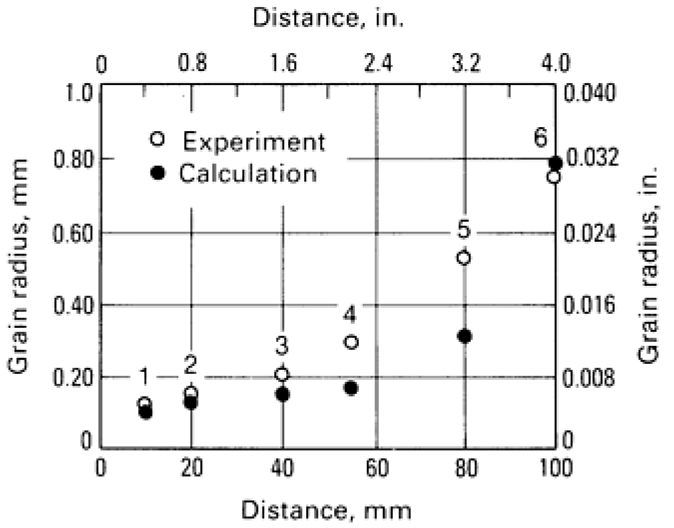

Fig. 17 Experimental and calculated grain radii at the locations of the thermocouples that recorded the cast iron cooling curves shown in Fig. 16. Source: Ref 39

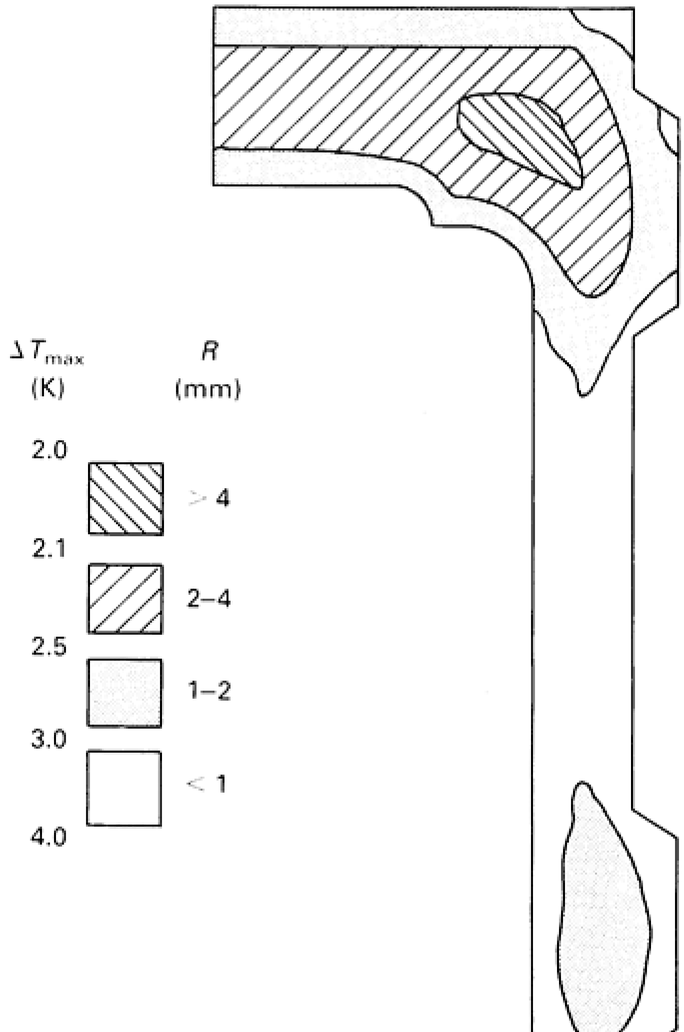

Fig. 18 Map of calculated maximum undercooling ΔT_{max} within a longitudinal section of an axisymmetric casting. Because undercooling can be directly related to the average grain size using the nucleation law, this

figure also maps the average grain radius *R* within the casting.

- A
- **acid**
  - A term applied to slags, refractories, and minerals containing a high percentage of silica.
- **acidity**
  - The degree to which a material is acid. Furnace refractories are ranked by their acidity.
- **acid process**
  - A steelmaking method using an acid refractory-lined furnace. Neither sulfur nor phosphorus is removed.
- **acid refractory**
  - Siliceous ceramic materials of a high melting temperature, such as silica brick, used for metallurgical furnace linings. Compare with basic refractory .
- **addition agent**
  - (1) Any material added to a charge of molten metal in a bath or ladle to bring the alloy to specifications. (2) Reagent added to plating bath.
- **additive**
  - Any material added to molding sand for reasons other than bonding, for example, seacoal, pitch, graphite, cereals.
- **aerate**
  - To fluff up molding sand to reduce its density.
- **airblasting**
  - See blasting or blast cleaning .
- **air channel**
  - A groove or hole that carries the vent from a core to the outside of a mold.
- **air dried**
  - Refers to the air drying of a core or mold without the application of heat.
- **air-dried strength**
  - Strength (compressive, shear, or tensile) of a refractory (sand) mixture after being air dried at room temperature.
- **air furnace**
  - Reverberatory-type furnace in which metal is melted by heat from fuel burning at one end of the hearth, passing over the bath toward the stack at the other end. Heat is also reflected from the roof and sidewalls. See also reverberatory furnace .
- **air hole**
  - A hole in a casting caused by air or gas trapped in the metal during solidification.
- **air setting**
  - The characteristic of some materials, such as refractory cements, core pastes, binders, and plastics, to take permanent set at normal air temperatures.
- **allowance**
  - In a foundry, the specified clearance. The difference in limiting sizes, such as minimum clearance or maximum interference between mating parts, as computed arithmetically. See also tolerance.
- **alpha process**
  - A shell molding and coremaking method in which a thin resinbonded shell is baked with a less expensive, highly permeable material.
- **alumina**
  - The mineral aluminum oxide (Al_2O_3) with a high melting point (refractory) that is sometimes used as a molding sand.
- **angularity**
  - The angular relationship of one surface to another. Specifically, the dimensional tolerance associated with such features on a casting.
- **arbitration bar**
  - A test bar, cast with a heat of material, used to determine chemical composition, hardness, tensile strength, and deflection and strength under transverse loading in order to establish the state of acceptability of the casting.

- **arbor**
  - A metal shape embedded in and used to support green or dry sand cores in the mold.
- **arc furnace**
  - A furnace in which metal is melted either directly by an electric arc between an electrode and the work or indirectly by an arc between two electrodes adjacent to the metal.
- **arc melting**
  - Melting metal in an electric arc furnace.
- **as-cast condition**
  - Castings as removed from the mold without subsequent heat treatment.
- **atmospheric riser**
  - A riser that uses atmospheric pressure to aid feeding. Essentially, a blind riser into which a small core or rod protrudes; the function of the core or rod is to provide an open passage so that the molten interior of the riser will not be under a partial vacuum when metal is withdrawn to feed the casting but will always be under atmospheric pressure.
- **austenite**
  - A solid solution of one or more elements in face-centered cubic iron (gamma iron). Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.
- **B**
- **back draft**
  - A reverse taper that prevents removal of a pattern from a mold or a core from a core box.
- **backing board (backing plate)**
  - A second bottom board on which molds are opened.
- **backup coat**
  - The ceramic slurry of dip coat that is applied in multiple layers to provide a ceramic shell of the desired thickness and strength for use as a mold.
- **bake**
  - Heating in an oven to a low controlled temperature to remove gases or to harden a binder.
- **baked core**
  - A core that has been heated through sufficient time and temperature to produce the desired physical properties attainable from its oxidizing or thermal-setting binders.
- **bank sand**
  - Sedimentary deposits, usually containing less than 5% clay, occurring in banks or pits, used in coremaking and in synthetic molding sands. See sand.
- **basic refractory**
  - A lime- or magnesia-base ceramic material of high melting temperature used for furnace linings. Compare with acid refractory .
- **batch**
  - An amount of core or mold sand or other material prepared at one time.
- **bath**
  - Molten metal on the hearth of a furnace, in a crucible, or in a ladle.
- **bead**
  - (1) Half-round cavity in a mold, or half-round projection or molding on a casting. (2) A single deposit of weld metal produced by fusion.
- **bedding**
  - Sinking a pattern down into the sand to the desired position and ramming the sand around it.
- **bedding a core**
  - Placing an irregularly shaped core on a bed of sand for drying.
- **bench molding**
  - Making sand molds by hand tamping loose or production patterns at a bench without the assistance of air or hydraulic action.
- **bentonite**
  - A colloidal claylike substance derived from the decomposition of volcanic ash composed chiefly of the minerals of the montmorillonite family. It is used for bonding molding sand.
- **bimetal**
  - A casting made of two different metals, usually produced by centrifugal casting .
- **binder**

- A material used to hold the grains of sand together in molds or cores. It may be cereal, oil, clay, or natural or organic resins.

- **blacking**
  - Carbonaceous materials, such as graphite or powdered carbon, usually mixed with a binder and frequently carried in suspension in water or other liquid used as a thin facing applied to surfaces of molds or cores to improve casting finish.
- **blasting or blast cleaning**
  - A process for cleaning or finishing metal objects with an air blast or centrifugal wheel that throws abrasive particles against the surface of the workpiece. Small, irregular particles of metal are used as the abrasive in gritblasting; sand, in sandblasting; and steel balls, in shotblasting.
- **bleed**
  - Refers to molten metal oozing out of a casting. It is stripped or removed from the mold before complete solidification.
- **blended sand**
  - A mixture of sands of different grain size and clay content that provides suitable characteristics for foundry use.
- **blind riser**
  - A riser that does not extend through the top of the mold.
- **blister**
  - A defect in metal, on or near the surface, resulting from the expansion of gas in a subsurface zone. It is characterized by a smooth bump on the surface of the casting and a hole inside the casting directly below the bump.
- **blow**
  - A term that describes the trapping of gas in castings, causing voids in the metal.
- **blowhole**
  - A void or large pore that may occur because of entrapped air, gas, or shrinkage; usually evident in heavy sections.
- **blow holes**
  - Holes in the head plate or blow plate of a core blowing machine through which sand is blown from the reservoir into the core box .
- **bond clay**
  - Any clay suitable for use as a bonding agent in molding sand.
- **bond strength**
  - The degree of cohesiveness that the bonding agent exhibits in holding sand grains together.
- **bonding agent**
  - Any material other than water that, when added to foundry sands, imparts strength either in the green, dry, or fired state.
- **boss**
  - A relatively short protrusion or projection from the surface of a forging or casting, often cylindrical in shape. Usually intended for drilling and tapping for attaching parts. See also locating boss .
- **bottom board**
  - A flat base for holding the flask in making sand molds.
- **bottom-pour ladle**
  - A ladle from which metal, usually steel, flows through a nozzle located at the bottom.
- **bottom running or pouring**
  - Filling of the mold cavity from the bottom by means of gates from the runner.
- **bridging**
  - (1) Premature solidification of metal across a mold section before the metal below or beyond solidifies. (2) Solidification of slag within a cupola at or just above the tuyeres.
- **buckle**
  - (1) Bulging of a large, flat face of a casting; in investment casting, caused by dip coat peeling from the pattern. (2) An indentation in a casting, resulting from expansion of the sand, can be termed the start of an expansion defect.
- **bumper**
  - A machine used for packing molding sand in a flask by repeated jarring or jolting. See also jolt ramming .
- **burned-in sand**

- A defect consisting of a mixture of sand and metal cohering to the surface of a casting.
- **burned-on sand**
  - A misnomer usually indicating metal penetration into sand resulting in a mixture of sand and metal adhering to the surface of a casting. See also metal penetration .
- **burnout**
  - Firing a mold at a high temperature to remove pattern material residue.
- **burned sand**
  - Sand in which the binder or bond has been removed or impaired by contact with molten metal.
- **C**
- **calcium silicon**
  - An alloy of calcium, silicon, and iron containing 28 to 35% Ca, 60 to 65% Si, and 6% Fe (max), used as a deoxidizer and degasser for steel and cast iron; sometimes called calcium silicide.
- **carbonaceous**
  - A material that contains carbon in any or all of its several allotropic forms.
- **carbon dioxide process (sodium silicate/CO_2)**
  - A process for hardening molds or cores in which carbon dioxide gas is blown through dry clay-free silica sand to precipitate silica in the form of a gel from the sodium silicate binder.
- **carbon refractory**
  - A manufactured refractory comprised substantially or entirely of carbon (including graphite).
- **castability**
  - (1) A complex combination of liquid-metal properties and solidification characteristics that promotes accurate and sound final castings. (2) The relative ease with which a molten metal flows through a mold or casting die.
- **castable**
  - A combination of refractory grain and suitable bonding agent that, after the addition of a proper liquid, is generally poured into place to form a refractory shape or structure that becomes rigid because of chemical action.
- **casting**
  - (1) Metal object cast to the required shape by pouring or injecting liquid metal into a mold, as distinct from one shaped by a mechanical process. (2) Pouring molten metal into a mold to produce an object of desired shape.
- **casting defect**
  - Any imperfection in a casting that does not satisfy one or more of the required design or quality specifications. This term is often used in a limited sense for those flaws formed by improper casting solidification.
- **casting section thickness**
  - The wall thickness of the casting. Because the casting may not have a uniform thickness, the section thickness may be specified at a specific place on the casting. Also, it is sometimes useful to use the average, minimum, or typical wall thickness to describe a casting.
- **casting shrinkage**
  - The amount of dimensional change per unit length of the casting as it solidifies in the mold or die and cools to room temperature after removal from the mold or die. There are three distinct types of casting shrinkage. Liquid shrinkage refers to the reduction in volume of liquid metal as it cools to the liquidus. Solidification shrinkage is the reduction in volume of metal from the beginning to the end of solidification. Solid shrinkage involves the reduction in volume of metal from the solidus to room temperature.
- **casting stresses**
  - Stresses set up in a casting because of geometry and casting shrinkage.
- **casting thickness**
  - See casting section thickness .
- **casting volume**
  - The total cubic units (mm^3 or $in.^3$) of cast metal in the casting.
- **casting yield**
  - The weight of a casting(s) divided by the total weight of metal poured into the mold, expressed as a percentage.
- **cast iron**
  - A generic term for a large family of cast ferrous alloys in which the carbon content exceeds the solubility of carbon in austenite at the eutectic temperature. Most cast irons contain at least 2% C,

plus silicon and sulfur, and may or may not contain other alloying elements. For the various forms, the word cast is often left out, resulting in compacted graphite iron , gray iron , white iron , malleable iron , and ductile iron .

- **cast structure**
  - The internal physical structure of a casting evidenced by the shape and orientation of crystals and the segregation of impurities.
- **cavity**
  - The mold or die impression that gives a casting its external shape.
- **cementite**
  - A very hard and brittle compound of iron and carbon corresponding to the empirical formula Fe_3C, commonly known as iron carbide.
- **centerline shrinkage**
  - Shrinkage or porosity occurring along the central plane or axis of a cast part.
- **centrifugal casting**
  - The process of filling molds by (1) pouring metal into a sand or permanent mold that is revolving about either its horizontal or its vertical axis or (2) pouring metal into a mold that is subsequently revolved before solidification of the metal is complete. See also centrifuge casting .
- **centrifuge casting**
  - A casting technique in which mold cavities are spaced symmetrically about a vertical axial common downgate. The entire assembly is rotated about that axis during pouring and solidification.
- **ceramic**
  - Material of a nonmetallic nature, usually refractory, made from fused, sintered, or cemented metallic oxides.
- **ceramic molding**
  - A precision casting process that employs permanent patterns and fine-grain slurry for making molds. Unlike monolithic investment molds, which are similar in composition, ceramic molds consist of a cope and a drag or, if the casting shape permits, a drag only.
- **CG iron**
  - Same as compacted graphite iron .
- **chaplet**
  - Metal support that holds a core in place within a mold; molten metal solidifies around a chaplet and fuses it into the finished casting.
- **charge**
  - (1) The materials placed in a melting furnace. (2) Castings placed in a heat-treating furnace.
- **check**
  - A minute crack in the surface of a casting caused by unequal expansion or contraction during cooling.
- **chill**
  - (1) A metal or graphite insert embedded in the surface of a sand mold or core or placed in a mold cavity to increase the cooling rate at that point. (2) White iron occurring on a gray or ductile iron casting, such as the chill in the wedge test. See also chilled iron . Compare with inverse chill .
- **chill coating**
  - Applying a coating to a chill that forms part of the mold cavity so that the metal does not adhere to it, or applying a special coating to the sand surface of the mold that causes the iron to undercool.
- **chilled iron**
  - Cast iron that is poured into a metal mold or against a mold insert so as to cause the rapid solidification that often tends to produce a white iron structure in the casting.
- **clay**
  - A natural, earthy, fine-grain material that develops plasticity when mixed with a limited amount of water. Foundry clays, which consist essentially of hydrous silicates of alumina, are used in molds and cores.
- **CO_2 process**
  - See carbon dioxide process .
- **coining**

- (1) The process of straightening and sizing castings by die pressing. (2) A press metalworking operation that establishes accurate dimensions of flat surfaces or depressions under predominantly compressive loading.

- **coke**
  - A porous, gray, infusible product resulting from the dry distillation of bituminous coal, petroleum, or coal tar pitch that drives off most of the volatile matter. Used as a fuel in cupola melting.
- **coke bed**
  - The first layer of coke placed in the cupola. Also the coke used as the foundation in constructing a large mold in a flask or pit.
- **coke breeze**
  - Fines from coke screenings, used in blacking mixes after grinding; also briquetted for cupola use.
- **coke furnace**
  - Type of pot or crucible furnace that uses coke as the fuel.
- **cold box process**
  - A two-part organic resin binder system mixed in conventional mixers and blown into shell or solid core shapes at room temperature. A vapor mixed with air is blown into the core, permitting instant setting and immediate pouring of metal around it.
- **cold chamber machine**
  - A die casting machine with an injection system that is charged with liquid metal from a separate furnace. Compare with hot chamber machine .
- **cold cracking**
  - Cracks in cold or nearly cold metal due to excessive internal stress caused by contraction. Often brought about when the mold is too hard or the casting is of unsuitable design.
- **cold lap**
  - Wrinkled markings on the surface of an ingot or casting from incipient freezing of the surface and too low a casting temperature.
- **cold-setting process**
  - Any of several systems for bonding mold or core aggregates by means of organic binders, relying on the use of catalysts rather than heat for polymerization (setting).
- **cold shot**
  - (1) A portion of the surface of an ingot or casting showing premature solidification; caused by splashing of molten metal onto a cold mold wall during pouring. (2) Small globule of metal embedded in, but not entirely fused with, the casting.
- **cold shut**
  - (1) A discontinuity that appears on the surface of cast metal as a result of two streams of liquid meeting and failing to unite. (2) A lap on the surface of a forging or billet that was closed without fusion during deformation. (3) Freezing of the top surface of an ingot before the mold is full.
- **collapsibility**
  - The tendency of a sand mixture to break down under the pressures and temperatures developed during casting.
- **columnar structure**
  - A coarse structure of parallel columns of grains, that is caused by highly directional solidification resulting from sharp thermal gradients.
- **combination die (multiple-cavity die)**
  - In die casting, a die with two or more different cavities for different castings.
- **combined carbon**
  - Carbon in iron that is combined chemically with other elements; not in the free state as graphite or temper carbon. The difference between the total carbon and the graphite carbon analyses. Contrast with free carbon .
- **compacted graphite iron**
  - Cast iron having a graphite shape intermediate between the flake form typical of gray iron and the spherical form of fully spherulitic ductile iron. Also known as CG iron or vermicular iron, compacted graphite iron is produced in a manner similar to that for ductile iron but with a technique that inhibits the formation of fully spherulitic graphite nodules.
- **constraint**
  - Any restriction that limits the transverse contraction normally associated with a longitudinal tension, and therefore causes a secondary tension in the transverse direction.

- **consumable-electrode remelting**
  - A process for refining metals in which an electric current passes between an electrode made of the metal to be refined and an ingot of the refined metal, which is contained in a water-cooled mold. As a result of the passage of electric current, droplets of molten metal form on the electrode and fall to the ingot. The refining action occurs from contact with the atmosphere, vacuum, or slag through which the drop falls. See electroslag remelting and vacuum arc remelting .
- **continuous casting**
  - A process for forming a bar of constant cross section directly from molten metal by gradually withdrawing the bar from a die as the metal flowing into the die solidifies.
- **contraction**
  - The volume change that occurs in metals and alloys upon solidification and cooling to room temperature.
- **convection**
  - The motion resulting in a fluid from the differences in density and the action of gravity. In heat transmission, this meaning has been extended to include both forced and natural motion or circulation.
- **cooling stresses**
  - Stresses developed during cooling by the uneven contraction of metal, generally due to nonuniform cooling.
- **cope**
  - The upper or topmost section of a flask , mold , or pattern .
- **core**
  - (1) A specially formed material inserted in a mold to shape the interior or other part of a casting that cannot be shaped as easily by the pattern. (2) In a ferrous alloy prepared for case hardening, that portion of the alloy that is not part of the case. Typically considered to be the portion that (a) appears light on an etched cross section, (b) has an essentially unaltered chemical composition, or (c) has a hardness, after hardening, less than a specified value.
- **core assembly**
  - A complex core consisting of a number of sections.
- **core binder**
  - Any material used to hold the grains of core sand together.
- **core blow**
  - A gas pocket in a casting adjacent to a cored cavity and caused by entrapped gases from the core.
- **core blower**
  - A machine for making foundry cores using compressed air to blow and pack the sand into the core box.
- **core box**
  - A wood, metal, or plastic structure containing a shaped cavity into which sand is packed to make a core.
- **core dryers**
  - Supports used to hold cores in shape during baking; constructed from metal or sand for conventional baking or from plastic material for use with dielectric core-baking equipment.
- **core filler**
  - Material, such as coke, cinder, and sawdust, used in place of sand in the interiors of large cores; usually added to aid collapsibility.
- **coring**
  - A variable composition between the center and the surface of a unit of structure (such as a dendrite, grain, or carbide particle) resulting from the nonequilibrium growth that occurs over a range of temperature.
- **core knockout machine**
  - A mechanical device for removing cores from castings.
- **coreless induction furnace**
  - An electric induction furnace for melting or holding molten die casting metals that does not utilize a steel core to direct the magnetic field.
- **core oil**
  - A binder for core sand that sets when baked and is destroyed by the heat from the cooling casting.
- **core plates**

- Heat-resistant plates used to support cores during baking; may be metallic or nonmetallic, the latter being a requisite for dielectric core baking.

- **core print**
  - Projections attached to a pattern in order to form recesses in the mold at points where cores are to be supported.
- **core sand**
  - Sand for making cores to which a binding material has been added to obtain good cohesion and permeability after drying; usually low in clays.
- **core shift**
  - A variation from the specified dimensions of a cored casting section due to a change in position of the core or misalignment of cores in assembly.
- **core vents**
  - (1) A wax product, round or oval in form, used to form the vent passage in a core. Also, a metal screen or slotted piece used to form the vent passage in the core box used in a core blowing machine. (2) Holes made in the core for the escape of gas.
- **core wash**
  - A suspension of a fine refractory applied to cores by brushing, dipping, or spraying to improve the surface of the cored portion of the casting.
- **core wires or rods**
  - Reinforcing wires or rods for fragile cores, often preformed into special shapes.
- **corundum**
  - Native alumina, or aluminum oxide, Al_2O_3, occurring as rhombohedral crystals and also in masses and variously colored grains. It is the hardest mineral except for the diamond. Corundum and its artificial counterparts are abrasives especially suited to the grinding of metals.
- **coupon**
  - A piece of metal from which a test specimen is to be prepared; often an extra piece (as on a casting or forging) or a separate piece made for test purposes (such as a test weldment).
- **cover core**
  - (1) A core set in place during the ramming of a mold to cover and complete a cavity partly formed by the withdrawal of a loose part of the pattern. Also used to form part or all of the cope surface of the mold cavity. (2) A core placed over another core to create a flat parting line .
- **critical dimension**
  - A dimension on a part that must be held within the specified tolerance for the part to function in its application. A noncritical tolerance may be for cost or weight savings or for manufacturing convenience, but is not essential for the products.
- **Croning process**
  - A shell molding process that uses a phenolic resin binder. Sometimes referred to as C process or Chronizing.
- **cross-sectional area**
  - The area measured at right angles to the molten metal flow stream at any specified portion of the gating system.
- **crucible**
  - A vessel or pot, made of a refractory substance or of a metal with a high melting point, used for melting metals or other substances.
- **crucible furnace**
  - A melting or holding furnace in which the molten metal is contained in a pot-shaped (hemispherical) shell. Electric heaters or fuel-fired burners outside the shell generate the heat that passes through the shell (crucible) to the molten metal.
- **crush**
  - (1) Buckling or breaking of a section of a casting mold due to incorrect register when the mold is closed. (2) An indentation in the surface of a casting due to displacement of sand when the mold was closed.
- **crush strip or bead**
  - An indentation in the parting line of a pattern plate that ensures that cope and drag will have good contact by producing a ridge of sand that crushes against the other surface of the mold or core.
- **cupola**
  - A cylindrical vertical furnace for melting metal, especially cast iron, by having the charge come in contact with the hot fuel, usually metallurgical coke.

- **curing time (no bake)**
  - The period of time needed before a sand mass reaches maximum hardness.
- **cut**
  - (1) To recondition molding sand by mixing on the floor with a shovel or blade-type machine. (2) To form the sprue cavity in a mold. (3) Defect in a casting resulting from erosion of the sand by metal flowing over the mold or cored surface.
- **cut off**
  - Removing a casting from the sprue by refractory wheel or saw, arc-air torch, or gas torch.
- **D**
- **daubing**
  - Filling of cracks in molds or cores by specially prepared pastes or coatings to prevent penetration of metal into these cracks during pouring.
- **dead-burned**
  - Term applied to materials that have been fired to a temperature sufficiently high to render them relatively resistant to moisture and contraction.
- **defect**
  - A discontinuity whose size, shape, orientation, or location makes it detrimental to the useful service of the part in which it occurs.
- **defective**
  - A quality control term describing a unit of product or service containing at least one defect or having several lesser imperfections that, in combination, cause the unit not to fulfill its anticipated function.
- **degasification**
  - See degassing .
- **degasifier**
  - A substance that can be added to molten metal to remove soluble gases that might otherwise be occluded or entrapped in the metal during solidification.
- **degassing**
  - (1) A chemical reaction resulting from a compound added to molten metal to remove gases from the metal. Inert gases are often used in this operation. (2) A fluxing procedure used for aluminum alloys in which nitrogen, chlorine, chlorine and nitrogen, and chlorine and argon are bubbled up through the metal to remove dissolved hydrogen gases and oxides from the alloy. See also flux .
- **dendrite**
  - A crystal that has a treelike branching pattern, being most evident in cast metals slowly cooled through the solidification range.
- **deoxidation**
  - Removal of excess oxygen from the molten metal; usually accomplished by adding materials with a high affinity for oxygen.
- **deoxidizer**
  - A substance that can be added to molten metal to remove either free or combined oxygen.
- **deoxidizing**
  - (1) The removal of oxygen from molten metals through the use of a suitable deoxidizer . (2) Sometimes refers to the removal of undesirable elements other than oxygen through the introduction of elements or compounds that readily react with them. (3) In metal finishing, the removal of oxide films from metal surfaces by chemical or electrochemical reaction.
- **dephosphorization**
  - The elimination of phosphorus from molten steel.
- **descaling**
  - A chemical or mechanical process for removing scale or investment material from castings.
- **desulfurizing**
  - The removal of sulfur from molten metal by reaction with a suitable slag or by the addition of suitable compounds.
- **dewaxing**
  - The process of removing the expendable wax pattern from an investment mold or shell mold; usually accomplished by melting out the application of heat or dissolving the wax with an appropriate solvent.
- **die casting**

- (1) A casting made in a die. (2) A casting process in which molten metal is forced under high pressure into the cavity of a metal mold.

- **die pull**
    - The direction in which the solidified casting must move when it is removed from the die. The die pull direction must be selected such that all points on the surface of the casting move away from the die cavity surfaces.
- **die separation**
    - The space between the two halves of a die casting die at the parting surface when the dies are closed. The separation may be the result of the internal cavity pressure exceeding the locking force of the machine or warpage of the die due to thermal gradients in the die steel.
- **dip coat**
    - (1) In the solid mold technique of investment casting, an extremely fine ceramic precoat applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. This coating is surrounded by coarser, less expensive, and more permeable investment to form the mold. (2) In the shell mold technique of investment casting, an extremely fine ceramic coating called the first coat, applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The first coat is followed by other dip coats of different viscosity and usually containing different grading of ceramic particles. After each dip, coarser stucco material is applied to the still-wet coating. A buildup of several coats forms an investment shell mold.
- **directional solidification**
    - Solidification of molten metal in such a manner that feed metal is always available for that portion that is just solidifying.
- **discontinuity**
    - Any interruption in the normal physical structure or configuration of a part, such as cracks, laps, seams, inclusions, or porosity. A discontinuity may or may not affect the utility of the part.
- **distortion**
    - Any deviation from the desired shape or contour.
- **dolomite brick**
    - A calcium magnesium carbonate ($Ca{\cdot}Mg(CO_3)_2$) used as a refractory brick that is manufactured substantially or entirely of dead-burned dolomite.
- **dowel**
    - (1) A wooden or metal pin of various types used in the parting surface of parted patterns and core boxes. (2) In die casting dies, metal pins to ensure correct registry of cover and ejector halves.
- **downgate**
    - Same as sprue .
- **draft**
    - (1) An angle or taper on the surface of a pattern, core box, punch, or die (or of the parts made with them) that facilitates removal of the parts from a mold or die cavity, or a core from a casting. (2) The change in cross section that occurs during rolling or cold drawing.
- **drag**
    - The bottom section of a flask , mold , or pattern .
- **draw**
    - A term used to denote the shrinkage that appears on the surface of a casting; formerly used to describe tempering.
- **drawing (pattern)**
    - Removing a pattern from a mold or a mold from a pattern in production work.
- **draw plate**
    - A plate attached to a pattern to facilitate drawing of a pattern from the mold.
- **drop**
    - A casting imperfection due to a portion of the sand dropping from the cope or other overhanging section of the mold.
- **dross**
    - The scum that forms on the surface of molten metal largely because of oxidation but sometimes because of the rising of impurities to the surface.
- **dry and baked compression test**
    - An American Foundrymen's Society test for determining the maximum compressive stress that a baked sand mixture is capable of developing.

- **dry permeability**
    - The property of a molded mass of sand, bonded or unbonded, dried at ~100 to 110 °C (~220 to 230 °F), and cooled to room temperature, that allows the transfer of gases resulting during the pouring of molten metal into a mold.
- **dry sand casting**
    - The process in which the sand molds are dried at above 100 °C (212 °F) before use.
- **dry sand mold**
    - A casting mold made of sand and then dried at ~100 °C (~220 °F) or above before being used. Contrast with green sand mold .
- **dry strength**
    - The maximum strength of a molded sand specimen that has been thoroughly dried at ~100 to 100 °C (~220 to 230 °F) and cooled to room temperature. Also known as dry bond strength.
- **dual-metal centrifugal casting**
    - Centrifugal castings produced by pouring a different metal into the rotating mold after the first metal poured has solidified. Also referred to as bimetal casting.
- **ductile iron**
    - A cast iron that has been treated while molten with an element such as magnesium or cerium to induce the formation of free graphite as nodules or spherulites, which imparts a measurable degree of ductility to the cast metal. Also known as nodular cast iron, spherulitic graphite cast iron, and SG iron.
- **E**
- **ejector**
    - A pin (rod) or mechanism that pushes the solidified die casting out of the die.
- **ejector pin**
    - See ejector .
- **electric arc furnace**
    - See arc furnace .
- **electric furnace**
    - A metal melting or holding furnace that produces heat from electricity. It may operate on the resistance or induction principle.
- **electrode**
    - Compressed graphite or carbon cylinder or rod used to conduct electric current in electric arc furnaces, arc lamps, carbon arc welding, and so forth.
- **electroslag remelting**
    - A consumable-electrode remelting process in which heat is generated by the passage of electric current through a conductive slag. The droplets of metal are refined by contact with the slag. Sometimes abbreviated ESR.
- **endothermic reaction**
    - Designating or pertaining to a reaction that involves the absorption of heat. See also exothermic reaction .
- **equiaxed grain structure**
    - A structure in which the grains have approximately the same dimensions in all directions.
- **ethyl silicate**
    - A strong bonding agent for sand and refractories used in preparing molds in the investment casting process.
- **eutectic**
    - (1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids upon cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectic point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction.
- **exothermic reaction**
    - Chemical reactions involving the liberation of heat, such as the burning of fuel or the deoxidizing of iron with aluminum. See also endothermic reaction .
- **expendable pattern**
    - A pattern that is destroyed in making a casting. It is usually made of wax (investment casting) or expanded polystyrene (lost foam casting).
- **F**

- **facing**
  - Any material applied in a wet or dry condition to the face of a mold or core to improve the surface of the casting. See also mold wash .
- **feeder (feeder head, feedhead)**
  - A riser .
- **feeding**
  - (1) In casting, providing molten metal to a region undergoing solidification, usually at a rate sufficient to fill the mold cavity ahead of the solidification front and to compensate for any shrinkage accompanying solidification. (2) Conveying metal stock or workpieces to a location for use or processing, such as wire to a consumable electrode, strip to a die, or workpieces to an assembler.
- **ferrite**
  - An essentially carbon-free solid solution in which alpha iron is the solvent, and which is characterized by a body-centered cubic crystal structure.
- **ferroalloy**
  - An alloy of iron that contains a sufficient amount of one or more other chemical elements to be useful as an agent for introducing these elements into molten metal, especially into steel or cast iron.
- **ferrous**
  - Metallic materials in which the principal component is iron.
- **fillet**
  - Concave corner piece usually used at the intersection of casting sections. Also the radius of metal at such junctions as opposed to an abrupt angular junction.
- **fillet radius**
  - Blend radius between two abutting walls.
- **fin**
  - Metal on a casting caused by an imperfect joint in the mold or die.
- **finish allowance**
  - Amount of stock left on the surface of a casting for machining.
- **firebrick**
  - A refractory brick, often made from fireclay , that is able to withstand high temperature (1500 to 1600 °C, or 2700 to 2900 °F) and is used to line furnaces, ladles, or other molten metal containment components.
- **fireclay**
  - A mineral aggregate that has as its essential constituent the hydrous silicates of aluminum with or without free silica. It is used in commercial refractory products.
- **fired mold**
  - A shell mold or solid mold that has been heated to a high temperature and is ready for casting.
- **flake graphite**
  - Graphitic carbon, in the form of platelets, occurring in the microstructure of gray iron .
- **flash**
  - A thin section or fin of metal formed at the mold, core, or die joint or parting in a casting due to the cope and drag not matching completely or where core and core print do not match.
- **flask**
  - A metal or wood frame used for making and holding a sand mold. The upper part is called the cope ; the lower, the drag .
- **flaw**
  - A nonspecific term often used to imply a cracklike discontinuity. See preferred terms discontinuity and defect .
- **floor molding**
  - Making sand molds from loose or production patterns of such size that they cannot be satisfactorily handled on a bench or molding machine, the equipment being located on the floor during the entire operation of making the mold.
- **flowability**
  - A characteristic of a foundry sand mixture that enables it to move under pressure or vibration so that it makes intimate contact with all surfaces of the pattern or core box.
- **fluidity**
  - The ability of liquid metal to run into and fill a mold or die cavity.

- **flux**
  - (1) In metal refining, a material used to remove undesirable substances, such as sand, ash, or dirt, as a molten mixture. It is also used as a protective covering for certain molten metal baths. Lime or limestone is generally used to remove sand, as in iron smelting; sand, to remove iron oxide in copper refining. (2) In brazing, cutting, soldering, or welding, material used to prevent the formation of or to dissolve and facilitate the removal of oxides and other undesirable substances.
- **foundry returns**
  - Metal in the form of gates, sprues, runners, risers, and scrapped castings of known composition returned to the furnace for remelting.
- **free carbon**
  - The part of the total carbon in steel or cast iron that is present in elemental form as graphite or temper carbon. Contrast with combined carbon .
- **free ferrite**
  - Ferrite formed into separate grains and not intimately associated with carbides as in pearlite.
- **freezing range**
  - That temperature range between liquidus and solidus temperatures in which molten and solid constituents coexist.
- **full mold**
  - A trade name for an expendable pattern casting process in which the polystyrene pattern is vaporized by the molten metal as the mold is poured.
- **G**
- **gassing**
  - (1) Absorption of gas by a metal. (2) Evolution of gas from a metal during melting operations or upon solidification. (3) Evolution of gas from an electrode during electrolysis.
- **gas holes**
  - Holes in castings or welds that are formed by gas escaping from molten metal as it solidifies. Gas holes may occur individually, in clusters, or throughout the solidified metal.
- **gas pocket**
  - A cavity caused by entrapped gas.
- **gas porosity**
  - Fine holes or pores within a metal that are caused by entrapped gas or by the evolution of dissolved gas during solidification.
- **gate**
  - The portion of the runner in a mold through which molten metal enters the mold cavity. The generic term is sometimes applied to the entire network of connecting channels that conduct metal into the mold cavity.
- **gated pattern**
  - A pattern that includes not only the contours of the part to be cast but also the gates.
- **gating system**
  - The complete assembly of sprues, runners, and gates in a mold through which metal flows to enter the casting cavity. The term is also applied to equivalent portions of the pattern.
- **gooseneck**
  - In die casting, a spout connecting a molten metal holding pot, or chamber, with a nozzle or sprue hole in the die and containing a passage through which molten metal is forced on its way to the die. It is the metal injection mechanism in a hot chamber machine .
- **grain**
  - An individual crystal in a polycrystalline metal or alloy; it may or may not contain twinned regions and subgrains.
- **grain fineness number**
  - A system developed by the American Foundrymen's Society for rapidly expressing the average grain size of a given sand. It approximates the number of meshes per inch of that sieve that would just pass the sample.
- **grain refinement**
  - The manipulation of the solidification process to cause more (and therefore smaller) grains to be formed and/or to cause the grains to form in specific shapes. The term refinement is usually used to denote a chemical addition to the metal, but can refer to control of the cooling rate.
- **grain refiner**
  - Any material added to a liquid metal for producing a finer grain size in the subsequent casting.

- **grain size**
  - For metals, a measure of the areas or volumes of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, grain size refers to that of the matrix unless otherwise specified. Grain size is reported in terms of number of grains per unit area or volume, in terms of average diameter, or as a grain size number derived from area measurements.
- **graphite**
  - One of the crystal forms of carbon; also the uncombined carbon in cast irons.
- **graphitic carbon**
  - Free carbon in steel or cast iron.
- **graphitization**
  - The formation of graphite in iron or steel. Where graphite is formed during solidification, the phenomenon is termed primary graphitization; where formed later by heat treatment, secondary graphitization.
- **gravity die casting**
  - See permanent mold .
- **gray iron**
  - Cast iron that contains a relatively large percentage of the carbon present in the form of flake graphite.
- **green sand**
  - A molding sand that has been tempered with water and is used for casting when still in the damp condition.
- **green sand core**
  - (1) A core made of green sand and used as-rammed. (2) A sand core that is used in the unbaked condition.
- **green sand mold**
  - A casting mold composed of moist prepared molding sand. Contrast with dry sand mold .
- **green strength**
  - The strength of a tempered sand mixture at room temperature.
- **grit**
  - Crushed ferrous or synthetic abrasive material in various mesh sizes that is used in abrasive blasting equipment to clean castings. See also blasting or blast cleaning .
- **gross porosity**
  - In weld metal or in a casting, pores, gas holes or globular voids that are larger and in much greater numbers than those obtained in good practice.
- **growth (cast iron)**
  - A permanent increase in the dimensions of cast iron resulting from repeated or prolonged heating at temperatures above 480 °C (900 °F) due either to graphitizing of carbides or oxidation.
- **H**
- **hardener**
  - An alloy rich in one or more alloying elements that is added to a melt to permit closer control of composition than is possible by the addition of pure metals, or to introduce refractory elements not readily alloyed with the base metal. Sometimes called master alloy or rich alloy.
- **hearth**
  - The bottom portions of certain furnaces, such as blast furnaces, air furnaces, and other reverberatory furnaces, that support the charge and sometimes collect and hold molten metal.
- **heat**
  - A stated tonnage of metal obtained from a period of continuous melting in a cupola or furnace, or the melting period required to handle this tonnage.
- **heat-disposable pattern**
  - A pattern formed from a wax- or plastic-base material that is melted from the mold cavity by the application of heat.
- **holding furnace**
  - A furnace into which molten metal can be transferred to be held at the proper temperature until it can be used to make castings.
- **hot box process**
  - A furan resin-base process similar to shell coremaking; cores produced with it are solid unless mandrelled out.

- **hot chamber machine**
  - A die casting machine in which the metal chamber under pressure is immersed in the molten metal in a furnace. Sometimes called a gooseneck machine.
- **hot crack**
  - A crack formed in a cast metal because of internal stress developed upon cooling following solidification. A hot crack is less open than a hot tear and usually exhibits less oxidation and decarburization along the fracture surface.
- **hot shortness**
  - A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.
- **hot tear**
  - A fracture formed in a metal during solidification because of hindered contraction . Compare with hot crack .
- **hot top**
  - (1) A reservoir, thermally insulated or heated, that holds molten metal on top of a mold for feeding of the ingot or casting as it contracts on solidifying, thus preventing the formation of pipe or voids. (2) A refractory-lined steel or iron casting that is inserted into the tip of the mold and is supported at various heights to feed the ingot as it solidifies.
- **I**
- **impregnation**
  - (1) Treatment of porous castings with a sealing medium to stop pressure leaks. (2) The process of filling the pores of a sintered compact, usually with a liquid such as a lubricant. (3) The process of mixing particles of a nonmetallic substance in a matrix of metal powder, as in diamond-impregnated tools.
- **inclusions**
  - Particles of foreign material in a metallic matrix. The particles are usually compounds (such as oxides, sulfides, or silicates), but may be of any substance that is foreign to (and essentially insoluble in) the matrix.
- **induction furnace**
  - An alternating current electric furnace in which the primary conductor is coiled and generates, by electro-magnetic induction, a secondary current that develops heat within the metal charge. See also coreless induction furnace .
- **induction heating or melting**
  - Heating or melting in an induction furnace .
- **inert gas**
  - A gas that will not support combustion or sustain any chemical reaction, for example, argon or helium.
- **ingate**
  - Same as gate .
- **ingot**
  - A casting of simple shape, suitable for hot working or remelting.
- **injection**
  - The process of forcing molten metal into the die casting die.
- **injection molding**
  - The injection of molten metal or other material under pressure into molds.
- **inoculant**
  - Materials that, when added to molten metal, modify the structure and thus change the physical and mechanical properties to a degree not explained on the basis of the change in composition resulting from their use.
- **inoculation**
  - The addition of a material to molten metal to form nuclei for crystallization. See also inoculant .
- **insert**
  - (1) A part formed from a second material, usually a metal, that is placed in the molds and appears as an integral structural part of the final casting. (2) A removable portion of a die or mold.
- **insulating pads and sleeves**

- Insulating material, such as gypsum, diatomaceous earth, and so forth, used to lower the rate of solidification. As sleeves on open risers, they are used to keep the metal liquid, thus increasing the feeding efficiency. Contrast with chill .
- **internal shrinkage**
  - A void or network of voids within a casting caused by inadequate feeding of that section during solidification.
- **internal stress**
  - See residual stress .
- **inverse chill**
  - The condition in a casting section in which the interior is mottled or white, while the other sections are gray iron. Also known as reverse chill, internal chill, and inverted chill.
- **inverse segregation**
  - Segregation in cast metal in which an excess of lower-melting constituents occurs in the earlier-freezing portions, apparently the result of liquid metal entering cavities developed in the earlier-solidified metal.
- **investing**
  - The process of pouring the investment slurry into a flask surrounding the pattern to form the mold.
- **investment**
  - A flowable mixture, or slurry, of a graded refractory filler, a binder, and a liquid vehicle that, when poured around the patterns, conforms to their shape and subsequently sets hard to form the investment mold.
- **investment casting**
  - (1) Casting metal into a mold produced by surrounding, or investing , an expendable pattern with a refractory slurry that sets at room temperature, after which the wax or plastic pattern is removed through the use of heat prior to filling the mold with liquid metal. Also called precision casting or lost wax process . (2) A part made by the investment casting process.
- **investment precoat**
  - See dip coat .
- **investment precoat**
  - An extremely fine investment coating applied as a thin slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The coating is surrounded by a coarser, cheaper, and more permeable investment to form the mold. See also dip coat .
- **investment shell**
  - Ceramic mold obtained by alternately dipping a pattern set up in dip coat slurry and stuccoing with coarse ceramic particles until the shell of desired thickness is obtained.
- **J**
- **jolt ramming**
  - Packing sand in a mold by raising and dropping the sand, pattern, and flask on a table. Jolt squeezers, jarring machines, and jolt rammers are machines using this principle. Also called jar ramming.
- **jolt-squeezer machine**
  - A combination machine that employs a jolt action followed by a squeezing action to compact the sand around the pattern.
- **K**
- **keel block**
  - A standard test casting, for steel and other high-shrinkage alloys, consisting of a rectangular bar that resembles the keel of a boat, attached to the bottom of a large riser, or shrinkhead. Keel blocks that have only one bar are often called Y-blocks; keel blocks having two bars, double keel blocks. Test specimens are machined from the rectangular bar, and the shrinkhead is discarded.
- **kiln**
  - An oven or furnace for burning, calcining, or drying a substance.
- **knockout**
  - (1) Removal of sand cores from a casting. (2) Jarring of an investment casting mold to remove the casting and investment from the flask. (3) A mechanism for freeing formed parts from a die used for stamping, blanking, drawing, forging or heading operations. (4) A partially pierced hole in a sheet metal part, where the slug remains in the hole and can be forced out by hand if a hole is needed.

- **L**
- **ladle**
  - Metal receptacle frequently lined with refractories used for transporting and pouring molten metal. Types include hand, bull, crane, bottom-pour, holding, teapot, shank, and lip-pour.
- **ladle brick**
  - Refractory brick suitable for lining ladles used to hold molten metal.
- **ladle coating**
  - The material used to coat metal ladles to prevent iron pickup in aluminum alloys. The material can only consist of sodium silicate, iron oxide, and water, applied to the ladle when it is heated.
- **ladle preheating**
  - The process of heating a ladle prior to the addition of molten metal. This procedure reduces metal heat loss and eliminates moisture-steam safety hazards.
- **launder**
  - A channel for transporting molten metal.
- **lining**
  - Internal refractory layer of firebrick, clay, sand, or other material in a furnace or ladle.
- **lip-pour ladle**
  - Ladle in which the molten metal is poured over a lip, much as water is poured out of a bucket.
- **liquation**
  - Partial melting of an alloy, usually as a result of coring or other compositional heterogeneities.
- **liquation temperature**
  - The lowest temperature at which partial melting can occur in an alloy that exhibits the greatest possible degree of segregation.
- **liquidus**
  - In a phase diagram, the locus of points representing the temperatures at which the various compositions in the system begin to freeze on cooling or finish melting on heating. See also solidus .
- **loam**
  - A molding material consisting of sand, silt, and clay, used over brickwork or other structural backup material for making massive castings, usually of iron or steel.
- **locating boss**
  - A boss -shaped feature on a casting to help locate the casting in an assembly or to locate the casting during secondary tooling operations.
- **lost foam casting (process)**
  - An expendable pattern process in which an expandable polystyrene pattern surrounded by the unbonded sand, is vaporized during pouring of the molten metal.
- **lost wax process**
  - An investment casting process in which a wax pattern is used.
- **M**
- **macroshrinkage**
  - Isolated, clustered, or interconnected voids in a casting that are detectable macroscopically. Such voids are usually associated with abrupt changes in section size and are caused by feeding that is insufficient to compensate for solidification shrinkage.
- **malleable iron**
  - A cast iron made by prolonged annealing of white iron in which decarburization, graphitization, or both take place to eliminate some or all of the cementite. The graphite is in the form of temper carbon. If decarburization is the predominant reaction, the product will exhibit a light fracture surface; hence whiteheart malleable. Otherwise, the fracture surface will be dark; hence blackheart malleable. Ferritic malleable has a predominantly ferritic matrix; pearlitic malleable may contain pearlite, spheroidite, or tempered martensite, depending on heat treatment and desired hardness.
- **malleablizing**
  - Annealing white iron in such a way that some or all of the combined carbon is transformed into graphite or, in some cases, so that part of the carbon is removed completely.
- **master alloy**
  - An alloy, rich in one or more desired addition elements, that is added to a melt to raise the percentage of a desired constituent.
- **master pattern**

- A pattern embodying a double contraction allowance in its construction, used for making castings to be employed as patterns in production work.
- **match plate**
  - A plate of metal or other material on which patterns for metal casting are mounted (or formed as an integral part) to facilitate molding. The pattern is divided along its parting plane by the plate.
- **melting point**
  - The temperature at which a pure metal, compound, or eutectic changes from solid to liquid; the temperature at which the liquid and the solid are in equilibrium. See also melting range .
- **melting range**
  - The range of temperatures over which an alloy other than a compound or eutectic changes from solid to liquid; the range of temperatures from solidus to liquidus at any given composition on a phase diagram .
- **metal penetration**
  - A surface condition in castings in which metal or metal oxides have filled voids between sand grains without displacing them.
- **microsegregation**
  - Segregation within a grain, crystal, or small particle. See also coring .
- **microshrinkage**
  - A casting imperfection, not detectable microscopically, consisting of interdendritic voids. Microshrinkage results from contraction during solidification where the opportunity to supply filler material is inadequate to compensate for shrinkage. Alloys with wide ranges in solidification temperature are particularly susceptible.
- **misrun**
  - Denotes an irregularity of the casting surface caused by incomplete filling of the mold due to low pouring temperatures, gas back pressure from inadequate venting of the mold, and inadequate gating.
- **mold**
  - The form, made of sand, metal, or refractory material, that contains the cavity into which molten metal is poured to produce a casting of desired shape.
- **mold cavity**
  - The space in a mold that is filled with liquid metal to form the casting upon solidification. The channels through which liquid metal enters the mold cavity (sprue, runner, gates) and reservoirs for liquid metal (risers) are not considered part of the mold cavity proper.
- **mold coating**
  - (1) Coating to prevent surface defects on permanent mold castings and die castings. (2) Coating on sand molds to prevent metal penetration and to improve metal finish. Also called mold facing or mold dressing.
- **molding machine**
  - A machine for making sand molds by mechanically compacting sand around a pattern.
- **molding sands**
  - Sands containing over 5% natural clay, usually between 8 and 20%. See also naturally bonded molding sand.
- **mold jacket**
  - Wood or metal form that is slipped over a sand mold for support during pouring.
- **mold shift**
  - A casting defect that results when the parts of the mold do not match at the parting line.
- **mold wash**
  - An aqueous or alcoholic emulsion or suspension of various materials used to coat the surface of a mold cavity.
- **mottled cast iron**
  - Iron that consists of a mixture of variable proportions of gray cast iron and white cast iron; such a material has a mottled fracture appearance.
- **mulling**
  - The mixing and kneading of molding sand with moisture and clay to develop suitable properties for molding.
- **N**
- **naturally bonded molding sand**
  - A sand containing sufficient bonding material as mined to be suitable for molding purposes.

- **no-bake binder**
  - A synthetic liquid resin sand binder that hardens completely at room temperature, generally not requiring baking; used in a cold-setting process .
- **nodular graphite**
  - Graphite in the nodular form as opposed to flake form (see flake graphite). Nodular graphite is characteristic of malleable iron. The graphite of nodular or ductile iron is spherulitic in form, but called nodular.
- **nodular iron**
  - See preferred term ductile iron .
- **nominal dimension**
  - The size of the dimension to which the tolerance is applied. For example, if a dimension is 50 mm ± 0.5 mm (2.00 in. ± 0.02 in.), the 50 mm (2.00 in.) is the nominal dimension, and the ±0.5 mm (±0.02 in.) is the tolerance.
- **normal segregation**
  - A concentration of alloying constituents that have low melting points in those portions of a casting that solidify last. Compare with inverse segregation .
- **nozzle**
  - (1) Pouring spout of a bottom-pour ladle. (2) On a hot chamber die casting machine, the thick-wall tube that carries the pressurized molten metal from the gooseneck to the die.
- **nucleation**
  - The initiation of a phase transformation at discrete sites, with the new phase growing on the nuclei. See nucleus (1).
- **nucleus**
  - (1) The first structurally stable particle capable of initiating recrystallization of a phase or the growth of a new phase and possessing an interface with the parent matrix. The term is also applied to a foreign particle that initiates such action. (2) The heavy central core of an atom, in which most of the mass and the total positive electric charge are concentrated.
- **O**
- **olivine**
  - A naturally occurring mineral of the composition $(Mg,Fe)_2SiO_4$ that is crushed and used as a molding sand.
- **open hearth furnace**
  - A reverberatory melting furnace with a shallow hearth and a low roof. The flame passes over the charge on the hearth, causing the charge to be heated both by direct flame and by radiation from the roof and sidewalls of the furnace.
- **open-sand casting**
  - Any casting made in a mold that has no cope or other covering.
- **oxidation**
  - A chemical reaction in which one substance is changed to another by oxygen combining with the substance. Much of the dross from holding and melting furnaces is the result of oxidation of the alloy held in the furnace.
- **oxidation losses**
  - Reduction in the amount of metal or alloy through oxidation. Such losses are usually the largest factor in melting loss.
- **oxygen lance**
  - A length of pipe used to convey oxygen either beneath or on top of the melt in a steelmaking furnace, or to the point of cutting in oxygen lance cutting.
- **P**
- **padding**
  - The process of adding metal to the cross section of a casting wall, usually extending from a riser, to ensure adequate feed metal to a localized area during solidification where a shrink would occur if the added metal were not present.
- **particle size**
  - The controlling lineal dimension of an individual particle, such as of sand, as determined by analysis with screens or other suitable instruments.
- **particle size distribution**
  - The percentage, by weight or by number, of each fraction into which a powder or sand sample has been classified with respect to sieve number or particle size .

- **parting**
  - (1) The zone of separation between cope and drag portions of the mold or flask in sand casting. (2) In the recovery of precious metals, the separation of silver from gold. (3) Cutting simultaneously along two parallel lines or along two lines that balance each other in side thrust. (4) A shearing operation used to produce two or more parts from a stamping.
- **parting compound**
  - A material dusted or sprayed on patterns to prevent adherence of sand and to promote easy separation of cope and drag parting surfaces when the cope is lifted from the drag.
- **parting line**
  - (1) The intersection of the parting plane of a casting mold or the parting plane between forging dies with the mold or die cavity. (2) A raised line or projection on the surface of a casting or forging that corresponds to said intersection.
- **parting plane**
  - (1) In casting, the dividing plane between mold halves. (2) In forging, the dividing plane between dies.
- **pattern**
  - (1) A form of wood, metal, or other material around which molding material is placed to make a mold for casting metals. (2) A form of wax- or plastic-base material around which refractory material is placed to make a mold for casting metals. (3) A full-scale reproduction of a part used as a guide in cutting.
- **pattern draft**
  - Taper allowed on the vertical faces of a pattern to permit easy withdrawal of the pattern from the mold or die.
- **pattern layout**
  - A full-size drawing of a pattern showing its arrangement and structural features.
- **patternmaker's shrinkage**
  - Contraction allowance made on patterns to compensate for the decrease in dimensions as the solidified casting cools in the mold from the freezing temperature of the metal to room temperature. The pattern is made larger by the amount of contraction that is characteristic of the particular metal to be used.
- **penetration**
  - See metal penetration .
- **permanent mold**
  - A metal, graphite or ceramic mold (other than an ingot mold) that is repeatedly used for the production of many castings of the same form. Liquid metal is poured in by gravity (gravity die casting).
- **permeability**
  - (1) In founding, the characteristics of molding materials that permit gases to pass through them. (2) In powder metallurgy, a property measured as the rate of passage under specified conditions of a liquid or gas through a compact. (3) A general term used to express various relationships between magnetic induction and magnetizing force. These relationships are either absolute permeability, which is a change in magnetic induction divided by the corresponding change in magnetizing force, or specific (relative) permeability, which is the ratio of the absolute permeability to the permeability of free space.
- **phase diagram**
  - A graphical representation of the temperature and composition limits of phase fields in an alloy system as they actually exist under the specific conditions of heating or cooling.
- **pinhole porosity**
  - Porosity consisting of numerous small gas holes distributed throughout the metal; found in weld metal, castings, and clectrodeposited metal.
- **pipe**
  - (1) The central cavity formed by contraction in metal, especially ingots, during solidification. (2) An imperfection in wrought or cast products resulting from such a cavity. (3) A tubular metal product, cast or wrought.
- **pit molding**
  - Molding method in which the drag is made in a pit or hole in the floor.
- **plaster molding**

- Molding in which a gypsum-bonded aggregate flour in the form of a water slurry is poured over a pattern, permitted to harden, and, after removal of the pattern, thoroughly dried. This technique is used to make smooth nonferrous castings of accurate size.

- **plunger**
  - Ram or piston that forces molten metal into a die in a die casting machine. Plunger machines are those having a plunger in continuous contact with molten metal.
- **porosity**
  - A characteristic of being porous, with voids or pores resulting from trapped air or shrinkage in a casting. See also gas porosity and pinhole porosity .
- **port**
  - The opening through which molten metal enters the injection cylinder of a die casting plunger machine, or is ladled into the injection cylinder of a cold chamber machine. See also cold chamber machine and plunger .
- **pot**
  - (1) A vessel for holding molten metal. (2) The electrolytic reduction cell used to make such metals as aluminum from a fused electrolyte.
- **pouring**
  - The transfer of molten metal from furnace to ladle, ladle to ladle, or ladle into molds.
- **pouring basin**
  - A basin on top of a mold that receives the molten metal before it enters the sprue or downgate.
- **precision casting**
  - A metal casting of reproducible, accurate dimensions, regardless of how it is made. Often used interchangeably with investment casting .
- **preformed ceramic core**
  - A preformed refractory aggregate inserted in a wax or plastic pattern to shape the interior of that part of a casting which cannot be shaped by the pattern. The wax is sometimes injected around the preformed core.
- **pressure casting**
  - (1) Making castings with pressure on the molten or plastic metal, as in injection molding , die casting , centrifugal casting , cold chamber pressure casting, and squeeze casting . (2) A casting made with pressure applied to the molten or plastic metal.
- **primary alloy**
  - Any alloy whose major constituent has been refined directly from ore, not recycled scrap metal. Compare with secondary alloy .
- **projected area**
  - The area of a cavity, or portion of a cavity, in a mold or die casting die measured from the projection on a plane that is normal to the direction of the mold or die opening.
- **R**
- **ramming**
  - (1) Packing sand, refractory, or other material into a compact mass. (2) The compacting of molding sand in forming a mold.
- **rattail**
  - A surface imperfection on a casting, occurring as one or more irregular lines, caused by the expansion of sand in the mold. Compare with buckle (2).
- **recrystallization**
  - A process in which the distorted grain structure of cold-worked metals is replaced by a new, strain-free grain structure during heating above a specific minimum temperature.
- **recrystallization temperature**
  - The lowest temperature at which the distorted grain structure of a cold-worked metal is replaced by a new, strain-free grain structure during prolonged heating. Time, purity of the metal, and prior deformation are important factors.
- **refractory**
  - (1) A material of very high melting point with properties that make it suitable for such uses as furnace linings and kiln construction. (2) The quality of resisting heat.
- **residual stress**
  - Stress present in a body that is free of external forces or thermal gradients.
- **reverberatory furnace**

- A furnace in which the flame used for melting the metal does not impinge on the metal surface itself, but is reflected off the walls of the roof of the furnace. The metal is actually melted by the generation of heat from the walls and the roof of the furnace.

- **rheocasting**
  - Casting of a continuously stirred semisolid metal slurry.
- **rigging**
  - The engineering design, layout, and fabrication of pattern equipment for producing castings; including a study of the casting solidification program, feeding and gating, risering, skimmers, and fitting flasks.
- **riser**
  - A reservoir of molten metal connected to a casting to provide additional metal to the casting, required as the result of shrinkage before and during solidification.
- **runner**
  - (1) A channel through which molten metal flows from one receptacle to another. (2) The portion of the gate assembly of a casting that connects the sprue with the gate(s). (3) Parts of patterns and finished castings corresponding to the portion of the gate assembly described in (2).
- **runner box**
  - A distribution box that divides molten metal into several streams before it enters the mold cavity.
- **runout**
  - (1) The unintentional escape of molten metal from a mold, crucible, or furnace. (2) The defect in a casting caused by the escape of metal from the mold.
- **S**
- **sag**
  - An increase or decrease in the section thickness of a casting caused by insufficient strength of the mold sand of the cope or of the core.
- **sand**
  - A granular material naturally or artificially produced by the disintegration or crushing of rocks or mineral deposits. In casting, the term denotes an aggregate, with an individual particle (grain) size of 0.06 to 2 mm (0.002 to 0.08 in.) in diameter, that is largely free of finer constituents such as silt and clay, which are often present in natural sand deposits. The most commonly used foundry sand is silica ; however, zircon , olivine , alumina , and other crushed ceramics are used for special applications.
- **sandblasting**
  - Abrasive blasting with sand. See blasting or blast cleaning and compare with shotblasting .
- **sand casting**
  - Metal castings produced in sand molds.
- **sand grain distribution**
  - Variation or uniformity in particle size of a sand aggregate when properly screened by standard screen sizes.
- **sand reclamation**
  - Processing of used foundry sand by thermal, air, or hydraulic methods so that it can be used in place of new sand without substantially changing the foundry sand practice.
- **sand tempering**
  - Adding sufficient moisture to molding sand to make it workable.
- **scab**
  - A defect on the surface of a casting that appears as a rough, slightly raised surface blemish, crusted over by a thin porous layer of metal, under which is a honeycomb or cavity that usually contains a layer of sand; defect common to thin-wall portions of the casting or around hot areas of the mold.
- **scaling (scale)**
  - Surface oxidation, consisting of partially adherent layers of corrosion products, left on metals by heating or casting in air or in other oxidizing atmospheres.
- **screen**
  - One of a set of sieves designated by the size of the openings, used to classify granular aggregates such as sand, ore, or coke by particle size.
- **screen analysis**
  - See sieve analysis .
- **seam**

- (1) A surface defect on a casting related to but of lesser degree than a cold shut . (2) A ridge on the surface of a casting caused by a crack in the mold face.

- **secondary alloy**
  - Any alloy whose major constituent is obtained from recycled scrap metal. Compare with primary alloy .
- **segregation**
  - A casting defect involving a concentration of alloying elements at specific regions, usually as a result of the primary crystallization of one phase with the subsequent concentration of other elements in the remaining liquid. Microsegregation refers to normal segregation on a microscopic scale in which material richer in an alloying element freezes in successive layers on the dendrites (coring) and in constituent network. Macrosegregation refers to gross differences in concentration (for example, from one area of a casting to another). See also inverse segregation and normal segregation .
- **semipermanent mold**
  - A permanent mold in which sand cores are used.
- **shakeout**
  - Removal of castings from a sand mold. See also knockout .
- **Shaw (Osborn-Shaw) Process**
  - See ceramic molding .
- **shell molding**
  - Forming a mold from thermo-setting resin-bonded sand mixtures brought in contact with preheated (150 to 260 °C, or 300 to 500 °F) metal patterns, resulting in a firm shell with a cavity corresponding to the outline of the pattern. Also called Croning process .
- **shift**
  - A casting imperfection caused by the mismatch of cope and drag or of cores and mold.
- **shot**
  - (1) Small, spherical particles of metal. (2) The injection of molten metal into a die casting die. The metal is injected so quickly that it can be compared to the shooting of a gun.
- **shotblasting**
  - Blasting with metal shot ; usually used to remove deposits or mill scale more rapidly or more effectively than can be done by sandblasting .
- **shrinkage**
  - See casting shrinkage .
- **shrinkage cavity**
  - A void left in cast metal as a result of solidification shrinkage. See also casting shrinkage .
- **shrinkage cracks**
  - Cracks that form in metal as a result of the pulling apart of grains by contraction before complete solidification.
- **sieve analysis**
  - Particle size distribution ; usually expressed as the weight percentage retained on each of a series of standard sieves of decreasing size and the percentage passed by the sieve of finest size. Synonymous with sieve classification.
- **silica**
  - Silicon dioxide (SiO_2); the primary ingredient of sand and acid refractories.
- **silica flour**
  - A sand additive, containing about 99.5% silica, commonly produced by pulverizing quartz sand in large ball mills to a mesh size of 80 to 325.
- **skim gate**
  - A gating arrangement designed to prevent the passage of slag and other undesirable materials into a casting.
- **skimming**
  - Removing or holding back dirt or slag from the surface of the molten metal before or during pouring.
- **skin drying**
  - Drying the surface of the mold by direct application of heat.
- **slag**

    - A nonmetallic product resulting from the mutual dissolution of flux and nonmetallic impurities in smelting, refining, and certain welding operations. In steelmaking operations, the slag serves to protect the molten metal from the air and to extract certain impurities.
- **slag inclusion**
    - Slag or dross entrapped in a metal.
- **slip flask**
    - A tapered flask that depends on a movable strip of metal to hold the sand in position. After closing the mold, the strip is retracted and the flask can be removed and reused. Molds made in this manner are usually supported by a mold jacket during pouring.
- **slush casting**
    - A hollow casting usually made of an alloy with a low but wide melting temperature range. After the desired thickness of metal has solidified in the mold, the remaining liquid is poured out.
- **snap flask**
    - A foundry flask hinged on one corner so that it can be opened and removed from the mold for reuse before the metal is poured.
- **solid shrinkage**
    - See casting shrinkage .
- **solidification**
    - The change in state from liquid to solid upon cooling through the melting temperature or melting range.
- **solidification shrinkage**
    - See casting shrinkage .
- **solidus**
    - In a phase diagram, the locus of points representing the temperatures at which various compositions stop freezing upon cooling or begin to melt upon heating. See also liquidus .
- **solute**
    - A metal or substance dissolved in a major constituent; the component that is dissolved in the solvent.
- **solvent**
    - The base metal or major constituent in a solution; the component that dissolves the solvent.
- **sprue**
    - (1) The mold channel that connects the pouring basin with the runner or, in the absence of a pouring basin, directly into which molten metal is poured. Sometimes referred to as downsprue or downgate. (2) Sometimes used to mean all gates, risers, runners, and similar scrap that are removed from castings after shakeout.
- **squeeze casting**
    - A hybrid liquid-metal forging process in which liquid metal is forced into a permanent mold by a hydraulic press.
- **stack molding**
    - A molding method that makes use of both faces of a mold section, with one face acting as the drag and the other as the cope. Sections, when assembled to other similar sections, form several tiers of mold cavities, and all castings are poured together through a common sprue.
- **stopper rod**
    - A device in a bottom-pour ladle for controlling the flow of metal through the nozzle into a mold. The stopper rod consists of a steel rod, protective refractory sleeves, and a graphite stopper head.
- **stopping off**
    - Filling in a portion of a mold cavity to keep out molten metal.
- **strainer core**
    - A perforated core in the gating system for preventing slag and other extraneous material from entering the casting cavity.
- **stripping**
    - Removing the pattern from the mold or the core box from the core.
- **styrofoam pattern**
    - An expendable pattern of foamed plastic, especially expanded polystyrene, used in manufacturing castings by the lost foam process.
- **supercooling**
    - Lowering the temperature of a molten metal below its liquidus during cooling.
- **superheat**

    - Any increment of temperature above the melting point of a metal; sometimes construed to be any increment of temperature above normal casting temperatures introduced for the purpose of refining, alloying, or improving fluidity.
- **superheating**
    - Raising the temperature of molten metal above the normal melting temperature for more complete refining and greater fluidity.
- **supersaturated**
    - A metastable solution in which the dissolved material exceeds the amount the solvent can hold in normal equilibrium at the temperature and other conditions that prevail.
- **surface area**
    - The actual area of the surface of a casting or cavity. The surface area is always greater than the projected area .
- **sweep**
    - A type of pattern that is a template cut to the profile of the desired mold shape that, when revolved around a stake or spindle, produces that shape in the mold.
- **T**
- **teapot ladle**
    - A ladle in which, by means of an external spout, metal is removed from the bottom rather than the top of the ladle.
- **temper**
    - (1) To moisten green sand for casting molds with water. (2) In heat treatment, to reheat hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process is also sometimes applied to normalized steel. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties or reduction in area during cold working.
- **thermal expansion**
    - The increase in linear dimensions of a material accompanying an increase in temperature.
- **thin-wall casting**
    - A term used to define a casting that has the minimum wall thickness to satisfy its service function.
- **tie bar**
    - A bar-shaped connection added to a casting to prevent distortion caused by uneven contraction between two separated members of the casting.
- **tolerance**
    - The specified permissible deviation from a specified nominal dimension, or the permissible variation in size or other quality characteristic of a part.
- **tramp element**
    - Contaminant in the components of a furnace charge, or in the molten metal or castings, whose presence is thought to be either unimportant or undesirable to the quality of the casting. Also called trace element.
- **transfer ladle**
    - A ladle that can be supported on a monorail or carried in a shank and used to transfer metal from the melting furnace to the holding furnace or from the furnace to the pouring ladles.
- **tumbling**
    - Rotating workpieces, usually castings or forgings, in a barrel partially filled with metal slugs or abrasives, to remove sand, scale, or fins. It may be done dry or with an aqueous solution added to the contents of the barrel. Sometimes called rumbling or rattling.
- **tuyere**
    - An opening in a cupola, blast furnace, or converter for the introduction of air or inert gas.
- **U**
- **undercooling**
    - Same as supercooling .
- **undercut**
    - A recess having an opening smaller than the internal configuration, thus preventing the mechanical removal of a one-piece core.
- **V**

- **vacuum arc remelting**
  - A consumable-electrode remelting process in which heat is generated by an electric arc between the electrode and the ingot. The process is performed inside a vacuum chamber. Exposure of the droplets of molten metal to the reduced pressure reduces the amount of dissolved gas in the metal. Sometimes abbreviated VAR.
- **vacuum casting**
  - A casting process in which metal is melted and poured under very low atmospheric pressure; a form of permanent mold casting in which the mold is inserted into liquid metal, vacuum is applied, and metal is drawn up into the cavity.
- **vacuum degassing**
  - The use of vacuum techniques to remove dissolved gases from molten alloys.
- **vacuum induction melting**
  - A process for remelting and refining metals in which the metal is melted inside a vacuum chamber by induction heating. The metal can be melted in a crucible and then poured into a mold. Sometimes abbreviated VIM.
- **vacuum melting**
  - Melting in a vacuum to prevent contamination from air and to remove gases already dissolved in the metal; the solidification can also be carried out in a vacuum or at low pressure.
- **vacuum molding**
  - See V process .
- **vacuum refining**
  - Melting in a vacuum to remove gaseous contaminants from the metal.
- **vent**
  - A small opening or passage in a mold or core to facilitate the escape of gases when the mold is poured.
- **vermicular iron**
  - Same as compacted graphite iron .
- **void**
  - A shrinkage cavity produced in castings during solidification.
- **V process**
  - A molding process in which the sand is held in place in the mold by vacuum. The mold halves are covered with a thin sheet of plastic to retain the vacuum.
- **W**
- **warpage**
  - Deformation other than contraction that develops in a casting between solidification and room temperature; also the distortion that occurs during annealing, stress relieving, and high-temperature service.
- **wash**
  - (1) A coating applied to the face of a mold prior to casting. (2) An imperfection at a cast surface similar to a cut (3).
- **wax pattern**
  - A precise duplicate, allowing for shrinkage, of the casting and required gates, usually formed by pouring or injecting molten wax into a die or mold.
- **white iron**
  - Cast iron that shows a white fracture because the carbon is in combined form.
- **Y**
- **yield**
  - Comparison of casting weight to the total weight of metal poured into the mold.
- **Z**
- **zircon**
  - The mineral zircon silicate ($ZrSiO_4$), a very high melting point acid refractory material used as a molding sand.
- **zone melting**
  - Highly localized melting, usually by induction heating, of a small volume of an otherwise solid piece, usually a rod. By moving the induction coil along the rod, the melted zone can be transferred from one end to the other. In a binary mixture where there is a large difference in composition on the liquidus and solidus lines, high purity can be attained by concentrating one of the constituents in the liquid as it moves along the rod.

- **Abbreviations and Symbols**

- ***a***
  - atomic distance between crystallographic planes parallel to interface; jump distance; crystal lattice length along the *a* axis; activity
- a_0
  - length scale related to interatomic distance; molecular diameter
- ***A***
  - area
- A_m
  - area occupied by one mole at the interface
- A_{nL}
  - nucleant-liquid interfacial area
- A_{nS}
  - nucleant-solid interfacial area
- A_{SL}
  - solid-liquid interfacial area
- **ac**
  - alternating current
- **at.%**
  - atomic percent
- **atm**
  - atmosphere (pressure)
- **A**
  - ampere
- Å
  - angstrom
- **ABST**
  - alpha-beta solution treatment
- **AC**
  - air cool
- **ACI**
  - Alloy Casting Institute
- **ADCI**
  - American Die Casting Institute
- **ADI**
  - austempered ductile iron
- **AFS**
  - American Foundrymen's Society
- **AGV**
  - automatic guided vehicle
- **AISI**
  - American Iron and Steel Institute
- **ANSI**
  - American National Standards Institute
- **AOD**
  - argon oxygen decarburization
- **ASTM**
  - American Society for Testing and Materials
- **AS/RS**
  - automatic storage and retrieval systems

- **AWS**
  - American Welding Society
- ***b***
  - crystal lattice length along the *b* axis
- **bcc**
  - body-centered cubic
- **BCIRA**
  - British Cast Iron Research Association
- **BEM**
  - boundary element method
- **BOP**
  - basic oxygen process
- **BST**
  - beta solution treatment
- **BUS**
  - broken-up structure
- ***c***
  - crystal lattice length along the *c* axis
- C_a
  - number of surface atoms of the nucleation site per unit volume of liquid
- C_B
  - composition of ideal solution
- C_E
  - eutectic composition
- $C_{i\infty}$
  - uniform level of solute that exists at sufficiently large distance from interface
- C_L
  - solute composition in the liquid
- C^*_L
  - liquid concentration in mutual equilibrium across a plane solid-liquid interface
- C_{max}
  - maximum composition
- C_{min}
  - minimum composition
- C_o
  - initial alloy composition
- C_P
  - heat capacity
- C_P^s
  - specific heat of the sample
- C_S
  - solid composition of an alloy; solute composition in the solid
- $\overline{C}_S$
  - mean solid composition
- C^*_S
  - solid concentration in mutual equilibrium across a plane solid-liquid interface
- C_0
  - initial concentration
- ΔC_L
  - change in liquid solubility
- ΔC_S
  - change in solid solubility
- $C(n)$
  - metastable equilibrium concentration of clusters of a given size
- $C(n_{cr})$
  - concentration of critical clusters

- **cpm**
  - cycles per minute
- **cps**
  - cycles per second
- **cpt**
  - critical preheating temperature
- **csg**
  - constructive solid geometry
- **C**
  - concentration
- **C_l**
  - number of atoms per cubic meter in the liquid
- **CAB**
  - calcium argon blowing
- **CAD**
  - computer-aided design
- **CADTA**
  - computer-aided differential thermal analysis
- **CAE**
  - computer-aided engineering
- **CAM**
  - computer-aided manufacturing
- **CE**
  - carbon equivalent
- **CET**
  - columnar-equiaxed transition
- **CG**
  - compacted graphite
- **CIM**
  - computer-integrated manufacturing
- **CLA**
  - counter-gravity low-pressure casting of air-melted alloys
- **CLAS**
  - counter-gravity low-pressure air-melted sand casting
- **CLV**
  - counter-gravity low-pressure casting of vacuum-melted alloys
- **CMM**
  - coordinate measuring machine(s)
- **CNC**
  - computerized numerical control
- **CRE**
  - carbon removal efficiency
- **CRR**
  - carbon removal rate
- **CS**
  - ceramic shell; constitutional supercooling
- **CSP**
  - constitutional supercooling parameter
- **CST**
  - constitutional solution treatment
- **CV**
  - check valve casting
- **CVD**
  - chemical vapor deposition
- **CVM**
  - control volume method
- **CVN**

    - Charpy V-notch (impact test or specimen)
- ***d***
    - particle-solid distance; used in mathematical expressions involving a derivative (denotes rate of change); depth; diameter
- d_S
    - contact distance between particles
- d_0
    - minimum separation distance between particle and solid (; 10^{-5} cm)
- d_1
    - minimum separation (; 10^{-7} cm)
- ***da*/*dN***
    - fatigue crack growth rate
- ***D***
    - diameter; distance; diffusivity; diffusion coefficient; density
- D_C^{γ}
    - diffusivity of carbon in austenite
- D_{eff}
    - effective diffusion coefficient
- D_L
    - liquid diffusivity
- $D_{L,i}$
    - liquid diffusivity of solute *i*
- D_S
    - diffusion coefficient in the solid
- **dc**
    - direct current
- **diam**
    - diameter
- **D**
    - ingot diameter
- **DAS**
    - dendrite arm spacing
- **DCEP**
    - direct current electrode positive
- **DCRF**
    - Die Casting Research Foundation
- **DIS**
    - Draft International Standard
- **DOC**
    - Department of Commerce
- **DS**
    - directional solidification
- **DT**
    - drop tower
- ***e***
    - natural log base, 2.71828; electron
- e_P
    - particle charge
- e_S
    - solid charge
- ***et al.***
    - and others
- ***E***
    - modulus of elasticity
- E_c
    - elastic modulus of composite
- E_f

    - elastic modulus of fiber
- **E_m**
    - elastic modulus of matrix
- **EAF**
    - electric arc furnace
- **EB**
    - electron beam
- **EDM**
    - electrical discharge machining
- **EPC**
    - evaporative pattern casting
- **EPS**
    - expanded polystyrene pattern
- **Eq**
    - equation
- **ESR**
    - electroslag remelting
- **ESW**
    - electroslag welding
- **EVA**
    - ethylene-vinyl acetate co-polymer
- **f**
    - fraction
- **f_E**
    - volume fraction of the eutectic phase
- **f_S**
    - volume fraction of the solid
- **f_α**
    - volume fraction of α phase
- **f_β**
    - volume fraction of β phase
- **$f(\theta)$**
    - shape factor
- **F**
    - faceting factor
- **F_r**
    - repulsive force
- **ΔF**
    - change in free energy
- **fcc**
    - face-centered cubic
- **ft**
    - foot
- **FC**
    - furnace cool
- **FCAW**
    - flux cored arc welding
- **FDM**
    - finite difference method
- **FEM**
    - finite element method
- **F(f)**
    - function of volume fraction f_α and f_β
- **FG**
    - flake graphic
- **Fig.**
    - figure

- **FM**
  - full mold
- **FM (process)**
  - *fonte mince* (thin iron) process
- **FRC**
  - free radical cure
- **FRM**
  - fiber-reinforced metals
- ***g***
  - acceleration due to gravity
- ***G***
  - modulus of rigidity; temperature gradient; thermal gradient
- **G_L**
  - temperature gradient in the liquid; molar free energy in the liquid
- **G_M**
  - average temperature gradient in the two-phase region
- **G_S**
  - temperature gradient in the liquid; molar free energy of the solid
- **ΔG_{cr}**
  - activation barrier for nucleation
- **ΔG_m**
  - molar free energy change of mixing
- **$\Delta G(r)$**
  - free energy change to form a cluster of size *r*
- **g**
  - gram; gas
- **gal.**
  - gallon
- **GFN**
  - grain fineness number
- **GMAW**
  - gas metal arc welding
- **GPa**
  - gigapascal
- **Gr**
  - graphite
- **GTAW**
  - gas tungsten arc welding
- ***h***
  - contact distance between particles
- ***H***
  - enthalpy; height; magnetic field strength
- **H_L**
  - enthalpy of the liquid
- **H_S**
  - enthalpy of the solid
- ΔH_f^A
  - latent heat of pure solvent A
- **ΔH_m**
  - heat of mixing
- **ΔH_s**
  - enthalpy of sublimation per mole
- **ΔH_v**
  - enthalpy of vaporization per mole
- **h**
  - height above substrate; hour

- **hcp**
  - hexagonal close-packed
- **hp**
  - horsepower
- **ΔH**
  - heat of solidification
- **HAZ**
  - heat-affected zone
- **HB**
  - Brinell hardness
- **HIP**
  - hot isostatic pressing
- **HK**
  - Knoop hardness
- **HR**
  - Rockwell hardness (requires scale designation, such as HRC for Rockwell C hardness)
- **HSLA**
  - high-strength low-alloy (steel)
- **HTH**
  - high-temperature hydrogenation
- **HV**
  - Vickers hardness
- **HVC**
  - hydrovac process
- **Hz**
  - hertz
- ***i***
  - solute
- ***I***
  - inductor current
- ***I*(P)**
  - Ivantsov function
- **in.**
  - inch
- **IACS**
  - International Annealed Copper Standard
- **ICFTA**
  - International Committee of Foundry Technical Associations
- **ID**
  - inner diameter
- **ISO**
  - International Organization for Standardization
- **JIS**
  - Japanese Industrial Standard
- ***k***
  - equilibrium partition coefficient; Boltzman constant; solute distribution coefficient
- k_{ef}
  - effective partition coefficient
- k_N
  - nonequilibrium partition coefficient
- k_v
  - dependence of partition coefficient on velocity
- ***K***
  - thermal conductivity; modulus constant; stress intensity factor
- K_{Ic}
  - plane-strain fracture toughness
- K_L

    - thermal conductivity of the liquid
- K_P
    - thermal conductivity of the particle at the interface
- K_S
    - thermal conductivity of the solid
- K_t
    - theoretical stress concentration factor
- **kg**
    - kilogram
- **km**
    - kilometer
- **kPa**
    - kilopascal
- **ksi**
    - kips (1000 lb) per square inch
- **kV**
    - kilovolt
- **K**
    - interface curvature; permeability; Kelvin
- l_i
    - characteristic diffusion length
- l_t
    - characteristic conduction length
- L
    - length; latent heat per unit volume
- **l**
    - cell length
- l^{b}
    - thickness of the beta phase
- **lb**
    - pound
- **ln**
    - natural logarithm (base *e*)
- **L**
    - liquid; liter
- **LBE**
    - lance bubble equilibrium
- **LF**
    - ladle furnace
- **LF/VD**
    - ladle furnace vacuum degassing
- **LF/VD-VAD**
    - ladle furnace and vacuum arc degassing
- **LMR**
    - liquid metal refining
- m_L
    - liquidus slope
- m_S
    - solidus slope
- $m\alpha$
    - slope of liquidus line of α phase
- $m\beta$
    - slope of liquidus line of β phase
- M_s
    - martensite start temperature
- **m**
    - meter

- **mg**
  - milligram
- **min**
  - minimum; minute
- **mips**
  - million instructions per second
- **mL**
  - milliliter
- **mm**
  - millimeter
- **mph**
  - miles per hour
- **M**
  - metal
- **MDI**
  - methyl di-isocyanate
- **Mg**
  - megagram (metric tonne)
- **MHD**
  - magnetohydrodynamic (casting)
- **MINT**
  - metal in-line treatment
- **MMC**
  - metal-matrix composite
- **MPa**
  - megapascal
- ***n***
  - planar nucleant substrate; strain-hardening exponent
- ***n*'**
  - strain-hardening coefficient
- **n_{cr}**
  - number of atoms in a cluster
- ***N***
  - number of cycles to failure
- **nm**
  - nanometer
- **N**
  - newton
- **NASA**
  - National Aeronautics and Space Administration
- **NC**
  - numerical control

  - phenolic urethane cold box
- **PUN**
  - phenolic urethane no-bake
- **PWHT**
  - postweld heat treatment
- ***q***
  - fatigue notch sensitivity factor
- ***Q***
  - activation energy for liquid diffusion; quality index
- **QLR**
  - quick lining remover
- **QT**
  - quenched and tempered
- ***r***
  - particle radius; radius of any particle with no irregularities
- ***r****
  - spherical radius
- r_b
  - radius of any particle irregularity or bump
- r_{cr}
  - critical cluster size

- r_{Gr}
  - radius of graphite
- r_P
  - paraboloid tip radius
- $r\gamma$
  - radius of austenite
- R
  - gas constant; growth rate; stress (load) ratio; radius; gas constant
- R_{cr}
  - critical interface growth rate
- R_{Gr}
  - rate of growth of graphite
- R_{screw}
  - growth by screw dislocation
- R_{step}
  - growth on the step of a defect boundary
- R_{2D}
  - growth by two-dimensional nucleation
- **rem**
  - remainder
- **RE**
  - rare earth
- **Ref**
  - reference
- **RF**
  - radio frequency
- S
  - applied stress
- S_L
  - entropy of the liquid
- S_S
  - entropy of the solid
- ΔS
  - entropy of fusion per unit volume
- ΔS_m
  - entropy change upon mixing
- SR
  - segregation ratio
- **s**
  - second
- **scfm**
  - standard cubic feet per minute
- **S**
  - solid
- $\mathrm{S_{cr}}$
  - number of atoms surrounding a cluster
- **SAE**
  - Society of Automotive Engineers
- **SAW**
  - submerged arc welding

  - solution algorithm
- **SPAR**
  - Space Processing Applications Rocket
- **SR**
  - stress relieved
- **SSVOD**
  - strong stirred vacuum oxygen decarburization
- **STP**
  - standard temperature and pressure
- t
  - time; thickness
- t_f
  - local solidification time
- T
  - temperature; cooling rate
- T^*
  - actual temperature of the moving interface
- T_b
  - dendrite base temperature
- T_c
  - transition temperature
- T_E
  - eutectic temperature
- T_f
  - equilibrium temperature; furnace temperature
- T_{fK}
  - equilibrium temperature between liquid and solid across interface with curvature K
- T_G
  - growth temperature
- T_L
  - liquidus temperature
- $T_{L\infty}$
  - liquidus temperature related to bulk liquid concentration
- T_m
  - melting temperature
- T_n

    - temperature of the standard sample
- $\boldsymbol{T}_{\mathbf{p}}$
    - peritectic temperature
- $\boldsymbol{T}_{\mathbf{s}}$
    - temperature of the sample
- $\boldsymbol{T}_{\mathbf{S}}$
    - solidus temperature
- $\boldsymbol{T}_{\mathbf{sol}}$
    - solidus temperature
- $\boldsymbol{T}\infty$
    - actual temperature of the bulk liquid
- $\Delta \boldsymbol{T}$
    - undercooling
- $<\Delta \boldsymbol{T}>$
    - mean undercooling
- $\Delta \boldsymbol{T}_{\mathbf{c}}$
    - average chemical undercooling of the interface; undercooling at columnar front
- $\Delta \boldsymbol{T}_{\mathbf{K}}$
    - kinetic undercooling; curvature undercooling
- $\Delta \boldsymbol{T}_{\mathbf{n}}$
    - critical undercooling for nucleation on a substrate
- $\Delta \boldsymbol{T}_{\mathbf{o}}$
    - freezing range of alloy (T_L - T_S)
- **TAC**
    - treatment of aluminum in crucible
- **TCT**
    - thermochemical treatment
- **THT**
    - transient heat transfer
- **TNT**
    - trinitrotoluene
- **TPRE**
    - twin-plane reentrant edge mechanism
- $\boldsymbol{u}$
    - bulk liquid velocity
- $\boldsymbol{u}_{\mathbf{n}}$
    - flow velocity normal to the isotherms
- $\boldsymbol{U}$
    - velocity of isotherms
- $\boldsymbol{U}_{\mathbf{TL}}$
    - liquidus isotherm velocity
- **u**
    - velocity of interdendritic liquid
- **UBC**
    - used beverage container
- **UNS**
    - Unified Numbering System (ASTM-SAE)
- **UTS**
    - ultimate tensile strength
- $\boldsymbol{v}$
    - velocity; volume
- $\boldsymbol{v}_{\mathbf{a}}$
    - absolute velocity for planar interface stability
- $\boldsymbol{v}_{\mathbf{cr}}$
    - critical velocity
- $\boldsymbol{V}$
    - volume; velocity

- $\boldsymbol{V}_{\mathbf{a}}$
  - atomic volume
- V_m^{Gr}
  - molar volume of graphite
- V_m^{g}
  - molar volume of austenite
- $\boldsymbol{V}_{\mathbf{s}}$
  - volume of the sample
- $\boldsymbol{V}_{\mathrm{SC}}$
  - spherical cap volume
- $\boldsymbol{V}_{\mathbf{0}}$
  - atomic volume
- **vol**
  - volume
- **vol%**
  - volume percent
- **V**
  - voltage
- **VAC-ESR**
  - electroslag remelting under reduced pressure
- **VAD**
  - vacuum arc degassing
- **VADER**
  - vacuum arc double electric remelting
- **VAR**
  - vacuum arc remelting
- **V-D**
  - vacuum degassing
- **VID**
  - vacuum induction degassing
- **VIDP**
  - vacuum induction degassing and pouring
- **VIM**
  - vacuum induction melting
- **VIM/VID**
  - vacuum induction melting and degassing
- **VOD**
  - vacuum oxygen decarburization (ladle metallurgy)
- **VODC**
  - vacuum oxygen decarburization (converter metallurgy)
- **VOID**
  - vacuum oxygen induction decarburization
- ***W***
  - width; weight
- **wt%**
  - weight percent
- **W**
  - watt
- **WQ**
  - water quench
- **WQT**
  - water quenched and tempered
- **WRC**
  - Welding Research Council
- $\boldsymbol{X}^{\mathbf{Gr}}$
  - molar fraction of carbon in graphite

- $\boldsymbol{X^{\gamma/Gr}}$
  - molar fraction of austenite at the austenite/graphite boundary
- $\boldsymbol{X^{\gamma/L}}$
  - molar fraction of austenite at the austenite/liquid boundary
- **yr**
  - year
- ***z****
  - ratio between number of near-neighbor atoms in plane of interface and total number of near-neighbor atoms in the bulk
- **α**
  - angle; thermal diffusivity; shape factor of the interface
- $\boldsymbol{\alpha_L}$
  - thermal diffusivity of the liquid
- $\boldsymbol{\alpha_S}$
  - thermal diffusivity of the solid
- **γ**
  - austenite; interfacial energy
- Γ
  - Gibbs-Thomson coefficient; capillary constant
- $\boldsymbol{\delta_c}$
  - thickness of liquid diffusion boundary layer; solute boundary layer ahead of the interface
- $\boldsymbol{\delta i}$
  - thickness of the diffusion boundary layer
- $\boldsymbol{\delta_{PL}}$
  - interface energy between particle and liquid
- $\boldsymbol{\delta_{PS}}$
  - interface energy between particle and solid
- $\boldsymbol{\delta_{SL}}$
  - interface energy between solid and liquid
- $\boldsymbol{\delta_t}$
  - thickness of the thermal boundary layer
- Δ
  - change in quantity; an increment; a range
- ∇
  - vector differential operator
- **ε**
  - strain
- $\dot{\epsilon}$
  - strain rate
- **η**
  - viscosity of the liquid; heat transfer coefficient
- **η***
  - effective viscosity
- $\boldsymbol{\eta_0}$
  - viscosity of the suspending fluid
- **θ**
  - contact angle
- **λ**
  - cell spacing, dendrite arm spacing, lamellar spacing or eutectic spacing
- $\bar{\lambda}$
  - mean value of the primary and secondary dendrite arm spacing
- **<λ>**
  - mean spacing
- $\boldsymbol{\lambda_{br}}$
  - critical spacing (diverging lamellae)
- $\boldsymbol{\lambda_{ex}}$
  - extremum spacing

- **λ_{min}**
    - critical spacing (converging lamellae)
- **λ_z**
    - secondary dendrite arm spacing
- **λ_l**
    - primary dendrite arm spacing
- **μ**
    - chemical potential; viscosity
- **μin.**
    - microinch
- **μm**
    - micron (micrometer)
- **ν**
    - Poisson's ratio
- **ν_{SL}**
    - jump frequency associated with atom jumps from the liquid to join the cluster
- **π**
    - pi (3.141592)
- **ρ**
    - density
- **Δρ**
    - density difference between liquid and the particle
- **ρ_L**
    - density of the liquid
- **ρ_P**
    - particle density
- **σ**
    - solid-liquid interfacial tension; interfacial energy; tensile stress
- **σ_{LS}**
    - liquid-solid interfacial energy
- **τ**
    - shear stress
- *f*
    - regularity constant
- **Ω**
    - net interatomic interaction; ohm
- **Ω_c**
    - solutal supersaturation at the interface
- °
    - angular measure; degree
- **°C**
    - degree Celsius (centigrade)
- **°F**
    - degree Fahrenheit
- **€**
    - direction of reaction
- ÷
    - divided by
- =
    - equals
- ≈
    - approximately equals
- ~
    - approximately; similar to
- ≠
    - not equal to
- ≡

    - identical with
- >
    - greater than
- **?**
    - much greater than
- ≥
    - greater than or equal to
- <
    - less than
- **=**
    - much less than
- ≤
    - less than or equal to
- ∞
    - infinity
- ∝
    - is proportional to; varies as
- $\int$
    - integral of
- ±
    - maximum deviation
- **-**
    - minus; negative ion charge
- ×
    - diameters (magnification); multiplied by
- ·
    - multiplied by
- /
    - per
- **%**
    - percent
- +
    - plus; positive ion charge
- $\sqrt{\ }$
    - square root of

o **Greek Alphabet**
